Gather a history from the responsive patient, relatives, and bystanders. If the patient is a priority for transport, you will have to try to gather information from bystanders during the scene size-up or primary assessment or your partner will have to gather it. (Even if the patient is now responsive, he may not recall much, if anything, about how the seizure occurred or progressed.) The following are pertinent questions to ask, and the answers will be important information to pass along to the hospital staff:

- Was the patient awake during the seizure?
- Was the muscle activity a twitching or jerking motion?
- Was the muscle activity isolated to one part of the body or generalized at the time the seizure started? (Most seizures will begin as generalized; some may start focally, then generalize.)
- When did the seizure start?
- How long did the seizure last? (Remember, however, that bystanders tend to overestimate seizure duration.)
- Did the patient experience an aura before the seizure (an unusual sensation that may precede a seizure episode by hours or only a few seconds)?
- Did the patient hit his head or fall?
- Did the patient bite his tongue or mouth?
- Was there a loss of bowel or bladder control?
- Is there any recent history of fever, headache, or stiff neck?
- Is the patient allergic to any medications?
- What medications does the patient take? Are any to control seizures?
- Did the patient take his seizure medication as prescribed?
- Does the patient have a history of epilepsy, previous seizures, diabetes, stroke, or heart disease?
- When was the last time the patient suffered a seizure?
- Was this a typical type of seizure for him to suffer?
- When did the patient last have something to eat or drink?
- Did the patient hit his head or fall?
- What was the patient doing immediately prior to the seizure activity? (Could there have been a fall or injury that caused the seizure, rather than the seizure causing the fall or injury?)

Initially, the postictal patient may not be able to provide you with much of a history. As he progressively improves, the questioning will be easier and the information gathered much more pertinent.

Prescription medications found at the scene or on the patient may provide you with an indication of a medical history of a seizure disorder or epilepsy (Table 19-2). It is important to be familiar with these medications since seizures can be mistaken for other disorders. For instance, some seizures produce behavioral changes that may be interpreted as the patient being drunk or under the influence of drugs.

**Signs and Symptoms.** The most commonly recognized type of seizure activity is the generalized
tonic-clonic (grand mal) seizure. The signs and symptoms of each more common type of seizure were described in the previous section. General signs and symptoms that may indicate seizure activity are:

- Convulsions (jerky muscular movement)
- Rigid muscular contraction or muscle spasm
- Bitten tongue
- Excessive saliva
- Urinary or bowel incontinence
- Chewing movement, smacking lips, wringing hands, or some other repetitive activity
- Localized twitching of muscles
- Visual hallucinations (flashing lights, images)
- Olfactory hallucination (smells)

**Emergency Medical Care**

The EMT must focus on controlling the airway and breathing in the seizing patient. Do not spend unnecessary time trying to determine the exact cause or specific type of seizure. Manage the immediate life threats and transport the patient.

1. **Position the patient.** The postictal patient should be placed in a lateral recumbent (recovery) position to protect the airway and facilitate drainage of secretions. If a spinal injury is suspected, the patient should be properly immobilized in a supine position. However, if the immobilized patient vomits, you should immediately turn the backboard and patient as a unit on the side so that the patient’s airway can be cleared more easily. If the patient requires ventilation, position him in a supine position.

2. **Maintain a patent airway.** If the patient is actively seizing or unresponsive, it may be necessary to insert a nasopharyngeal airway. Since the nasopharyngeal airway is flexible, in contrast to the rigid oropharyngeal airway, it is the airway of choice. Do not force anything into the mouth or between the teeth. You may actually do more harm by breaking the teeth. Do not place your fingers in the patient’s mouth or place any object between the front teeth.

    **If the patient is in status epilepticus—seizing for over 5 minutes or having seizures that occur consecutively without a period of responsiveness between them—open the airway with a head-tilt, chin-lift maneuver and insert a nasopharyngeal airway. Begin positive pressure ventilation with supplemental oxygen. Immediately begin transport and continuously reassess the patient en route to the medical facility.**

3. **Suction.** Suction any secretions, blood, or vomitus.

4. **Assist ventilation.** If the seizures last longer than 5 minutes or the breathing status is inadequate during the postictal phase, begin positive pressure ventilation with supplemental oxygen.

5. **Prevent injury to the patient.** Move objects away from the seizing patient so he does not injure himself. Protect the head, arms, and legs. Do not restrain the patient or try to control the movements. Loosen ties, shirt collars, or other tight clothing.

6. **Maintain adequate oxygenation.** If the breathing is adequate in the postictal phase and the SpO2 is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there is no need to administer supplemental oxygen. If the SpO2 is ≥94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used. If bag-valve ventilation is being performed, ensure a high concentration of supplemental oxygen is being delivered. Oxygen administration may actually shorten the postictal period.

7. **Transport.** You must contact medical direction or follow local protocol if confronted with a patient who refuses emergency care or transportation. Basically, if this is a normal seizure for the patient, it may not be necessary to seek additional medical treatment, as long as the patient is awake and competent to refuse. However, if anything is abnormal about the seizure, more than one seizure occurred, or the seizure has lasted longer than 5 minutes, the patient must be transported for further evaluation. Follow your local protocol.

**Reassessment**

Be prepared to manage additional seizures. Monitor the airway, breathing, and circulation. Repeat and record the vital signs. Document and communicate any changes to the receiving medical facility.

**Summary: Assessment and Care for Seizures**

To review assessment findings and emergency care for seizures, see Figures 19-5 and 19-6.
SEIZURES
The following findings may be associated with seizures.

Scene Size-up
Is seizure due to trauma or a medical problem? Look for:
- Mechanism of injury
- Alcohol, drugs, or other substances that are commonly abused
- Position and location of patient
- Confined spaces

Primary Assessment

General Impression
- Is the patient actively seizing?
- Vomitus or secretions in mouth?
- Are all body parts involved in the convulsion?

Mental Status
- Is the patient postictal?
- Alert to unresponsive
- Confused or disoriented

Airway
- Obstruction by tongue
- Obstruction by vomitus or secretions
  - In an epileptic patient who is unresponsive or actively seizing for greater than 5 minutes, insert a nasopharyngeal airway. If the patient is seizing from a cause other than epilepsy (e.g., severe head injury), immediately insert a nasopharyngeal airway and begin positive pressure ventilation with supplemental oxygen attached to the reservoir.

Breathing
- Shallow respirations
- Absent respirations

Circulation
- Heart rate may be increased.
- Skin may be hot and moist.
- Cyanosis may be present.

Status: Priority Patient If
- Patient has been actively seizing for greater than 5 minutes.
- Patient remains unresponsive between seizures.
- Seizure has a cause other than epilepsy (e.g., hypoxia, head injury).
- Patient is pregnant.
- Patient remains unresponsive following seizure with no improvement.

Secondary Assessment

History
- Signs and symptoms of typical epileptic seizure:
  - Aura (unusual sensation)
  - Unresponsiveness
  - Tonic phase (rigid muscles)
  - Hypertonic phase (extremely rigid muscles with back arched)
  - Tonic-clonic phase (jerky movements)
  - Postictal phase (recovery period)
  - Other (e.g., hyperventilation, excessive salivation, exhaustion, hemiplegia)
- Signs and symptoms of seizure from causes other than epilepsy:
  - Unresponsiveness
  - Jerky movements (convulsions)
  - Excessive salivation
  - Hot, wet skin
  - Cyanosis
- Ask the following questions:
  - How long did the seizure last?
  - Did the patient have an aura and know he was going to seize?
  - Did the patient possibly injure himself?
  - Is the patient allergic to any medications?
  - Does the patient take seizure medication?
  - Did the patient take his seizure medication today?
  - When was the last time the patient suffered a seizure?
  - Was or is this seizure typical?

Physical Exam

Head, neck, and face:
- Excessive salivation
- Possible cyanosis to mucous membrane and face
- Bitten tongue
- Unequal pupils

Extremities:
- Weak or paralyzed on one side
- General weakness
- Deformities, pain, and swelling from fractures resulting from convolution
- Unequal grip strength on one side of body

Baseline Vital Signs
- BP: increased or normal
- HR: increased
- RR: increased, irregular, decreased, shallow, or absent
- Skin: warm to hot, moist to wet
- Pupils: possibly unequal and dilated, sluggish to respond
- \( \text{SpO}_2 \): may be <94% as a result of the seizure or as an indication of hypoxia causing the seizure
- BGL: a blood glucose level of <60 mg/dL may be the cause of the seizure
SYNCOPE

Syncope, or fainting, is a sudden and temporary loss of consciousness. It occurs when, for some reason, there is a temporary lack of blood flow to the brain and the brain is deprived of oxygen for a brief period.

A common cause of syncope is an overwhelming influence of the parasympathetic nervous system that causes blood vessels to dilate throughout the body. With a patient in a standing or seated position, gravity causes the blood to pool in the lower extremities, decreasing blood flow and perfusion to the brain. The hypoperfused brain no longer functions adequately and the patient has a syncopal episode. This type of faint is commonly referred to as a vasovagal faint. A large portion of the parasympathetic nervous system is transmitted through the vagus nerve, which has a dilating effect on the vessels. Hence the name vagal (vagus nerve). It is important to note that vasovagal syncope is diagnosed (even in young patients) when other serious causes have been excluded.

Some patients feel as though everything is going dark, and then they suddenly become unresponsive. Syncope usually occurs when the patient is standing up or when the patient suddenly stands up from a sitting position. The collapse that follows puts the body in a horizontal position, distributing the pull of gravity along the length of the body and allowing blood circulation to the brain to improve. As a result of being in a horizontal position, the patient generally recovers rapidly.

Bystanders may confuse a syncopal episode with a seizure because the patient may experience a short period of jerky muscle movement during the episode (Table 19-3). The difference is that with syncope:

- The episode usually begins in a standing position.
- The patient remembers feeling faint or light-headed.
- The patient becomes responsive almost immediately after becoming supine.
- The skin is usually pale and moist.

Many patients who faint are afraid that something serious is wrong with them. Conduct primary and secondary assessments. Place the patient in a supine position to allow for improved blood flow to the brain, and provide reassurance. Your protocol may also instruct you to elevate the legs 8 to 12 inches. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there is no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child. Ventilations may be difficult to deliver because of resistance related to convulsions.

4. If breathing is adequate, administer oxygen to maintain an SpO₂ of ≥94%.
5. Place the patient in a lateral recumbent position.
6. Consider advanced life support backup if the patient is actively seizing.
7. Transport.
8. Perform a reassessment every 5 minutes.
hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used. Keep the patient in a supine position and assess the vital signs.

Because most patients fully recover before you even arrive at the scene, many refuse transport. However,
A seizure results from abnormal impulses within the brain. The impulses cause certain signs and symptoms to occur based on the type of seizure and what area of the brain is affected. Epilepsy is the most common cause of seizures; however, there are patients in whom there is no known cause for the seizure activity. A convulsion is the jerky muscular movement most often associated with seizure activity. This is only one phase of the seizure and usually lasts for 1–2 minutes. The typical generalized tonic-clonic seizure patient has an aura, a tonic phase, a hypertonc phase, a clonic phase, and then a postictal phase. Most seizures are self-limited and last for only a few minutes. If the seizure lasts longer than 5 minutes or if the patient seizes and then seizes again without a period of consciousness between, he is experiencing status epilepticus. This is a severe condition and a dire emergency that requires immediate and aggressive emergency care and transport.

There are two major categories of seizures: generalized and partial. Generalized seizures typically involve both hemispheres of the brain or the wake/sleep area, causing unconsciousness. Partial seizures usually only involve one cerebral hemisphere, thus the patient maintains some level of consciousness during the seizure. A simple partial seizure does not produce a loss of consciousness, whereas a complex partial seizure is associated with an altered mental status. Syncope, or fainting, is a condition that may be fairly benign or may be an indication of a serious underlying medical problem. The patient who experiences a simple episode of syncope will recover quickly once he is placed in a supine position and adequate blood flow returns to the brain.

### Summary

A seizure results from abnormal impulses within the brain. The impulses cause certain signs and symptoms to occur based on the type of seizure and what area of the brain is affected. Epilepsy is the most common cause of seizures; however, there are patients in whom there is no known cause for the seizure activity. A convulsion is the jerky muscular movement most often associated with seizure activity. This is only one phase of the seizure and usually lasts for 1–2 minutes. The typical generalized tonic-clonic seizure patient has an aura, a tonic phase, a hypertonc phase, a clonic phase, and then a postictal phase. Most seizures are self-limited and last for only a few minutes. If the seizure lasts longer than 5 minutes or if the patient seizes and then seizes again without a period of consciousness between, he is experiencing status epilepticus. This is a severe condition and a dire emergency that requires immediate and aggressive emergency care and transport.

There are two major categories of seizures: generalized and partial. Generalized seizures typically involve both hemispheres of the brain or the wake/sleep area, causing unconsciousness. Partial seizures usually only involve one cerebral hemisphere, thus the patient maintains some level of consciousness during the seizure. A simple partial seizure does not produce a loss of consciousness, whereas a complex partial seizure is associated with an altered mental status.

Syncope, or fainting, is a condition that may be fairly benign or may be an indication of a serious underlying medical problem. The patient who experiences a simple episode of syncope will recover quickly once he is placed in a supine position and adequate blood flow returns to the brain.

### Chapter Review

**Differentiation Between Seizures and Syncope**

### Some Serious Causes of Syncope

- Myocardial infarction
- Cardiac dysrhythmias
- Stroke or TIA
- Hypovolemia or blood loss
- Drug use or poisoning
- Pulmonary embolism
- Cardiac tamponade
The breathing is deep at a rate of about 20 per minute. You and your partner gather the jump kit, suction unit, backboard, head immobilization device, and a set of cervical spinal immobilization collars, and load them onto the stretcher.

As you approach, a large crowd surrounds the patient. She is supine and actively seizing. Firefighter Demarco is cradling her head to protect it from striking the hard floor and maintaining an airway with a jaw thrust. The patient’s sister is at her side, holding her hand. You and your partner introduce yourself as EMTs and ask for the patient’s name. The sister states, “She is my sister and she is an epileptic. Her name is Carmen Escobar.” In an attempt to determine if the patient has injured herself, you ask, “Did she fall to the ground or strike anything as she began to seize?” The sister indicates that Carmen said she felt a seizure coming on, and her sister gently helped Carmen to the ground. There are no immediate indications of a mechanism of injury.

Primary Assessment
Your general impression of the patient is a young adult female who has a history of epilepsy. The patient is having generalized seizure activity throughout her body. Your partner assesses the airway, breathing, and circulation. The airway has been opened and is being maintained by the firefighter Emergency Medical Responder. Carmen’s breathing is irregular and shallow at approximately 18 per minute. The pulse is strong at a rate of approximately 110 per minute. You ask, “How long has she been seizing?” The sister answers, “About 3 minutes.” You ask, “Do you know if this is a typical type seizure for her?” She replies, “Carmen gets this unusual taste in her mouth, then goes unconscious, seizes for a few minutes, and then becomes real tired and weak.”

Carmen’s seizure activity abruptly stops. You immediately reassess her airway, which appears to be patent. The breathing is deep at a rate of about 20 per minute. The pulse remains strong at approximately 110 per minute. The skin is warm and moist. The SpO2 reading is 91% on room air so you apply a nasal cannula at 2 lpm.

Carmen makes incomprehensible sounds. You ask, “Can you tell me your name?” She mumbles, “Carmen.”

Secondary Assessment
You begin by gathering a history. Carmen appears to be slowly regaining her orientation, so you first direct the questions to her. When she is unable to answer some questions, you then seek an answer from her sister. In your questioning, you determine that Carmen has recurring seizures as a result of her epilepsy, and that they are controlled with her medication.

She states that this seizure was normal for her condition, and she experienced nothing unusual. She states, “I had this metallic taste in my mouth, so I knew I was about to seize. I told my sister to help me to the floor. After that, I don’t remember anything until I woke up and saw you here.” You ask, “How do you feel right now?” Carmen responds, “I feel like I just did aerobics for about 3 hours! I’m totally exhausted, and I just feel like sleeping. I also feel so embarrassed.”

She has no allergies and is on Tegretol to control the seizures. You ask, “Have you taken your medication as prescribed?” Carmen states, “Yes, I took it this morning. I have about one seizure a month even with the medication.” She has no other pertinent past medical history and her last intake of food or drink was about an hour prior to the episode. She was simply walking down the concourse in the mall looking at crafts when she experienced the aura and subsequent seizure.

Carmen’s baseline vital signs are as follows: breathing normal at 16 per minute; radial pulse strong at 92 per minute; skin warm, normal color, and slightly moist; pupils equal and reactive; and blood pressure 134/82 mmHg. The patient complains the nasal prongs are irritating her nose. The pulse oximeter reveals an SpO2 of 98% and no signs of respiratory distress, poor perfusion, hypoxia, or hypoxemia, so you elect to remove the nasal cannula. The BGL is 86 mg/dL when checked on the glucose meter.

Reassessment
Carmen is helped up to a nearby bench. She refuses to be transported to the hospital. You contact medical direction and report the history and physical exam findings. Medical direction instructs you to document your history and physical exam findings on an EMS report form, inform the patient that you are requesting that she be transported to the medical facility, and have her and her sister sign the refusal form. The patient complies. You quickly reassess the vital signs. Before you leave, you ask Carmen if she is feeling any abnormal symptoms. She says, “No, this is a typical seizure for me, and I’m used to it. I don’t know why they called the ambulance anyway. Thanks for your help, though.”

“If you should suffer another seizure, be sure to contact us,” you say. As you pack up your equipment, Carmen and her sister walk off into the crowd.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.
IN REVIEW

1. Explain why the airway is frequently compromised in the actively seizing or postictal patient.
2. List pertinent questions to ask the seizure patient, relatives, or bystanders during the history.
3. Name the five stages of a generalized tonic-clonic seizure and the signs and symptoms associated with each stage.
4. Describe the emergency care steps recommended for treating a generalized seizure.
5. Define status epilepticus and describe how you would care for a patient who is in status epilepticus.
6. List the common conditions or injuries that may cause seizures.
7. Define and describe syncope and explain how you can distinguish it from a seizure.

CRITICAL THINKING

You arrive on the scene of a construction accident and find a 34-year-old male patient who was struck in the head by a falling brick. You note obvious trauma to the head. The patient is having convulsive-type movement. Blood and vomitus are coming from his mouth. The radial pulse is 142 bpm. The skin is moist and warm with cyanosis noted to the nail beds. You don’t note any other injury to the body.

1. How would you manage the airway in this patient?
2. Would spinal injury management be a consideration?
3. What type of seizure do you suspect the patient is experiencing?
4. What do you suspect is the cause of the seizure?
5. What emergency care would you provide for the patient?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • **Medicine** (Content Area: Endocrine Disorders)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

20-1. Define key terms introduced in this chapter.
20-2. Describe the following regarding glucose:
   a. The function of glucose in the body
   b. Response of brain cells and other body cells to insufficient glucose levels
   c. Relationships of glucose and water

20-3. Describe how insulin and glucagon function to control blood glucose levels.
20-4. Describe how glucose levels are regulated in normal metabolism.
20-5. Explain the purposes and process of checking blood glucose levels.
20-6. Discuss the pathophysiology of diabetes mellitus (DM) and contrast type 1 insulin-dependent diabetes mellitus (IDDM) with type 2 non-insulin-dependent diabetes mellitus (NIDDM).
20-7. Discuss the pathophysiology, assessment, and emergency medical care of a hypoglycemic emergency.
20-8. Identify indications and contraindications to the administration of oral glucose.
20-9. Discuss the pathophysiology, assessment, and emergency medical care of diabetic ketoacidosis (DKA).
20-10. Compare and contrast the speed of onset and the signs and symptoms of hypoglycemia and hyperglycemia.
20-11. Describe the primary differences between DKA and hyperglycemic hyperosmolar nonketotic syndrome (HHNS).
20-12. Discuss the pathophysiology, assessment, and emergency medical care of HHNS.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

diabetes mellitus (DM) p. 562
hyperglycemia p. 566
insulin p. 563
diabetic ketoacidosis (DKA) p. 567
hyperglycemic hyperosmolar nonketotic syndrome (HHNS) p. 568
oral glucose p. 570
glucagon p. 563
type 1 diabetes p. 567
glucose p. 562
type 2 diabetes p. 567
**Diabetes mellitus (DM)** is a disease that frequently causes changes in the patient’s mental status resulting from alterations in the blood glucose (blood sugar) level. The mental state may range from disorientation to complete unresponsiveness. Significant deterioration of the mental status from acute diabetic emergencies can lead to serious airway and breathing compromise. Brain cell damage and death may occur if the blood glucose reaches a very low level. Acute diabetic emergencies may include hypoglycemia, in which the blood glucose level is too low, or diabetic ketoacidosis or hyperglycemic hyperosmolar nonketotic syndrome, in which the blood glucose level is excessively high. It is important for the EMT to recognize and provide emergency care for patients who are experiencing an acute diabetic emergency.

More than 10 million Americans have been diagnosed with diabetes mellitus. Unfortunately, approximately 5.4 million other Americans have diabetes but have not yet been diagnosed. Many times, a person’s first indication of having the disease is a change in mental status, such as confusion, disorientation, or even loss of consciousness. Prompt recognition and appropriate emergency care of a patient who has an altered mental status because of an acute diabetic emergency is crucial.

**Glucose (Sugar)**

There are three major food sources for the body’s cells. They are carbohydrates, fats, and proteins. Carbohydrates are a primary energy source for the cells. Three major sources of carbohydrates are sucrose (table sugar), lactose (milk and dairy products), and starches (potatoes, bread). These sugars are called complex sugars because of their structure. In the body, the complex sugars are broken down into simple sugars to be absorbed through the digestive tract and into the bloodstream. The simple sugars are glucose, galactose, and fructose.

After carbohydrate digestion, approximately 80 percent of the simple sugar is in the form of glucose. Following absorption by the digestive tract, close to 95 percent of the simple sugar entering the body to be used by the cells is in the form of glucose. Therefore, glucose is by far the most important sugar in the body. This is why the sugar levels in the blood are referred to as the blood glucose level.

Glucose is a major source of fuel for the cells. Maintenance of the glucose level in the blood is crucial to normal function of cells. Some cells are able to use fats and proteins as energy sources if little or no glucose is available in the blood; however, the brain cells are not able to use anything but glucose. Thus, cells in the rest of the body can continue to function by using other energy sources, whereas the brain cells (which do not store glucose), when deprived of glucose, will dysfunction, shut down, and eventually begin to die. When cells other than brain cells use other energy sources such as fats, they produce harmful by-products that eventually affect the cell function adversely.

---

**INTRODUCTION**

**UNDERSTANDING DIABETES MELLITUS**

In order to have a basic understanding of diabetic emergencies, it is first necessary to understand normal metabolism—that is, how sugar acts within the body and how some of the hormones from the endocrine system control the movement and maintain the level of glucose in the blood when the body is functioning normally.

---

**Case Study**

**The Dispatch**

EMS Unit 106—proceed to 514 Chicago Avenue—you have a 66-year-old male patient who appears to be disoriented and belligerent. Be advised, the neighbor placed the call. Time out is 1402 hours.

**Upon Arrival**

As you and your partner approach the house, a woman walks out the front door. She says, “It’s Mr. Bennet. I found him in my garden next door. When I asked what he was doing, he began cursing at me. He’s always such a nice man. I can’t believe how he’s acting. Now he isn’t making much sense when I talk to him.” You proceed into the house and find the patient sitting on the edge of the couch mumbling incomprehensible words.

**How would you proceed to assess and care for this patient?**

*During this chapter, you will learn about assessment and emergency care for a patient suffering from an acute diabetic emergency. Later, we will return to the case and apply the procedures learned.*
Brain cells are extremely sensitive to a lack of glucose. They are almost immediately affected and will respond quickly to the decrease in available glucose. The brain cells cannot make glucose, they cannot store glucose for more than a few minutes, nor can they collect glucose in a concentration from the blood. As already noted, the consequences of the lack of glucose to brain cells for a short period of time are brain cell dysfunction. The most common sign of brain cell dysfunction is an altered mental status. As the glucose becomes more depleted, the mental status deteriorates further. If the drop in the blood glucose level is severe and prolonged, the brain cells will eventually die.

Because glucose is a large molecule, it has a tendency to attract water when it moves, an action known as osmotic pressure. It acts similarly to sodium, in a sense. There is a familiar saying, “Where sodium goes, water goes.” This means that when sodium crosses into a cell, water will follow it and cause the cell to swell. If the patient is losing large amounts of sodium from urination or sweating, the sodium will draw out a large amount of water, and the patient will become dehydrated from the water loss.

The glucose molecule will also cause water to follow it. Thus, if a large amount of glucose moves across a membrane, a large amount of water will follow it. This is one reason why glucose administration is dangerous and proven to be detrimental in patients with a head injury or stroke. By giving glucose, the brain allows more glucose to cross into the cells and the glucose brings water with it. This causes brain cells to swell, leading to more edema (swelling) within the skull, which worsens the head injury or stroke.

**PATHOPHYSIOLOGY PEARLS**

As glucose molecules cross over a membrane, they pull water with them. The fact that glucose will move directly into brain cells without the aid of insulin explains how glucose can worsen edema in the patient with a head injury or stroke. An increase in glucose may also increase the demand for oxygen, because the cells of the body require oxygen to help convert glucose into energy.

Frequently, excess glucose spills off into the urine and the patient urinates large amounts of glucose, excreting with it water that was not reabsorbed into the body because the glucose molecule drew it into the urine. The patient may eventually become dehydrated, which is a common complication in a diabetic patient.

**Hormones That Control Blood Glucose Levels**

The two hormones primarily responsible for controlling levels of blood glucose are insulin and glucagon, both of which are secreted by the pancreas. Insulin and glucagon have opposite effects on blood glucose level.

**Insulin**

Insulin is secreted when the blood glucose level is elevated. It has three main functions:

1. It increases the movement of glucose out of the blood and into the cells.
2. It causes the liver to take up the glucose out of the blood and convert it into glycogen, the stored form of glucose.
3. It decreases the blood glucose level by the actions listed in 1 and 2: facilitating the movement of the glucose into the cells and the liver.

Many people believe that insulin carries glucose into the cells. That is not true. What occurs is that insulin attaches to the cell at a specific (receptor) site and causes another channel on the cell membrane to open. A protein then carries the glucose into the cell through this channel. Thus, insulin facilitates the movement of glucose into the cell. If insulin is not available, glucose moves into the cell at a rate approximately 10 times slower. This causes glucose to build up in the bloodstream, causing the blood glucose level to increase. Ironically, as the blood glucose level is drastically increasing because of the lack of the insulin necessary to facilitate moving it into the cells, the cells are beginning to starve because they have no fuel or energy source. The cells begin to look for an alternative energy source, which is normally fats and proteins (Figure 20-1). One organ that does not need insulin to help move glucose into the cells is the brain. Glucose will cross the blood-brain barrier readily, whether insulin is present or not. However, while the other cells can use fats and proteins for energy, the brain can only use glucose. As glucose becomes depleted in the blood, the brain begins to suffer severely and begins to dysfunction as it loses its energy source. If left untreated, the brain cells will eventually die. Therefore, a patient with a low blood glucose level is in a serious condition and requires immediate emergency care.

**PATHOPHYSIOLOGY PEARLS**

Insulin is not required to move glucose across the blood-brain barrier and into the brain cells. In a diabetic with a high blood glucose level and a low or absent insulin level, the brain will continue to get glucose from the blood while the other cells in the body are starving for glucose and beginning to use fat and protein for energy.

**Glucagon**

As mentioned earlier, the function of glucagon is exactly the opposite of insulin's function. Insulin is secreted when the blood glucose level is high and works to decrease the blood glucose level (by helping to move glucose out of the blood and into the cells). Glucagon, on the other hand, is secreted when the blood glucose
level is low and will work to increase the blood glucose level. The major functions of glucagon are:

1. It converts glycogen stored in the liver back into glucose and releases it into the blood.
2. It converts other, noncarbohydrate substances into glucose in the liver.
3. It increases and maintains the blood glucose level by the actions listed in 1 and 2: converting glycogen and other substances into glucose.

Glucagon’s major role in the body is to raise and maintain the blood glucose level. When the blood glucose level decreases to approximately 70 mg/dL, glucagon is secreted. As just noted, glucagon then begins to convert liver glycogen and other substances into glucose to raise and maintain the blood glucose level until the next meal.

### Other Hormones

Many other hormones are also released to help maintain the blood glucose level. One of these hormones is epinephrine (adrenaline). Epinephrine is released by the adrenal glands when the blood glucose level decreases to a dangerously low level. Epinephrine stops the secretion of insulin and promotes the release of stored glucose from the liver as well as the conversion of other substances into glucose. Many of the signs you see in a patient with a low blood glucose level are caused by epinephrine. We will discuss the signs and symptoms later in the section on hypoglycemia (low blood glucose).

### Normal Metabolism and Glucose Regulation

The blood glucose level of a person who has fasted for 8–12 hours would normally read 80–90 mg/dL. Because patients are not always in a fasting state when you test their blood glucose level, many sources use much wider ranges of 70–120 mg/dL as a normal blood glucose level.

Because the brain is extremely sensitive to alterations in the blood glucose level, it is necessary for the body to maintain the blood glucose level within this very narrow range. As already explained, this is accomplished primarily by insulin and glucagon (Figure 20-2). Within 1 hour after a meal, a person’s blood glucose level increases to 120–140 mg/dL. When the blood glucose rises, it triggers the pancreas to secrete insulin, which is released from the pancreas and immediately begins to increase the movement of the glucose into the cells. About two-thirds of the glucose is taken up by the liver, which converts it to glycogen and stores it in the liver and muscles for later use. The brain takes up as much glucose as it needs without the aid of insulin. Obviously, these processes of moving glucose out of the bloodstream and into the cells, the liver, and the brain deplete the blood of glucose—in other words, lower the blood glucose level. Consequently, a few hours after a meal, the blood glucose level drops back to a normal level. As the blood glucose level decreases, the amount of insulin being secreted from the pancreas also decreases.

Eventually, as the cells continue to require and use insulin in the hours after a meal, the blood glucose level drops near the lower end of the normal range. The pancreas recognizes the decreased blood glucose level and secretes glucagon. The glucagon causes the liver to begin converting the glycogen (stored glucose) back into glucose and releasing it into the bloodstream. Other, noncarbohydrate substances will also be converted into glucose. This will raise the blood glucose level and maintain it in that normal range until the next meal.
**Normal Glucose Regulation**

1. Eat a meal
2. BGL increased and maintained
3. Insulin secreted
4. Cells uptake glucose
5. Liver creates glycogen
6. BGL = blood glucose level

**Glucose Regulation in Diabetes**

1. Eat a meal
2. BGL increased and maintained
3. More glucagon secreted
4. More glucose produced by glycogenolysis and gluconeogenesis
5. Glycogen produces glucose
6. Noncarbohydrates produce glucose
7. BGL increased
8. Insulin secreted
9. Cells uptake glucose
10. Liver creates glycogen
11. BGL = blood glucose level

**FIGURE 20-2** Normal glucose regulation.
Glycogen stores in the liver can last for up to 24–48 hours. After that, there is typically no more glycogen left in the liver to be converted into glucose and the blood glucose may drop drastically, while fats and proteins will begin to be used by the body cells at a high rate for energy.

### Checking the Blood Glucose Level

Portable blood glucose meters, commonly referred to as glucometers by EMS personnel, are available to both the EMS crew and the diabetic patient. These devices can fairly accurately determine the blood glucose level (BGL): the amount of glucose in the blood. (Glucose is a simple form of sugar; therefore, the terms glucose and sugar are usually used interchangeably.) The glucose meter analyzes a drop of capillary blood, typically obtained from a finger stick to the patient, and provides a numerical reading that indicates the concentration of glucose in the blood.

Blood glucose is measured in milligrams per deciliter (mg/dL). A normal blood glucose range is 80–120 mg/dL. A reading less than 80 mg/dL may indicate a lower-than-normal level of glucose (sugar) in the blood, whereas a reading greater than 120 mg/dL may indicate a higher-than-normal amount of glucose in the blood.

It is important to determine when the patient last had something to eat or drink. The blood glucose level in a nondiabetic patient following a meal will typically rise to 120–140 mg/dL. Thus, this is not considered abnormal. Likewise, after an 8- to 12-hour fast, a nondiabetic patient’s glucose will typically read 80–90 mg/dL. However, in the diabetic patient, the blood glucose may be as high as 120 mg/dL after an 8- to 12-hour fast. Blood glucose readings as high as 200 mg/dL may be normal in a diabetic patient.

**Hypoglycemia** is typically defined as a BGL of 60 mg/dL or less with signs or symptoms of hypoglycemia or a BGL of less than 50 mg/dL with or without signs or symptoms of hypoglycemia. The primary sign of hypoglycemia is an altered mental status. **Hyperglycemia** can be defined as a persistent BGL greater than 120 mg/dL.

### Testing the Blood Glucose Level with a Glucose Meter

The blood glucose level should be tested prior to the administration of any oral glucose or sugar-containing solution. In order to test the blood glucose level with a glucose meter, you will need the following supplies and equipment:

- Glucose meter
- Glucose meter test strips
- Lancet
- Lancet device (optional)
- Alcohol swabs

To get an accurate glucose reading, you need to get a good blood sample. To obtain a good blood sample, follow the steps in Table 20-1. Also see EMT Skills 20-1.

### Diabetes Mellitus (DM)

Diabetes mellitus (DM) is a condition in which there is disturbance in the metabolism of carbohydrates, fats, and proteins. The primary problem in this condition is either (1) a lack of insulin being secreted by the pancreas or (2) the inability of the cell receptors to recognize the insulin and allow the glucose to enter at a normal rate.

If there is no insulin or a minimal amount of insulin in the blood, the cells will take up glucose at a much slower rate. Or, if there is enough insulin but there is a deficit in the cell receptor sites that prevents them from recognizing and attaching insulin, this will also cause a drastic reduction in the amount of glucose that is allowed to enter the cell. Either of these situations will cause an excessive amount of glucose to collect in the blood and raise the blood glucose level. In both situations, because the glucose is not able to enter the cells at a normal rate, the cells begin to starve for energy and must use other sources, such as fat. Even though the blood is filled with glucose molecules, they are not available to the cells for energy production.

One point that you must remember: Although the cells in the body are deprived of glucose, the brain is
not, because insulin is not required for glucose to cross over into the brain cells. Therefore, in this situation, the brain has more glucose than it needs while the body cells are starving for glucose.

A patient with diabetes mellitus typically has an abnormally elevated blood glucose level because of a lack of insulin. An elevated blood glucose level is referred to as hyperglycemia. When the blood glucose level increases to about 185 mg/dL, the kidneys cannot reabsorb the high amount of glucose and begin to spill it out into the urine. Once the patient reaches a blood glucose level of 225 mg/dL, a significant amount of glucose will be lost in the urine. Remember the properties of glucose. It is a large molecule and will draw water to it. The excess glucose in the urine will draw water to be urinated out with it, leading to large amounts of body water loss. Over a period of time, this can lead to dehydration.

Because of the higher-than-normal loss of body water, diabetes mellitus patients typically complain of frequent thirst (polydipsia) and frequent urination (polyuria). Also, because the cells are starving for energy, the patient is typically hungry (polyphagia). This is referred to as the three Ps. The three Ps are signs that commonly alert physicians to a possible diagnosis of diabetes mellitus. Unfortunately, the first sign of the patient’s diabetes mellitus may be one of the severe hyperglycemic conditions that we will discuss later in the section.

There are four types of diabetes mellitus. The two that you will most often find in the prehospital environment are type 1 diabetes and type 2 diabetes. Type 1 is also referred to as insulin-dependent diabetes mellitus (IDDM), since these patients are required to inject insulin to regulate their blood glucose levels. The type 1 patient’s pancreas usually does not secrete any insulin. These patients are typically younger when the diabetes occurs, most commonly under the age of 40. The peak age for onset of type 1 diabetes mellitus is 10–14 years. The patients are typically lean from weight loss. Their blood glucose levels are extremely high if untreated. These patients will suffer from the three Ps. Type 1 diabetics often have difficulty keeping their blood glucose level within the normal range, with the possibility of having too high or too low a blood glucose level. Therefore, they are prone to suffering from a hyperglycemic condition called diabetic ketoacidosis (DKA). They may also suffer from hypoglycemia (low blood glucose). Type 1 diabetes is less common than type 2 diabetes.

### TABLE 20-1 Steps for Glucose Measurement

1. **Prepare the lancet and lancet device.** A lancet alone could be used to prick the finger; however, it is usually more comfortable for the patient and easier for the EMT to use a lancet device to stick the finger to obtain the blood sample. The lancet device makes it easier to gauge the depth of the stick and provides an extremely quick prick of the finger.
2. **Let the arm hang down at the patient’s side if possible.** This will allow for better blood flow to the fingers. If the fingers are cold, attempt to quickly warm the fingers by placing them in your hands for a brief period. This will provide better blood flow to the finger and a better sample.
3. **Remove a new test strip from the vial. Insert the test strip.** The glucose meter will turn on automatically. (This step may vary, depending on the type of glucose meter. Follow the manufacturer’s recommendations.)
4. **Match the code number on the LED screen to the code number on the test strip vial.**
5. **When the blood drop symbol flashes on the LED screen, you are ready to continue with the test.**
6. **Grasp the finger near the site to be pricked.** Cleanse it with an alcohol swab and let it dry completely before pricking the site. Squeeze the finger, forcing blood into the tip for 3 seconds.
7. **Keeping the hand downward, if possible, prick the side of the fingertip** and squeeze gently until a drop of blood is formed. Waste the first drop of blood onto a dressing and use the second drop for the test.
8. **Drop the blood onto the specified area on the test strip.** Some test strips may require that the finger be brought to the edge of the test strip, where the blood is absorbed by the strip. Be sure you completely understand the type of test strip you are using and the manufacturer’s recommendations on its use. (There is a wide variety of test strips that may require blood placement in different areas on the strip. If the designated test area is not completely covered, it may be necessary to apply a second drop of blood to the site. Typically, this has been done within 15 seconds of the first drop.)
9. **The blood glucose value will be displayed,** normally within 40–45 seconds. Record the value.
10. **Remove the test strip and place it in a biohazard container.** Turn the glucose meter off.

**PATHOPHYSIOLOGY PEARLS**

Diabetic patients with high blood glucose levels have a tendency to lose large amounts of body water through excessive urination. If a patient presents with signs of dehydration, check the blood glucose level.

Type 2 diabetes is also referred to as non-insulin-dependent diabetes mellitus (NIDDM), because type 2 patients usually do not have to take insulin. However, they do have to regulate their diet and exercise and take oral drugs to help the pancreas secrete more insulin or to make the insulin that is secreted more effective in facilitating movement of glucose into the cells. Type 2 diabetic patients are usually middle-aged or older. They are typically overweight. Like type 1 diabetics, they suffer from high blood glucose levels if untreated and they may also present with a history of the three Ps. These
patients are prone to a hyperglycemic condition called **hypoglycemic hyperosmolar nonketotic syndrome (HHNS)**.

It is estimated that 1–2 percent of the population has a true form of diabetes mellitus. Of these, approximately 25 percent suffer from type 1 (IDDM) and the remaining 75 percent suffer from type 2 (NIDDM). Diabetes mellitus is more common in Caucasians than in non-Caucasians.

The patient with diabetes mellitus is prone to a wide variety of diseases and disorders involving the blood vessels—such as heart attack, stroke, and kidney failure—from blockage of the vessels by fat deposits. The blood glucose level is typically high in the patient with diabetes mellitus. A blood glucose reading that is randomly taken may be greater than 200 mg/dL, compared to 70–120 mg/dL in a patient without diabetes mellitus. A fasting blood glucose level in a patient with diabetes mellitus averages greater than 140 mg/dL, as compared to 80–90 mg/dL in the patient without diabetes mellitus.

**ACUTE DIABETIC EMERGENCIES**

The emergency conditions that you may be called to manage in the prehospital environment are related to a patient suffering from either a low blood glucose level (hypoglycemia) or a high blood glucose level (hyperglycemia). They are at two ends of a continuum of blood glucose levels (Figure 20-3).

**Hypoglycemia**

*Hypoglycemia* is the term for a low blood glucose level (*hypo* = low, *glyco* = glucose, *emia* = blood). This condition is more common in type 1 IDDM patients than in type 2 NIDDM patients. Hypoglycemia is the most dangerous acute complication of diabetes mellitus. It is estimated that 9–120 episodes of hypoglycemia will occur per 100 diabetic patients per year. It is one of the most common causes of coma in the diabetic patient.

**Pathophysiology of Hypoglycemia**

Hypoglycemia occurs when the amount of glucose in the blood falls below the normal lower limit. As noted earlier, it is typically defined as a blood glucose level less than 60 mg/dL with signs and symptoms of hypoglycemia or less than 50 mg/dL with or without signs and symptoms. The most common sign of hypoglycemia is an altered mental status. This is due to the sensitivity of the brain to a drop in the blood glucose level. As already discussed, the brain cells can use only glucose as an energy source, unlike other cells that can burn fat and protein for energy. As the blood glucose level continues to drop, the mental status of the patient continues to deteriorate. If the blood glucose level is not restored, the brain cells will begin to die.

Hypoglycemia usually occurs in type 1 IDDM in which the patient must take insulin to regulate his blood glucose levels. This patient takes his insulin, but with excessive results (blood glucose levels decrease too much), for one of the following reasons:

- The patient takes his insulin and does not eat a meal.
- The patient takes his insulin, eats a meal, but drastically increases his activity beyond normal.
- The patient takes too much insulin—either takes too much at one time or forgets and takes an extra dose.

Type 2 NIDDM patients can also suffer hypoglycemia. The oral medications that they take can cause the blood glucose level to drop too far, resulting in hypoglycemia. Because these oral medications have long-lasting effects, hypoglycemia can be prolonged or can recur if these patients are not monitored.

When there is too much insulin in the blood—either because the patient did not eat after injecting the insulin or he took too much for the amount he ate—the insulin causes the cells in the body to take up most of the glucose from the blood, leaving very little for the brain. Remember that one of insulin’s major functions is to help move glucose into the cell. If the patient takes his insulin, eats a meal, and then decides to run 5 miles, which is not a normal activity for the patient, the high activity will cause body cells to use the glucose at a much faster rate, leaving little behind in the blood for the brain. Either of these imbalances—too much insulin or too much exercise—will deplete the blood of glucose and cause the brain cells to begin to fail.

Deterioration of the mental status is a gauge of low blood glucose level and brain cell dysfunction. As the brain cells become more and more deprived of glucose, the mental status will deteriorate further. The patient’s brain needs an influx of glucose quickly to reverse the brain cell dysfunction and prevent brain cell death.
Assessment Findings in Hypoglycemia

Hypoglycemia has commonly been referred to as “insulin shock” because of the shocklike signs and symptoms commonly seen with the condition. Many of these are caused by release of epinephrine.

As the blood glucose level drops, epinephrine is secreted at higher levels. The effect of the epinephrine is to shut down secretion of insulin and to stimulate secretion of glucagon, which, in turn, converts stored glycogen and other noncarbohydrate substances into glucose. As a result, many of the signs and symptoms seen in hypoglycemia are associated with the epinephrine circulating in the body. These signs and symptoms appear to be very similar to those in a patient in shock from poor perfusion.

PATHOPHYSIOLOGY PEARLS

When the blood glucose level is decreasing, epinephrine (adrenaline) is released. This produces the tachycardia, diaphoresis, and pale, cool skin typically seen in the hypoglycemic patient. The bizarre behavior, agitation, disorientation, and other mental status changes seen in hypoglycemic patients are due directly to an inadequate amount of glucose being provided to the brain cells.

The other signs and symptoms seen in hypoglycemia are from the brain dysfunction. The onset of hypoglycemia signs and symptoms is rapid, from a few minutes to about 20 minutes in most patients who become hypoglycemic. This is due to the rapid decline of brain function and secretion of epinephrine associated with the lack of glucose.

Signs and Symptoms Caused by Epinephrine Release

- Diaphoresis (sweating)
- Tremors
- Weakness
- Hunger
- Tachycardia (increased heart rate)
- Dizziness
- Pale, cool, clammy skin
- Warm sensation

Signs and Symptoms Caused by Brain Cell Dysfunction

- Confusion
- Drowsiness
- Disorientation
- Unresponsiveness
- Seizures (may occur in severe cases)
- Strokelike symptoms including hemiparesis

The hypoglycemic patient may present with bizarre or even violent behavior and, for this reason, the patient’s condition may be mistaken for a behavioral or psychiatric disorder, drug use, or alcohol intoxication. This is potentially a tragic mistake since hypoglycemia can be fatal if not recognized and treated quickly. There are numerous cases of patients dying as a result of misinterpretation of the signs and symptoms of hypoglycemia. These patients are generally unaware of their actions. Coma (which is unresponsiveness to any noxious stimuli such as pain) may also result from hypoglycemia. Look for a medical identification bracelet, anklet, or necklace during your physical examination.

The severity of the signs and symptoms as correlated to the blood glucose level varies from patient to patient. One patient may be completely unresponsive at a blood glucose level of 45 mg/dL, whereas another at the same blood glucose level may still be responsive but confused. Have a high index of suspicion and do not develop tunnel vision when treating patients. Any patient who presents with an altered mental status, bizarre behavior, violence, or an intoxicated appearance, even if alcohol is smelled on the breath, must be assessed for possible hypoglycemia. This is when the glucose meter provides some valuable information. If the patient appears to be intoxicated and the blood glucose reading comes back as 58 mg/dL, you would treat the patient for hypoglycemia. If the same patient had a blood glucose reading of 124 mg/dL, you would treat him as intoxicated. As a note of interest, alcohol will inhibit the body’s ability to convert other noncarbohydrate substances into glucose during hypoglycemia, allowing the blood glucose level to decrease more rapidly. So a diabetic who has been drinking may, as a consequence, also be hypoglycemic.

Hypoglycemia Unawareness

Patients with long-term diabetes mellitus usually recognize their own signs and symptoms that occur when their blood glucose levels are decreasing and they are becoming hypoglycemic. They will ingest a high-sugar food to raise the blood glucose level. Over time, however, the signs and symptoms of hypoglycemia may begin to change. They may not recognize the change, continuing to look for the old signs and symptoms. This may cause them to allow their blood glucose levels to drop significantly without any intervention as the signs and symptoms go unrecognized, and they suddenly experience hypoglycemia.

Emergency Care for Hypoglycemia

The patient suffering from hypoglycemia must be given sugar to increase the blood glucose level as quickly as possible to prevent the brain cells from dying. You would provide the same treatment as outlined earlier in the chapter for a patient with an altered mental status and unknown history. Your management is based on the patient’s mental status.

If the patient is unresponsive, is unable to swallow, or is unable to obey your commands:

1. Establish an open airway.
2. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion
are present, there may be no need to administer supplemental oxygen. If the SpO$_2$ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO$_2$ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

3. Provide positive pressure ventilation if the breathing is inadequate (either an inadequate rate or an inadequate tidal volume).

4. Contact advanced life support.

5. Assess the blood glucose level.

   *If the patient has an altered mental status but is responsive, is able to swallow, and is able to obey your commands:*

1. Ensure the airway is patent.
2. Assess the blood glucose level if your protocol permits.
3. Administer one tube of oral glucose.

Be sure to continuously reassess the patient’s condition for improvement or deterioration. Pay particular attention to the airway and breathing status.

**Oral Glucose**

*Oral glucose* is the medication of choice in the emergency medical care of the diabetic patient with an altered mental status. Once it is administered, this heavy sugar gel raises the amount of glucose circulating in the blood, which increases the amount of glucose available to the brain. Since the brain cells need glucose to function, lowered levels of glucose alter their ability to function properly, causing a decrease in mental status. When the blood glucose level increases, the brain receives an increased amount of glucose and is able to restore brain cell function, bringing about an improvement in mental status.

See Figures 20-4 and 20-5 which illustrate methods of administering or assisting a patient with oral glucose. See Figure 20-6 for a detailed summary of the criteria and techniques for administration of oral glucose.

*Oral glucose may be administered only if the patient meets all of the following three criteria: (1) has an altered mental status, (2) has history of diabetes controlled by medication or a blood glucose reading less than 60 mg/dL, and (3) has the ability to swallow.* Some patients may meet one or two of these criteria, but not all three. For example, the patient may have an altered mental status and be able to swallow but have no known history of diabetes mellitus or have a blood glucose reading greater than 60 mg/dL. Or the patient may have an altered mental status and a history of diabetes controlled by medication or a blood glucose level less than 60 mg/dL but his level of responsiveness is so depressed that he cannot swallow safely. When using a glucose meter, follow your local protocol. Some protocols require the administration of glucose when the BGL is less than 70 mg/dL.

*In cases like the ones just described, in which all three criteria are not met, do not administer oral glucose.* Instead, provide emergency medical care for a patient with altered mental status and an unknown history: Maintain an open airway, suction as needed, maintain oxygen therapy, be prepared to assist ventilations, place the patient in a lateral recumbent position, and transport. Contact medical direction for further orders.

**Hyperglycemia**

*Hyperglycemia* is the term for a high blood glucose level (*hyper* = high, *glyco* = glucose, *emia* = blood). There are two conditions that may result from extreme hyperglycemia: diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic syndrome (HHNS). As noted earlier, DKA is more commonly seen in the type 1 diabetic,
Oral Glucose

Medication Name
Oral glucose is the generic name. Two of the trade names of oral glucose are:

- Glucose
- Insta-Glucose

Indications
Oral glucose should be administered to a patient who meets all three of the following criteria:

- An altered mental status
- A history of diabetes controlled by medication or a blood glucose level less than 60 mg/dL
- The ability to swallow the medication

Contraindications
Oral glucose should not be administered to a patient who:

- Is either unresponsive or unable to swallow the medication
- Has a confirmed blood glucose level greater than 60 mg/dL

Medication Form
Gel, in toothpaste-type tubes.

Dosage
Oral glucose is a viscous gel typically packaged in toothpaste-type tubes. The typical dosage is one tube.

Administration

To administer oral glucose:

1. Obtain an order from medical direction. Off-line medical direction would allow the EMT to administer the oral glucose without direct consultation with medical direction. An on-line order may be given by direct consultation with medical direction via phone or radio prior to the administration of the medication.
2. Ensure the signs and symptoms are consistent with hypoglycemia. If protocol permits, obtain a blood glucose reading.
3. Ensure that the patient is responsive and able to swallow the medication and protect his airway. Monitor the patient’s airway closely during the administration to avoid accidental blockage by or aspiration of the oral glucose.
4. There are two ways to administer the medication. One way is to hold back the patient’s cheek and squeeze small portions of the contents of the tube into the mouth between the cheek and gum (Figure 20-4). The other way is to place small portions of the oral glucose on a tongue depressor, pull back the cheek, and slide the tongue depressor to deposit the medication between the cheek and gum (Figure 20-5). An alternative method is to have the patient squeeze the glucose himself into his mouth. This ensures he is alert enough to swallow it. Whichever method you choose, do not squeeze a large amount of glucose into the patient’s mouth at one time. This may cause the patient to choke or aspirate the contents. Also, lightly massage the area between the cheek and gum to disperse the gel and increase absorption.

Actions
Increases blood glucose level. Increases glucose available to the brain.

Side Effects
There are no side effects of oral glucose when administered properly. However, the thickness of the gel may cause an airway obstruction or the substance may be aspirated in the patient without a gag reflex.

Reassessment
If the patient loses responsiveness or has a seizure, remove the tongue depressor from the mouth and be prepared to suction. Reassess the patient’s mental status to determine if the medication has had an effect. Remember, it may take more than 20 minutes before you start seeing any improvement in the patient’s mental status following the administration of oral glucose. Reassess the blood glucose level if protocol permits. If the patient’s mental status continues to deteriorate, manage the airway and breathing. Make sure that oxygen is flowing to the patient at the highest possible concentration. Constantly monitor the patient’s airway and breathing.

whereas HHNS is more common in the type 2 diabetic. In both conditions, the blood glucose level increases drastically. Unlike hypoglycemia, which is a lack of glucose in the blood, in hyperglycemic conditions there is a lack of insulin and an excessive amount of glucose in the blood. In hyperglycemic conditions, the brain has more glucose than it knows what to do with.

PATHOPHYSIOLOGY PEARLS
Hyperglycemic patients have too much glucose in the blood and not enough insulin. The cells in the body are starving, even though the blood glucose level may be extremely high, because there is not enough insulin to move the glucose into the cells. At the same time, however, the brain is getting more than an adequate amount of glucose.
Hyperglycemic Condition: Diabetic Ketoacidosis (DKA)

Pathophysiology of DKA

The name itself, diabetic ketoacidosis, indicates what is occurring in the condition. The blood glucose level is elevated, typically greater than 350 mg/dL, because of an inadequate amount of insulin. The brain has an excess amount of glucose; therefore, it is not suffering from low blood glucose. However, the other cells in the body are starving for glucose, because there is an inadequate amount of insulin to help move the glucose out of the blood and into the cells at a fast enough rate. The cells begin to burn fat for energy as the glucose collects in the blood.

This causes two problems within the body: dehydration and acidosis (Figure 20-7 ■). First, the excess glucose from the blood begins to spill into the urine,
drawing large amounts of water with it. The patient begins to urinate frequently as a consequence of the excessive glucose, simultaneously eliminating large amounts of water attracted to the glucose. This leads to dehydration in the patient. Second, because all cells (those other than brain cells) that rely on insulin to move glucose across their cell membrane are receiving very little glucose from the blood, they think that they are starving and signal the brain to produce more glucose. The pancreas secretes glucagon in response to the cells’ request for more glucose, although the blood glucose level is already excessively high. In response to the request for more glucose, the liver converts glycogen into glucose and releases it into the blood, which exacerbates the spillage of glucose into the urine and the consequent dehydration. Additionally, because the liver cells are not taking in glucose, the liver begins to metabolize fats for energy, which produces a by-product called ketones. The ketones produce a form of a strong acid. As the liver metabolizes more fat, acid levels in the body begin to increase to dangerous levels (acidosis).

These two problems, dehydration and acidosis, lead to many of the signs and symptoms seen in DKA and may eventually cause the brain to fail. In addition to dehydration and acidosis, an electrolyte imbalance develops, which may lead to cardiac disturbances. Since it takes quite a bit of time for the effects of the acid and dehydration to occur, the signs and symptoms of DKA usually do not occur for up to several days.

You might expect to find one of the following factors:

**Factors Causing Hyperglycemia in the Diabetic Ketoacidosis (DKA) Patient**

- The patient is suffering from an infection that has upset the insulin and glucose balance.
- The patient takes an inadequate dose of insulin.
- The patient is taking medications such as thiazide, Dilantin, or steroids.
- The patient has suffered some type of stress such as surgery, trauma, pregnancy, or heart attack.
- The patient had a change in diet in which he has overeaten or increased his carbohydrate or sugar intake.

**PATHOPHYSIOLOGY PEALS**

An altered mental status in the diabetic ketoacidosis patient is not from a lack of glucose to the brain; rather, the altered mental status results from dehydration, fluid shift, and acidosis affecting the brain cells. It takes time for the dehydration, fluid shift, and acidosis to build to critical levels; thus, the onset of signs and symptoms is usually days in hyperglycemia, not minutes as in hypoglycemia.

**Assessment Findings in DKA**

The signs and symptoms of DKA are produced primarily by the dehydration and acid buildup. The name of the condition explains the signs and symptoms one would expect from the condition. The word *diabetes* means excessive urination. *Ketoacidosis* refers to the production of ketones, which also produces strong acids, from the cells’ use of fat as an energy source. Diabetic ketoacidosis is a condition with excessive urination and a buildup of acid from ketone production. Therefore, look for signs of dehydration and acid buildup.

**Signs and Symptoms of Diabetic Ketoacidosis (DKA)**

- Polyuria (excessive urination)
- Polyphagia (excessive hunger)
- Polydipsia (excessive thirst)
- Nausea and vomiting
- Poor skin turgor
- Tachycardia
- Rapid deep respirations (called Kussmaul respirations)
- Fruity or acetone odor on the breath
- Positive orthostatic tilt test
- Blood glucose level (BGL) >350 mg/dL
- Muscle cramps
- Abdominal pain (in 50 percent of patients; more common in children with DKA)
- Warm, dry, flushed skin
- Altered mental status
- Coma (very late)

**ASSESSMENT TIPS**

Poor skin turgor in elderly patients is caused by the normal loss of skin elasticity. Therefore, poor skin turgor does not tell you much about the elderly patient’s hydration status.

As mentioned previously, DKA progresses slowly over a few days. The signs or symptoms related to dehydration are polyuria, polydipsia, poor skin turgor, tachycardia, and positive orthostatic tilt test. The nausea, vomiting, and muscle cramps are typically due to electrolyte disturbances from the loss of sodium, potassium, and magnesium. The acid in the body will produce Kussmaul respirations, warm and dry skin, and the fruity odor on the breath.

Kussmaul respirations are a pattern of very deep and rapid breathing that is commonly seen in the patient with DKA. It is an attempt by the body to blow off carbon dioxide to reduce the acid load in the body. Carbon dioxide will produce another form of acid called carbonic acid. If the patient can blow off large amounts of carbon dioxide by hyperventilating (deep and rapid breathing), he can then reduce the amount of carbonic acid and thus reduce the total amount of acid in the body. As the ketone acid in the body increases, the patient will breathe deeper and faster in an attempt to keep the acid load under control. The fruity odor, which smells like Juicy Fruit gum or acetone, is from the ketones building up in the body.
The patient with diabetic ketoacidosis is typically dehydrated and acidotic. Thus, the treatment is aimed at reducing the blood glucose level and rehydrating the patient. It may be prudent to contact an advanced life support unit to begin rehydration in the field. Follow your local protocol.

In the patient with diabetic ketoacidosis, the prehospital emergency medical care will include the following:

1. Establish and maintain a patent airway.
2. If breathing is adequate and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%.
3. If the breathing is inadequate (either an inadequate rate or an inadequate tidal volume), provide positive pressure ventilation with oxygen connected to the ventilation device.
4. If your protocol permits, determine the blood glucose level.
5. If you are unsure about the condition, administer oral glucose if the patient is able to swallow.
6. Contact medical direction for further orders.

Oral glucose should be considered in any patient who has a history of diabetes who presents with any of the signs and symptoms of diabetic emergency conditions.

### Emergency Care for DKA

As an EMT, you may not be expected to distinguish between hypoglycemic and hyperglycemic conditions unless you are able to use a glucose meter. Although the signs and symptoms may differ dramatically between hypoglycemia and hyperglycemia, both conditions may produce an altered mental status (Table 20-2). The patient will typically have a history of diabetes mellitus and will usually be on either insulin or an oral hypoglycemic agent to manage the blood glucose.

Both the dehydration and the acid load endanger the normal function of the body. The altered mental status is produced by the brain becoming dehydrated and from the effects of acid on the brain cells. Remember, the brain in the patient with DKA has more glucose than it can deal with. That is why the progression of the signs and symptoms of DKA occurs over a few days, since it can take a much longer period of time for the dehydration and acid to affect the brain. This is unlike hypoglycemia, which has an onset of only a few minutes to 20 minutes because of the more acute effects of low blood glucose levels on the brain.

### ASSOCIATE TIPS

Many people are unable to smell acetone; thus, you or your partner may not be able to smell the fruity odor on the DKA patient’s breath.
altered mental status, whether that patient is suffering from hypoglycemia or from hyperglycemia—you may not know which if a glucose meter is not used. If your protocol allows you to measure the blood glucose, do so to determine if the patient is hypoglycemic or hyperglycemic.

You may wonder why it is acceptable to give oral glucose to a patient who may be suffering from a hyperglycemic condition (too much glucose in the blood) when no glucose reading is available. The reason why oral glucose may be given to a patient who has a history of diabetes who is possibly hyperglycemic is that if the patient is not a confirmed hyperglycemic patient and turns out to be hypoglycemic, the patient may suffer possible brain cell damage if glucose is withheld. Remember, when brain cells are deprived of glucose during hypoglycemia they will begin to die. On the other hand, if oral glucose is administered to a hyperglycemic patient, the amount of glucose given is not going to raise the blood glucose drastically and will have little effect on the brain. In other words, the hypoglycemic patient could end up dead if not treated with glucose, while the additional glucose will usually not harm the hyperglycemic patient. Therefore, it is better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so.

**Assessment Tips**

When possible, glucose administration should be guided by a glucose meter reading. It is well documented that administering glucose to a patient with a stroke, head injury, or other intracranial problem may worsen the neurological outcome. A low blood glucose measurement will help to rule out those conditions and ensure that glucose administration is both needed and safe for the patient.

**Hyperglycemic Condition:**

**Hyperglycemic Hyperosmolar Nonketotic Syndrome (HHNS)**

**Pathophysiology of HHNS**

The pathophysiology of HHNS is similar to diabetic ketoacidosis. Again, the name of the condition provides an understanding of what is occurring and how the two conditions differ. HHNS is a hyperglycemic condition that causes the blood glucose level to increase drastically. The blood glucose will typically rise to 600–1,200 mg/dL, thus the hyperglycemic reference in the name. Because of the high blood glucose level, the kidneys begin to spill off large amounts of glucose in the urine. The glucose draws large amounts of water with it into the urine, which is called a hyperosmolar effect. This causes the patient to suffer from significant dehydration.

HHNS is more common in the type 2 NIDDM patient. This is because the type 2 patient’s pancreas is able to produce and secrete some insulin, so some glucose is still getting into the cells (Figure 20-8 ■). The glucose entering the cells keeps the amount of fat being metabolized by the liver to a lesser amount than is seen in DKA. If there is not a significant amount of fat being metabolized, then there will be a lesser production of ketones as a by-product of fat breakdown. Therefore, there is not a collection of a large amount of ketones that would cause an acid load in the body, thus the nonketotic reference in the name.

The word syndrome in the name refers to a set of signs and symptoms. HHNS is a condition in which the patient becomes severely dehydrated from an extremely high blood glucose level. However, since the patient does not produce a massive amount of ketones, the patient will present with the signs of significant dehydration but with no signs of acidosis. The patient’s mental status will be altered because of dehydration of the brain tissue and not because of acidosis or a lack of glucose.

An episode of HHNS may be the first indication that a patient has a diabetic condition. It is most commonly found in type 2 NIDDM patients who are elderly. HHNS may also be precipitated by trauma, burns, dialysis, drugs, heart attack, stroke, infection, head injuries, and other endocrine disorders. HHNS carries a fairly high mortality rate. HHNS patients are more likely to have seizures than are hypoglycemic patients.

**Assessment Findings in HHNS**

The signs and symptoms of HHNS are similar to those of DKA with the exception that those caused by the acidosis in DKA are not present in HHNS (Table 20-2).

**Signs and Symptoms of Hyperglycemic Hyperosmolar Nonketotic Syndrome (HHNS)**

- Tachycardia
- Fever
- Positive orthostatic tilt test
- Dehydration
- Thirst (polydipsia)
- Dizziness
- Poor skin turgor
- Altered mental status
- Confusion
- Weakness
- Dry oral mucosa
- Dry, warm skin
- Polyuria (if dehydrated, the urine output will be scanty [oliguria])
- Nausea and vomiting

Note that there are no Kussmaul respirations or fruity odor on the breath with HHNS because there is no significant buildup of ketones in the body and therefore no significant acid load.
Some insulin is available which allows small amounts of glucose to get into the cells.

Because the cells are still not receiving an adequate amount of glucose, the liver converts glycogen to glucose, which raises the BGL.

Because the cells are receiving a small amount of glucose, a smaller amount of fat is metabolized for energy releasing smaller amounts of ketones (acids), which keep the body from becoming acidotic.

The excess glucose gets into the urine.

The glucose, being a large molecule, draws large amounts of water into the urine.

Large amounts of water are excreted with the glucose leading to dehydration.

Pathophysiology of hyperglycemic hyperosmolar nonketotic syndrome (HHNS).
**Emergency Medical Care for HHNS**

The emergency medical care for HHNS is basically the same as for DKA. Once again, if you are unsure or if your protocol does not permit you to attempt to distinguish between hypoglycemia, DKA, and HHNS, treat the patient as if he is hypoglycemic. Administering oral glucose to this patient will not drastically elevate his already high blood glucose level. Withholding glucose from a hypoglycemic patient that you mistake as DKA or HHNS may potentially result in brain damage or even the patient’s death. Err to benefit the patient and treat as hypoglycemia when unsure of the condition. Other signs and symptoms that may help you distinguish between hypoglycemia, HHNS, and DKA are listed in Table 20-2.

Emergency medical care for HHNS includes these steps:

1. Establish and maintain a patent airway.
2. If the breathing is adequate and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.
3. If the breathing is inadequate (either an inadequate rate or an inadequate tidal volume), provide positive pressure ventilation with oxygen connected to the ventilation device.
4. If your protocol permits, determine the blood glucose level.
5. If you are unsure about the condition, administer oral glucose if the patient is able to swallow.
6. Contact medical direction for further orders.

Like the DKA patient, the HHNS patient needs to be rehydrated with fluids. It may be necessary to call for advanced life support for this purpose. Follow your local protocols.

---

**ASSESSMENT-BASED APPROACH: ALTERED MENTAL STATUS IN A DIABETIC EMERGENCY**

The patient with an altered mental status who you suspect is experiencing an acute diabetic emergency is assessed in the same manner as the altered mental status patient with no known history. However, the patient may have prescription medications to control diabetes mellitus or you may have obtained a blood glucose level that indicates hypoglycemia. If you are unable to assess the blood glucose level with a glucose meter, you have to rely solely on your assessment findings to determine whether the patient is experiencing an acute diabetic emergency and what kind of diabetic emergency he is experiencing. If you are unsure or cannot confirm the condition with a glucose reading, it is better to err on the side of caution and administer oral glucose. If you are unable to confirm the blood glucose level and the actual acute diabetic emergency, an assessment-based approach to the patient is warranted.

**Scene Size-up and Primary Assessment**

If clues gathered during the scene size-up and primary assessment lead you to suspect that the patient may be diabetic, look for medical alert tags, tattoos, or other medical identification that confirms a diabetic history (Figure 20-9 ■). Some patients with insulin-dependent diabetes may be found wearing an insulin pump (Figure 20-10 ■).
History and Secondary Assessment

While asking the SAMPLE history questions, remember especially to ask the “M” question about medications. It is very important that the EMT recognize the prescribed medications that a diabetic patient might be taking. Presence of such a medication will help to establish the history of diabetes. Be sure to document and report such a medication to hospital personnel. Medications often taken by diabetics include:

- Insulin (Humulin, Novolin, Iletin, Semilente)
- Actos
- Diabinese, Glucamide
- Orinase
- Micronase, DiaBeta
- Tolnase
- Glucotrol
- Humalog
- Glucophage
- Glynase
- Exenatide (Byetta)
- Lantus

It is particularly important to determine—from the patient, family, or any bystanders—the answers to the following questions, with emphasis on the first four:

- Did the patient take his medication the day of the episode?
- Did the patient eat (or skip any) regular meals on that day?
- Did the patient vomit after eating a meal on that day?
- Did the patient do any unusual exercise or physical activity on that day?
- Was the onset of altered mental status gradual or fast?
- How long has the patient had the signs and symptoms?
- Are there any other signs or symptoms associated with the altered mental status?
- Is there any evidence of injury that might be the cause of the altered mental status?
- Was there any period in which the patient regained a normal mental status and then deteriorated again?
- Did the patient suffer a seizure?
- Does the patient appear to have a fever or other signs of infection?

An altered mental status from hypoglycemia will typically have a sudden onset. The signs and symptoms may progress rapidly over 5 to 30 minutes.

**Signs and Symptoms**

Signs and symptoms commonly associated with a patient who has an altered mental status and has a history of diabetes are (Figure 20-11 ■):

- Rapid onset of an altered mental status after missing or vomiting a meal, unusual exercise, or physical work
- Intoxicated appearance—from staggering or slurred speech to complete unresponsiveness
- Tachycardia (elevated heart rate)
- Cool, moist skin
- Hunger
- Seizure activity
- Uncharacteristic or bizarre behavior, combativeness
- Anxiousness or restlessness
- Bruising at insulin injection sites on the abdomen
- Blood glucose reading of <60 mg/dL

In addition, elderly patients frequently suffer signs and symptoms that mimic a stroke, such as weakness or paralysis on one side of the body. Keep in mind that some medications (beta blockers) may hide the signs of hypoglycemia.

**Emergency Medical Care**

Once you have confirmed an altered mental status and suspect a diabetic emergency that is likely a result of hypoglycemia, you will concentrate emergency care on correcting any life-threatening conditions and reversing the low blood glucose level that is likely to be the cause of the altered mental status.

1. **Establish and maintain an open airway.** If the patient’s mental status is severely altered, it may be necessary to suction the airway to clear secretions or vomitus and to insert an oropharyngeal or nasopharyngeal airway. If the breathing is adequate and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used. If breathing rate or depth is inadequate, assist breathing by positive pressure ventilation with supplemental oxygen.
2. **Determine if the patient is alert enough to swallow.** Oral glucose, the medication administered to the diabetic patient with a low blood glucose level, is given by mouth. If the patient is unable to swallow, you risk the chance that the patient will aspirate the medication or that the thick, sticky glucose will block the airway. One method to ensure that the patient is alert enough to swallow is to hand him the tube of glucose and instruct him to squeeze the contents into his mouth and swallow. Because the patient might be disoriented, it might take some coaching on your part to get the patient to comply with your command. If he is not alert enough to hold onto the tube or squeeze it in his mouth then you might want to reconsider the administration of glucose.

3. **Administer oral glucose.** Follow protocols established by your local or state medical direction. If the patient is no longer alert during the administration of oral glucose, stop the administration of the medication. Immediately reassess the patient’s airway, breathing, and circulation. Prepare to suction.

4. **Transport.**

**Reassessment**

Once the oral glucose has been administered, reassess the patient’s mental status to determine if the medication has had an effect. Remember, it may take more than 20 minutes before you start seeing any improvement in the patient’s mental status following the administration of oral glucose. If local protocol permits, retest the blood glucose level, using the glucose meter, to determine if the blood glucose level is increasing.

If the blood glucose level is increasing and the mental status is improving, it is likely the patient is suffering from a low blood glucose level. If the blood glucose level is increasing but the patient’s mental status is not improving, the patient may be suffering from another condition in addition to the low blood glucose level, such as a stroke. If the blood glucose level remains low, it may indicate that the oral glucose has not yet reached the bloodstream and is not yet effective. If the patient is still able to swallow and alert enough to obey your commands, consult with medical direction for an order to administer an additional tube of oral glucose.

If the patient’s mental status continues to deteriorate or does not improve, manage the airway and breathing. Continue to oxygenate the patient. Communicate and record any changes in the patient’s condition.

**Summary: Assessment and Care**

To review assessment findings and emergency care for diabetic emergencies, see Figures 20-12a, 20-12b, and 20-13.

---

**Assessment Summary**

**ACUTE DIABETIC EMERGENCY: SUSPECTED HYPOGLYCEMIA**

The following are findings that may be associated with suspected hypoglycemia that presents with altered mental status.

**Scene Size-up**

Is altered mental status the result of a medical or a traumatic cause? Look for evidence of:
- Mechanism of injury
- Home or portable oxygen tanks or concentrators
- Alcohol and drug paraphernalia
- Chemicals at or around the scene
- Enclosed spaces
- Improperly vented heating devices in the winter months
- Medications

---

**Primary Assessment**

**General Impression**
- Unusual behavior for situation
- Patient may have agitated or confused facial expression

**Mental Status**
- Alert to unresponsive
- Restlessness
- Agitation
- Disorientation
- Bizarre behavior
- Aggressiveness

**Airway**
- Secretions and vomitus
- Occlusion from tongue

**Breathing**
- Signs of inadequate breathing

**Circulation**
- Tachycardia
- Pale, cool, clammy skin

**Status: Priority Patient**

---

**FIGURE 20-12a**  Assessment summary: altered mental status—diabetic emergency.
Secondary Assessment

Sample History

Signs and symptoms:
- Rapid onset of altered mental status
- Intoxicated appearance
- Tachycardia
- Pale, cool, clammy skin
- Hunger
- Seizures
- Bizarre behavior, restlessness, anxiety

Medications to control diabetes:
- Insulin (Humulin, Novolin, Iletin, Semilente)
- Actos
- Diabinese, Glucamide
- Orinase
- Micronase, DiaBeta
- Glynase
- Tolinase
- Glucotrol
- Humalog
- Glucophage
- Glynase
- Exenatide (Byetta)
- Lantus

Key questions to ask: Did the patient . . .
- Take his medication this day?
- Eat or skip any regular meals?
- Vomit after eating a meal this day?
- Do any unusual exercise or physical activity this day?

Physical Exam

Head, neck, and face:
- Dilated pupils
- Sensation of hunger

Abdomen:
- Pale, cool skin
- Diaphoresis

Extremities:
- Bruising at insulin injection sites
- Weakness or paralysis on one side (especially elderly)

Blood glucose reading

Baseline Vital Signs

BP: normal to low
HR: increased (tachycardia)
RR: may be increased, normal, or low
Skin: pale, cool, and diaphoretic
Pupils: dilated; sluggish to respond
SpO₂: ≥ 94%

Emergency Care Protocol

ACUTE DIABETIC EMERGENCY

1. Establish and maintain an open airway.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. If breathing is adequate, administer oxygen to maintain an SpO₂ of >94%.
5. If the patient has an altered mental status with signs and symptoms of hypoglycemia, has a history of medication to control diabetes or has a blood glucose reading less than 60 mg/dL, and is alert enough to swallow, administer oral glucose:
   - Oral glucose (Glucose or Insta-Glucose) is a concentrated sugar solution that is absorbed and raises the blood glucose level.

   - Obtain an order from medical direction.
   - Ensure the patient is alert enough to swallow.
   - Obtain a blood glucose reading if protocol permits prior to the administration of glucose.
   - Squeeze contents of tube between the cheek and gum or place it between the cheek and gum with a tongue depressor or have the patient self-administer the glucose.
   - No side effects should be seen with oral glucose.
6. Consider advanced life support.
7. Transport in a lateral recumbent (coma or recovery) position.
8. Reassess every 5 minutes.
9. Oral glucose may take up to 20 minutes to get a response from the patient.
**Emergency Care Algorithm**

**ACUTE DIABETIC EMERGENCY**

1. **Mechanism of injury present?**
   - Yes: Consider manual in-line stabilization
   - No: Assess mental status

2. **Assess mental status**
   - Altered but responds to verbal stimuli and obeys commands:
     - Consider oxygen
     - Assess circulation
     - Secondary assessment
     - History of diabetes and on medication to control diabetes or blood glucose <60 mg/dl with signs and symptoms of hypoglycemia
   - Unable to obey commands, responds only to painful stimuli or unresponsive:
     - Airway open?
       - Yes: Suction if necessary
         - Head-tilt, chin-lift or jaw-thrust maneuver
       - No: Assess breathing
         - Adequate: Administer oxygen
         - Inadequate: PPV with O₂

3. **Patient able to swallow?**
   - Yes: Administer oral glucose
   - No: Transport

4. **Transport**
   - Reassessment

---

**FIGURE 20-13** Emergency care algorithm: acute diabetic emergency.

- **PPV** = positive pressure ventilation
- **Cream** = assessment
- **Green** = key decision points
- **Blue** = interventions
Testing the Blood Glucose Level with a Glucose Meter

- **20-1A** Prepare the glucose meter.
- **20-1B** Clean the site.
- **20-1C** Perform the finger stick.
- **20-1D** Waste the first drop of blood onto a dressing. Drop the second blood drop onto the test strip.
- **20-1E** Read the blood glucose value displayed on the glucose meter.
SUMMARY

An altered mental status resulting from an acute diabetic emergency, especially hypoglycemia, is a significant medical condition that requires prompt assessment and emergency care. The patient with an altered mental status may not be able to protect his own airway. Place the patient in the lateral recumbent position to facilitate drainage of secretions or vomitus from the airway. Suction is necessary. Carefully assess the ventilatory status of the patient. If the ventilation is inadequate, even if the patient is still breathing, place the patient in a supine position and assist the patient’s spontaneous breathing with a bag-valve mask, using positive pressure and supplemental oxygen.

Your local protocol may not allow you to distinguish between the diabetic emergency conditions hypoglycemia, DKA, and HHNS, although there are fairly significant differences among them. Primarily, hypoglycemia patients experience a rapid onset of an altered mental status (minutes), whereas the DKA or HHNS patient suffers an altered mental status only after being ill for a day or two or more. The skin may also provide a good clue to the different conditions. The hypoglycemic patient has pale, cool, clammy skin from the release of adrenaline (epinephrine) in the body. The DKA or HHNS patient presents with warm, dry skin. The DKA patient may present with rapid deep respirations (Kussmaul respirations) and a fruity odor on the breath. In hypoglycemia and HHNS, the respirations are typically normal. In hypoglycemia, the respirations may become slow and shallow as the brain cells begin to die from the lack of glucose.

Case Study Follow-up

Scene Size-up
You have been dispatched to a 66-year-old male patient who was found acting oddly by his neighbor. As you approach the scene, the neighbor meets you on the front porch. She states that her neighbor, Mr. Bennet, was out earlier in her garden acting extremely strange and now is in his house on the couch talking but not making any sense. You proceed into the house with caution and find the patient in the living room. The scene appears to be in order with no sign of trauma. As you approach the patient, you begin the primary assessment, you ask your partner to check the house for medications. Your partner finds diphenoxin near the kitchen sink and insulin in the refrigerator.

Primary Assessment
Your general impression is that the patient appears to be pale and perspiring profusely. As you approach, you ask him his name. He responds with mumbled words. You assume the airway is open, and his breathing appears to be adequate. The respirations are at approximately 15 per minute. You assess the radial pulse, which is approximately 100 and strong. His skin is pale, moist and cool. Because Mr. Bennet’s mental status appears to be altered and his skin is pale, moist and cool, your partner places a nasal cannula on the patient at 4 lpm. Your partner also applies the pulse oximeter.

Secondary Assessment
Since Mr. Bennet is not able to respond appropriately to your questions, you perform a rapid secondary assessment. His pupils are equal and respond sluggishly to light. No jugular vein distention is noted in the neck. The breath sounds are equal bilaterally. His abdomen is soft and no tenderness is noted. Mr. Bennet has good pulses in all extremities. He is able to obey your commands. The grip strength is equal but weak in both upper extremities. The strength in the lower extremities is equal but weak. You find no evidence of trauma anywhere on the body. You find no medical alert identification tag.

Mr. Bennet’s blood pressure is 102/60 mmHg. His heart rate is 108 per minute. Respirations are 16 per minute and of normal depth. His skin is pale, cool, and moist. His SpO₂ reading is 97% while on the nasal cannula. You record the baseline vitals.

During the secondary assessment, you gather a SAMPLE history. Upon questioning, the neighbor states that she found the patient out in her garden about 15 minutes prior to calling EMS. She says, “Mr. Bennet was acting strange and not himself.” The neighbor thinks the patient has a heart and sugar problem. She does not know much more about him. Mr. Bennet is disoriented and does not know his name, where he is, who his neighbor is, or what day it is.

By now you are able to determine that Mr. Bennet has an altered mental status, is able to swallow adequately, has a history of diabetes, and is taking medication for the diabetes (as indicated by his neighbor’s mention of “a sugar problem” and the insulin your partner found). His blood glucose level is 48 mg/dL on the glucometer. You administer one tube of oral glucose according to
standing orders from medical direction, place the patient so that he is lying on his left side on the ambulance cot, and begin transport.

**Reassessment**

En route to the hospital you notice that Mr. Bennet is beginning to respond more quickly to commands and questions. He can tell you his name and where he is. His airway is clear and breathing remains adequate. His pulse rate decreases to 86 per minute and his skin becomes less pale, drier, and warmer. You reassess the vital signs and record them. The pulse oximeter reading is 99% and he is showing no signs of hypoxia, so you decrease the liter flow on the nasal cannula to 2 lpm.

As you arrive at the hospital, Mr. Bennet is alert and oriented to person, place, and time. He has no complaints and appears in no distress. You give the hospital an oral report of the change in the patient’s condition and help transfer him to the hospital bed. You and your partner complete a prehospital care report, restock the ambulance, and prepare for another call.

**Case Study Follow-up continued**

1. Describe the disease process associated with hypoglycemia.
2. Name the common signs and symptoms of a patient with hypoglycemia.
3. Describe the emergency medical care for a patient who is hypoglycemic.
4. Explain why airway management is a major concern in the patient with an altered mental status that results from hypoglycemia.
5. List the indications for oral glucose.
6. List the contraindications for oral glucose.
7. Describe two methods of administering oral glucose.
8. Describe the role of medical direction in emergency care for the diabetic patient.
9. Discuss the disease process associated with diabetic ketoacidosis (DKA).
10. Name the common signs and symptoms of a patient with diabetic ketoacidosis.
11. Describe the emergency medical care for a patient with diabetic ketoacidosis.
12. Discuss the disease process associated with hyperglycemic hyperosmolar nonketotic syndrome (HHNS).
13. Name the common signs and symptoms of a patient with hyperglycemic hyperosmolar nonketotic syndrome.
14. Describe the emergency medical care for a patient with hyperglycemic hyperosmolar nonketotic syndrome.

**IN REVIEW**

1. Describe the disease process associated with hypoglycemia.
2. Name the common signs and symptoms of a patient with hypoglycemia.
3. Describe the emergency medical care for a patient who is hypoglycemic.
4. Explain why airway management is a major concern in the patient with an altered mental status that results from hypoglycemia.
5. List the indications for oral glucose.
6. List the contraindications for oral glucose.
7. Describe two methods of administering oral glucose.
8. Describe the role of medical direction in emergency care for the diabetic patient.
9. Discuss the disease process associated with diabetic ketoacidosis (DKA).
10. Name the common signs and symptoms of a patient with diabetic ketoacidosis.
11. Describe the emergency medical care for a patient with diabetic ketoacidosis.
12. Discuss the disease process associated with hyperglycemic hyperosmolar nonketotic syndrome (HHNS).
13. Name the common signs and symptoms of a patient with hyperglycemic hyperosmolar nonketotic syndrome.
14. Describe the emergency medical care for a patient with hyperglycemic hyperosmolar nonketotic syndrome.

**CRITICAL THINKING**

You arrive on the scene and find a 34-year-old female patient lying supine on the couch. As you enter the scene, you note that the patient is pale and very diaphoretic. She is not alert, and you hear sonorous sounds on inhalation. She responds to painful stimuli with moans. Her respirations are 12 per minute with adequate chest rise. Her radial pulse is 122 bpm. The skin is pale, cool, and clammy. Her BP is 108/62 mmHg. The neighbor who called 911 brings you the patient’s medications, which include Zoloft and Novolin. She doesn’t know any medical history regarding the patient. She states the patient called her about 20 minutes ago and told her she wasn’t feeling well. The neighbor decided to come check on her and found her on the couch and not responding.

1. What emergency care would you provide during the primary assessment?
2. Based on the signs, what condition do you suspect the patient is experiencing?
3. What other assessment procedures would be helpful to you in this patient?
4. What would you expect the blood glucose reading to be in this patient?
5. Why is the onset of the altered mental status significant in this patient?
Anaphylactic Reactions

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • Medicine (Content Area: Immunology)

COMPETENCY • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES • After reading this chapter, you should be able to:

21-1. Define key terms introduced in this chapter.
21-2. Explain the importance of being able to recognize and treat anaphylactic reactions.
21-3. Describe the pathophysiological process by which exposure to an antigen results in anaphylaxis.
21-4. Explain the life-threatening mechanisms of anaphylaxis, including airway compromise, impaired ventilation and oxygenation, and impaired perfusion.
21-5. Describe the difference between an anaphylactic and an anaphylactoid reaction.
21-6. Discuss the ways that an antigen can be introduced into the body and substances that commonly cause anaphylactic or anaphylactoid reactions.
21-7. Explain an assessment-based approach to anaphylactic reaction including scene size-up, primary and secondary assessments, and reassessment.
21-8. Recognize the signs and symptoms of anaphylactic reaction.
21-9. List the two key categories of signs and symptoms that specifically indicate a severe anaphylactic reaction.
21-10. Develop a treatment plan for the patient with an anaphylactic reaction.
21-11. Describe the role of epinephrine in the treatment of anaphylaxis and the criteria and procedure administration of epinephrine.

KEY TERMS • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

INTRODUCTION

Allergic reactions can occur at any time and to anyone. A wide variety of substances can produce such reactions. Foods, medications, insect stings—even exercise—are common causes. An allergic reaction may be as mild as a runny nose or mild skin rash. At the other end of the spectrum, however, is the life-threatening allergic reaction that is known as an anaphylactic reaction.

An anaphylactic reaction is a severe, exaggerated, systemic allergic reaction that is associated with severe swelling of the upper and lower airways, constriction of the bronchioles, leakage of fluid from the capillaries, systemic vessel dilation, and an increased production of mucus. An anaphylactic reaction may be so severe that the upper airway closes, the respirations become very labored because of high airway resistance from swollen and constricted bronchioles, and the blood pressure becomes dangerously low because of the dilation of the vessels and leakage of fluid from the capillaries.

Another frightening aspect of anaphylactic reactions is that they typically develop and become life threatening very quickly, within minutes after exposure to the cause of the reaction.

Because anaphylactic reactions are often hard to predict and have the potential to so quickly become life threatening, it is important for the EMT to recognize an anaphylactic reaction in a patient promptly and to manage it swiftly and effectively. Delay in emergency care can easily and rapidly lead to deterioration in the patient’s condition and even to death.

ANAPHYLACTIC REACTION

The body has a defense mechanism, known as the immune system, to fight off invasion by foreign substances. Foreign substances, called antigens (including a specific type of antigen called allergens), are recognized by the cells of the immune system and eventually destroyed. In most cases, this immune response takes place with no allergic reaction or with just a mild allergic reaction. Occasionally there is a severe, life-threatening anaphylactic reaction.

Pathophysiology of Anaphylactic Reaction

An antigen can enter the body through the skin, the gastrointestinal tract, or the respiratory tract. When one does, it sets off an immune response in which the immune system detects the antigen and produces antibodies. Antibodies are proteins that search for the antigen, combine with it, and help to destroy it. The type of antibody that is produced specific to anaphylaxis is called immunoglobin E and is abbreviated as IgE. Thus, this type of reaction in which antibodies are formed in response to an allergen introduced into the body is referred to as an IgE-mediated anaphylactic reaction.

Most antigens that enter the body are easily fought off by the immune system with no allergic response—that is, without producing any noticeable effects. If, however, the type of antigen called an allergen enters the body, the effect is quite different. Although allergens are often quite common and harmless to most individuals, they cause an abnormal response by the immune system known as an allergic reaction.

An allergic reaction is a misdirected and excessive response by the immune system to an allergen. The immune system overestimates the danger of the allergen and produces a greater-than-necessary response. The response can be local—that is, a response isolated to one area of the body—or it can be systemic—that is,
producing effects throughout the body. The response of the immune system to an allergen is often rapid, leading to the sudden onset of the allergic reaction.

The allergen itself is usually harmless to the patient, and most allergic reactions are mild, producing nothing more than discomfort, such as itching, a runny nose, and watery eyes—results of the body’s attempts to eliminate the allergen or antigen. Occasionally, however, a severe, life-threatening immune response occurs. Such a severe, life-threatening allergic reaction is known as an anaphylactic reaction and is also known as anaphylaxis or anaphylactic shock.

In an anaphylactic reaction, the entire body is affected by the release of chemical substances by the immune system. These chemical substances produce life-threatening reactions in the airway, lungs, blood vessels, and heart. Swelling in the upper airway can cause obstruction and a reduction of air to the lungs. Bronchoconstriction and swelling in the lower airways can cause severe breathing difficulty and possible hypoxia. Blood vessels dilate and capillaries can begin to leak, decreasing the blood pressure and causing shock (hypoperfusion). An increase in mucus production leads to further restriction of air movement, increased airway resistance, and the potential for plugging of smaller bronchioles.

An anaphylactic reaction is a life-threatening condition that requires prompt recognition and intervention and commonly leads to death without proper treatment.

**PATHOPHYSIOLOGY PEARLS**

The life-threatening signs and symptoms seen in anaphylactic reactions are produced by bronchoconstriction, increased capillary permeability, and vasodilation. Your emergency care for the patient with an anaphylactic reaction is geared toward reversing those three conditions.

**Sensitization**

An anaphylactic reaction may not occur the first time the body is exposed to and produces antibodies against a particular antigen. However, during that first exposure, a condition known as hypersensitivity develops, which means that at some subsequent time, when the person is again exposed to that same antigen and IgE antibodies are present, an anaphylactic reaction may occur. This process of developing hypersensitivity on first exposure to an antigen is known as sensitization and produces an IgE-mediated anaphylactic reaction. An IgE-mediated reaction is also called a classic anaphylactic reaction. (In some cases, an anaphylactoid or non-IgE-mediated reaction can occur the first time an antigen is introduced into the body. This type of reaction will be discussed in the next section.)

This is how sensitization works in the IgE-mediated anaphylactic reaction: When an antigen is introduced into the body, the body recognizes it as a foreign or “nonself” substance and forms IgE antibodies to fight off the antigen. The antibodies attach themselves to two types of cells in the body: mast cells and basophils. Mast cells are located in connective tissue and are concentrated around the heart, lungs, and vessels. Basophils are immature mast cells that circulate in the blood. The antibody may stay attached to the mast cells and basophils for minutes, days, weeks, months, or years. As long as the antibody is attached, the patient is said to be “sensitized” to the substance that generated the antibodies.

Once sensitization occurs, the patient is primed for a possible anaphylactic reaction. It may take several exposures to a foreign substance over a long period of time. For example, you may encounter a patient who had eaten crab meat for years without any noticeable reaction, but his consumption of crab on this occasion produced an anaphylactic reaction and a call to EMS. Because of such variations in sensitization, it is difficult to predict who is at risk of developing an anaphylactic reaction. However, once a patient has had an anaphylactic reaction, it should be assumed that he will react in a similar fashion to another exposure to the same antigen.

When the antigen is reintroduced into the body, it attaches to the IgE antibodies that are now located on the mast cells and basophils. The mast and basophil cell membranes break down and release chemical substances, referred to as chemical mediators. These chemical mediators then cause a cascade of events to occur that can lead to specific signs and symptoms and the life-threatening condition of anaphylaxis. The primary chemical mediator released from mast cells and basophils is histamine. Histamine causes bronchoconstriction, vasodilation, and an increase in capillary permeability (leakage).

**PATHOPHYSIOLOGY PEARLS**

The direct attachment of the antigen to the IgE antibody located on the mast cells and basophils causes the cell membrane to break down and release the chemical mediators that produce the anaphylactic reaction.

As already noted, the life-threatening responses that are directly produced from the release of the chemical mediators are bronchoconstriction, increase in capillary permeability, and vasodilation (Figure 21-1). These produce the majority of signs and symptoms seen in anaphylaxis. If the bronchoconstriction, increase in capillary permeability, and vasodilation can be reversed, the life-threatening condition and the signs and symptoms will be reversed.

**Anaphylactoid (Non-IgE-Mediated) Reaction**

In some reactions the chemical mediators can be released from the mast cells and basophils the first time the antigen is introduced into the body without the patient ever being sensitized. The antigen itself causes the release of the chemical mediators. This reaction, where no sensitization is required, is referred to as an anaphylactoid reaction.
or a non-IgE-mediated reaction. The body’s responses (bronchoconstriction, increased capillary permeability, and vasodilation) and the signs and symptoms are exactly the same as for an IgE-mediated anaphylactic reaction. Thus, the treatment is exactly the same. The primary difference, when you collect the history from the patient, is that he will not have had a previous exposure to the antigen, as the patient suffering from a true anaphylactic reaction would have had. See Table 21-1 for substances that commonly cause anaphylactoid reactions. For purposes of discussion in this chapter, reference to severe allergic reaction and anaphylactic reaction includes anaphylactoid reaction, since the signs and symptoms and treatment are exactly the same.

**Causes of Anaphylactic (IgE-Mediated) Reaction**

An anaphylactic reaction can be triggered by any of a large number of substances. The most common cause is medications that are either taken orally or injected. Some cases of anaphylactic reaction are idiopathic, which means that their causes cannot be identified. This is a difficult situation for the patient, since he does not know what substance may trigger another reaction.

An antigen may enter the body by:

- **Injection.** The substance is introduced directly into the body by bites, stings, needles, or infusions.
- **Ingestion.** The patient swallows the substance.
- **Inhalation.** The patient breathes the substance into his lungs.
- **Contact (absorption).** The antigen is absorbed through the skin.

Injection, especially intramuscular or intravenous injection, is the route most often associated with anaphylactic reactions. Penicillin is the most common cause of anaphylactic reactions. Some of the common causes of anaphylactic reactions are:

- **Venom** from insect bites or stings, especially of wasps, hornets, yellow jackets, and fire ants. Other bites or stings often causing reactions include those of deer flies, gnats, horse flies, mosquitoes, cockroaches, and miller moths. Snake and spider venom may also cause an anaphylactic reaction.
- **Foods,** including peanuts, other nuts, milk, eggs, shellfish, whitefish, food additives, chocolate, cottonseed oil, and berries.
- **Pollen** from plants, especially ragweed and grasses.
- **Medications** (see Table 21-2), including antibiotics, local anesthetics, aspirin, seizure medications, muscle relaxants, nonsteroidal anti-inflammatory agents, and vitamins. Insulin and tetanus and diphtheria toxoids may also produce an anaphylactic reaction. Remember, however, a side effect of a medication is not an allergic reaction to the drug (e.g., nausea after codeine administration).
- **A large number of other substances,** such as glue, can produce an anaphylactic reaction.
- **Exercise** may accentuate the anaphylactic response when certain foods have been ingested close to the time of exercise. This condition is most common in dedicated athletes.
- **Temperature,** both heat and cold, may trigger an anaphylactic reaction.
- **Latex,** most often found in examination gloves and other medical devices.

**Assessment-Based Approach to Anaphylactic Reaction**

Because the signs and symptoms of anaphylactic reaction are similar to those for many other medical problems, you may or may not be able to determine that the cause of the problem is a simple allergic reaction. However, a more serious and systemic anaphylactic reaction should be obvious from its characteristic extreme signs and symptoms.

**Scene Size-up**

During the scene size-up, you must be certain that your own safety is not in jeopardy, especially if the anaphylactic reaction is the result of a bite or sting. You might encounter a patient who disrupted a yellow jacket or wasp nest and was stung several times. The yellow jackets or wasps may still be at the scene and will attack once you exit the ambulance, exposing you to the risk of an anaphylactic reaction from the stings. If you detect the presence of large numbers of wasps or yellow jackets, you may have to wait until they settle or disperse before approaching the patient. It may be necessary to warn bystanders away from the scene to prevent them from becoming patients.

Because so many different substances may cause an anaphylactic reaction, the scene size-up may not provide any obvious clues as to the nature of the illness. A response to a restaurant or a home for a patient complaining of difficulty in breathing and itching after eating may cause you to suspect a possible anaphylactic reaction. Medications found at the scene may provide some clues. A patient at a health club, gym, or park who was exercising following ingestion of food may increase your suspicion that an anaphylactic reaction may be involved.
Primary Assessment

Because an anaphylactic reaction can be life threatening, the primary assessment is an extremely important part of the patient contact. In gathering your general impression of a patient with an anaphylactic reaction, you may note that he complains of “not feeling well” or of malaise, a generalized feeling of weakness or discomfort. Such a patient may display a sense of “impending doom.” The patient’s mental status may be anywhere on the continuum from responsive and alert, to responsive but disoriented, to unresponsive.

Closely assess the airway for signs of obstruction. Stridor or crowing sounds indicate significant swelling to the upper airway. Inserting an airway adjunct may not help relieve the obstruction if the swelling is at the level of the larynx. It may be necessary to provide positive pressure ventilation to force the air past the swollen upper airway. You may also find a swollen tongue that interferes with the airway. Wheezing may be prominent upon assessment of breathing. If a patient is severely disoriented, unresponsive, or breathing inadequately, immediately begin positive pressure ventilation with supplemental oxygen. If the breathing is adequate, provide supplemental oxygen if any signs of respiratory distress, poor perfusion, hypoxemia, or hypoxia are present. Maintain an SpO₂ reading at or above 94%.

PATHOPHYSIOLOGY PEARLS

Wheezing is caused by constriction and inflammation of the lining of the bronchioles, which results in an increase in airway resistance, which makes it more difficult for the patient to move air in and out of the alveoli. ■

Delivery of ventilations may be difficult because of the bronchoconstriction, inflammation, increased mucus production, and drastically increased resistance in the lower airway. You might find it hard to squeeze the bag of the bag-valve-mask device. If a pop-off relief valve is present on the bag-valve-mask device, it may be necessary to deactivate it or to place your thumb over it in order to deliver a sufficient tidal volume of air to ventilate the patient effectively.

Management of the airway may require endotracheal intubation, the placement of a tube in the trachea to facilitate breathing. In most jurisdictions, this must be performed by an advanced life support (ALS) team. Consider calling for ALS backup.

The pulse in a patient suffering from an anaphylactic reaction may be weak and rapid. The radial pulse may not be present because of the low blood pressure. Edema, or swelling, may be obvious in the face, neck, lips, tongue, hands, and feet (Figure 21-2a ■). The skin may be red and warm, or the patient’s skin may be cyanotic from inadequate breathing. You may notice hives, raised red blotches, all over the skin (Figures 21-2b and 21-2c ■). Hives are usually accompanied by severe itching. Hives (urticaria) and itching (pruritus) are the hallmark signs and symptoms of an allergic reaction.

Some of the early noticeable signs of anaphylaxis, which are nonspecific, are:

- Rhinitis (stuffy, runny, itchy nose)
- Tachycardia
- Pruritus (itching) that is localized or diffuse
• Faintness or light-headedness
• Warm, flushed skin (skin can appear pale)
• Agitation or anxiousness
• Urticaria (Hives)
• Edema (swelling) of the skin and other tissues such as the lips and tongue (angioedema or angioneurotic edema)

**ASSESSMENT TIPS**

Urticaria (hives) is the most common early physical assessment finding in anaphylaxis. Rhinitis (stuffy, runny, itchy nose) is an early sign indicating respiratory involvement.

Because of the potential seriousness of an anaphylactic reaction and its effects on the airway, lungs, blood vessels, and heart, the patient is considered a priority and should be prepared for immediate transport. If the patient exhibits signs of an anaphylactic reaction—that is, respiratory distress and/or shock (hypoperfusion)—before leaving the scene, determine if the patient has a prescribed epinephrine auto-injector. Inquire of relatives or any bystanders if the patient is unresponsive. If he has a prescribed epinephrine auto-injector, locate it (or them, if he has more than one) immediately.

**Secondary Assessment**

The secondary assessment should be conducted whether the patient’s signs and symptoms indicate a mild, moderate, or severe allergic reaction; however, if the patient exhibits signs of severe reaction, do not delay transport of the patient to complete the secondary assessment. Instead, perform the secondary assessment en route to the hospital.

**History.** Assess the history of the present illness. The OPQRST line of questioning can be used to do so. Information about the onset of the reaction is especially important. What was the patient doing prior to the onset? What seemed to trigger the signs and symptoms? Such questioning may actually identify the antigen causing the reaction. Determine if anything makes the signs or symptoms better or worse. Did the patient take any medications in an attempt to relieve the symptoms?

Time can be a critical factor in dealing with patients with an anaphylactic reaction. Most anaphylactic reactions are apparent within 20 minutes after exposure to the antigen; however, reaction time can vary from seconds to hours. As a general rule, the quicker the patient develops signs and symptoms after exposure, the more severe the reaction will be. Thus, if the reaction occurred within minutes after exposure, you should suspect and be prepared to manage a very severe anaphylactic reaction.

Obtain a history from the patient. If he is unable to speak or is unresponsive, try to obtain as much information as possible from relatives or bystanders while preparing the patient for transport, but without delaying transport if the patient’s signs and symptoms indicate a severe reaction. When taking the history, it is important to determine the following:

**Signs and Symptoms**

• Are the signs and symptoms consistent with an anaphylactic reaction?
• Do the signs and symptoms indicate a mild, moderate, or severe reaction?
• Are the signs and symptoms getting progressively worse or better?

**Allergies**

• Does the patient have a history of allergies to food, medications, plants, insect stings or bites, or other? Prior anaphylactic reaction? To what?

**Medications**

• Does the patient have a prescribed epinephrine auto-injector? (This must be determined early in the assessment for a patient with signs and symptoms of a severe reaction.)
• Has the patient taken any medications to relieve the current signs or symptoms, including over-the-counter medications such as Benadryl?
• What other medication is the patient taking? Any new medications prescribed?

**Pertinent Past History**

• Has the patient ever suffered an anaphylactic reaction in the past?
• How severe was the last reaction?
• Does the patient have any other significant illnesses?

**Last Oral Intake**

• When was the last time the patient had anything to eat or drink? What did he recently eat or drink?
• How much food or drink did the patient consume?

**Events Prior to Illness**

• What was the patient doing prior to onset of the anaphylactic reaction?
• What was the patient exposed to that may have caused the anaphylactic reaction?
• What was the route of exposure—injection, ingestion, inhalation, or contact?

**ASSESSMENT TIPS**

The faster the onset of the signs and symptoms of an anaphylactic reaction, the more severe and prolonged the reaction will probably be.

**Signs and Symptoms.** The signs and symptoms of an anaphylactic reaction involve the skin, respiratory system, cardiovascular system, gastrointestinal system, central nervous system, and genitourinary system. Most of the signs and symptoms are primarily caused by an increase in capillary permeability, vaso-dilation, or bronchial constriction and inflammation (see Table 21-3). The signs and symptoms vary with the
severity of the reaction. An anaphylactic reaction can produce serious compromise of respiratory function or circulatory function (shock, or hypoperfusion) or both. If hypoperfusion or shock is present along with other signs and symptoms of anaphylaxis, it is usually referred to as anaphylactic shock. You would see a decrease in the blood pressure in the patient. Common signs and symptoms of an anaphylactic reaction by body system include the following:

**Skin**
- Warm, tingling feeling in the face, mouth, chest, feet, and hands (early symptom)
- Intense itching (pruritus), especially of hands and feet (hallmark symptom)
- Hives (urticaria) (hallmark sign)
- Flushed or red skin
- Swelling to the face, lips, neck, hands, feet, and tongue
- Cyanosis (severe cases)

**Respiratory System**
- Patient complaints of a “lump in the throat”
- Tightness in the chest
- High-pitched cough
- Tachypnea (increased breathing rate)

**Cardiovascular System**
- Tachycardia (increased heart rate)
- Hypotension (decreased blood pressure)
- Irregular pulse
- Absent radial pulse (severe shock)

**Central Nervous System**
- Increased anxiety
- Light-headedness
- Unresponsiveness
- Disorientation
- Restlessness
- Seizures
- Headache

**Gastrointestinal System**
- Nausea/vomiting
- Abdominal cramping

</table>
• Diarrhea
• Difficulty in swallowing
• Loss of bowel control

**Genitourinary System**

• Urgent need to urinate
• Cramping of the uterus

**Generalized Signs and Symptoms**

• Itchy, watery eyes
• Runny or stuffy nose
• Sense of impending doom
• Complaints of “not feeling well”
• General weakness or discomfort

**Physical Exam.** Focus the physical exam on the patient's complaints involving the airway, breathing, and circulation. If the patient is unresponsive, conduct a rapid secondary assessment. Your major concerns in both the responsive and unresponsive patient are a compromised airway, inadequate breathing, and shock (hypoperfusion). Inspection of the face and neck typically reveals a swollen appearance and hives. The lips may also be swollen and cyanotic.

The two key categories of signs and symptoms that specifically indicate a severe anaphylactic reaction are:

- **Airway and respiratory compromise.** Airway occlusion; respiratory distress or respiratory failure with possible wheezing or stridor
- **Shock (hypoperfusion).** Absent or weak pulses; rapid heartbeat; decreased blood pressure; deteriorating mental status.

This patient needs immediate intervention and administration of epinephrine, if possible.

**ASSESSMENT TIPS**

If the face, neck, tongue, and lips are swollen, it is likely that the mucous lining of the larynx of the upper airway is also swollen. Stridorous sounds with respiration would be an indication of this swelling.

**PATHOPHYSIOLOGY PEARLS**

When the lining of the larynx swells, it swells inward, partially occluding the airway and increasing the resistance to airflow. This creates the stridorous sounds.

**PATHOPHYSIOLOGY PEARLS**

Vasodilation and increased capillary permeability can cause the loss of up to 37 percent of the circulating blood volume, leading to a decreased preload and cardiovascular collapse.

Retractions and poor rise and fall of the chest may be noted upon inspection. Diffuse wheezing may be heard on auscultation of the breath sounds. Diminished breath sounds bilaterally are a sign of inadequate respiration and an indication for immediate positive pressure ventilation. The bronchoconstriction may be so severe that air movement is minimal through the bronchioles and into the lungs; therefore, wheezing or breath sounds may not be heard, especially when severe respiratory distress is evident.

Quickly inspect the extremities for bites, stings, or injection marks. Redness may be noted around the bite or sting, providing a clue to the cause of the anaphylactic reaction. Check pulses and skin temperature, color, and condition for indications of shock (hypoperfusion).

**Baseline Vital Signs.** Assess the baseline vital signs, paying particular attention to the breathing, pulse, and blood pressure. The respiratory rate may be beyond the normal limits. Early in an anaphylactic reaction, you may find that the respiratory rate is fast and labored. As the condition progresses and the patient begins to tire, the breathing may become slower than normal and very shallow. Wheezes may be heard without a stethoscope. The breathing may also sound noisy, with a rattling sound on inspiration and exhalation, from the excessive mucus in the larger lower airways. The pulse is rapid and may be weak. In severe cases of anaphylaxis, the radial pulse may be absent or extremely weak. Unlike other types of shock, the skin is usually red, dry, and warm to the touch. Hives and itching are the most common complaints in all types of allergic reaction: mild, moderate, and severe. Hypotension is common in a severe reaction.

**PATHOPHYSIOLOGY PEARLS**

In a moderate-to-severe allergic reaction, in addition to the bronchoconstriction and edema (swelling) of the bronchiole lining in the lower airways, there is also an increase in mucus production. This mucus may begin to occlude the smaller bronchioles.

**ASSESSMENT TIPS**

What appears to be a mild allergic reaction can progress to a severe, life-threatening anaphylactic reaction within minutes.

Never underestimate the severity of an anaphylactic reaction. Because death can occur within minutes, immediate intervention is imperative. Do not mistake anaphylaxis for other conditions with similar signs and symptoms such as hyperventilation, anxiety attacks, alcohol intoxication, or hypoglycemia.

**Emergency Medical Care**

The key to emergency care in cases of allergic reaction is for the EMT to distinguish between a systemic reaction and a local reaction (Table 21-1). The local reaction typically does not require aggressive intervention or administration of medication by the EMT. In a patient with a local reaction, you will maintain adequate oxygenation and transport the patient while constantly assessing for
signs and symptoms of a systemic reaction. Epinephrine should be administered to patients with signs and symptoms of systemic reaction, especially if they present with hypotension, respiratory distress, or upper airway edema. Your major concern is that the mild local reaction may rapidly progress to a moderate-to-severe, or anaphylactic, reaction. Be prepared to manage the worst-case scenario and continuously reassess the patient’s condition.

Patients experiencing a systemic anaphylactic reaction require immediate and aggressive intervention by the EMT. Provide the following emergency care:

- **Maintain a patent airway.** The patient may initially present with airway compromise associated with swelling of the tissues lining the larynx. Since airway adjuncts are not effective in managing the obstruction, it may be necessary to force air past the swollen tissues by positive pressure ventilation. If using a bag-valve-mask device, you may find it much harder to compress the bag to deliver the contents. It may be necessary to deactivate the pop-off valve in order to deliver adequate ventilations. Inserting an oral or nasal airway in the unresponsive patient will help to prevent the tongue from occluding the airway.

- **Suction any secretions.** In the severe anaphylactic reaction, heavy secretions may be present. Clear the mouth of secretions by suction when necessary.

- **Maintain adequate oxygenation.** It is vital that hypoxia and hypoxemia is reversed. If the breathing is adequate, oxygen should be administered to maintain an SpO₂ of 94% or greater and signs of hypoxia are eliminated. If the patient is being artificially ventilated, supplemental oxygen must be delivered through the ventilation delivery device.

- **Be prepared to assist ventilation.** Patients with a mild allergic reaction may not exhibit any respiratory distress during the length of your contact. On the other hand, a patient’s condition may progress very rapidly over minutes, or more slowly over hours, and eventually produce severe respiratory distress. Have your ventilation equipment ready and prepared to begin positive pressure ventilation, if necessary. Continuously reassess the patient’s breathing status for signs of inadequate breathing.

- **Administer epinephrine by a prescribed auto-injector.** In any patient with signs and symptoms of a systemic anaphylactic reaction, especially when the patient presents with hypotension, respiratory distress, or upper airway edema, obtain an order from medical direction to administer the patient’s prescribed auto-injector. The order may be obtained on-line or off-line. If the patient is suffering from a mild or local allergic reaction and there are no signs of a systemic reaction, respiratory compromise (such as respiratory distress, stridor, or wheezing), or poor perfusion (weak pulses, decreasing mental status, or low blood pressure), do not administer epinephrine. Consult with medical direction for further orders. If an epinephrine auto-injector is not available, immediately begin transport.

- **Consider calling for advanced life support.** Because of the potential for severe compromise to the airway, breathing, and circulation, it may be necessary to request ALS for advanced airway control and further administration of medication.

- **Initiate early transport.** Do not unnecessarily delay transport of the patient. Continued assessment and emergency care can be done en route to the hospital.

### Reassessment

Reassessment is extremely important in the management of mild, moderate, and severe allergic reactions. The patient with a local reaction should be constantly monitored for indications that the reaction is worsening and that further intervention, such as epinephrine injection or airway control, may be needed. The patient who has received an epinephrine injection should be reassessed to determine if the injection has been effective in reversing the life-threatening condition.

Regardless of the severity of the reaction, closely reassess the airway, breathing, oxygenation, and circulation status. Signs of deterioration are wheezing or stridor, increased hoarseness or difficulty in speaking, signs of inadequate breathing, decreasing mental status, decreasing blood pressure, increasing heart rate, and weak or absent radial pulses. Reassess and record the baseline vital signs and other reassessment findings.

Reassess the patient 2 minutes after the injection of epinephrine. Look for improvement in the patient’s ability to breathe, improvement in his mental status, increasing SpO₂ reading, and an increase in the blood pressure. If the condition has not improved, it may be necessary to consult with medical direction about a second injection if another epinephrine auto-injector is available.

### Summary: Assessment and Care

To review assessment findings that may be associated with allergic reaction and emergency care for allergic reaction, see Figures 21-3 and 21-4.
Assessment Summary

ANAPHYLACTIC REACTION
The following findings may be associated with an anaphylactic reaction.

Scene Size-up
Ensure your own safety.
Look for evidence of cause of anaphylactic reaction:
- Injection (venom, medications)
- Ingestion (foods, medications)
- Inhalation (pollen, chemical irritants)
- Absorption (chemicals, plants)
Location of patient may provide clues as to cause (e.g., home, physician’s office, outdoors, restaurant).

Primary Assessment
General Impression
- Feeling of impending doom
- Malaise
- Weakness
- Discomfort
Mental Status
- Alert to unresponsive
- Decreasing mental status
- Increased anxiety
- Disorientation
- Restlessness
- Seizure activity
Airway
- Signs of laryngeal edema (stridor, crowing)
- Swollen tongue
Breathing
- Inadequate ventilation
- Wheezing
Circulation
- Weak pulses
- Tachycardia
- Red, warm, dry skin
- Cyanosis
Status: Priority Patient

Secondary Assessment
Sample History
Signs and symptoms:
- Tightness in chest
- High-pitched cough
- Impaired ability to talk or hoarseness
- Urgent need to urinate
- Uterine cramping
- Hives and itching
- Red flushed skin
- Stridor or crowing respirations
- Wheezing on auscultation
- Swelling to face, hands, and feet
Ask questions regarding the following:
- Does the patient have a history of allergy?
- When did the exposure to the allergen occur?
- Can the allergen be identified?
- Has the patient ever suffered an anaphylactic reaction before?
- If so, how severe was the reaction?
- Does the patient have an epinephrine auto-injector?

Physical Exam
Head, neck, and face:
- Edema to face, hands, neck, and lips
- Hives
- Itching
- Warm, tingling feeling
- Cyanosis
- Difficulty in swallowing
- Itchy and watery eyes
- Runny or stuffy nose
- Coughed-up mucus
- Headache
Chest:
- Retractions
- Accessory muscle use
- Wheezing in all lung lobes
Abdomen:
- Nausea/vomiting
- Abdominal cramping
- Diarrhea
- Loss of bowel control
Extremities:
- Warm, tingling feeling in hands and feet
- Itching, especially hands and feet
- Edema (swelling) to hands and feet
- Red, warm, dry skin
- Weak or absent peripheral pulses

Baseline Vital Signs
- BP: hypotension
- HR: tachycardia with weak peripheral pulses
- RR: tachypnea with wheezing and labored breathing
- Skin: red, warm, dry, hives, itching
- Pupils: normal to dilated and responsive to light
- \( \text{SpO}_2 < 94\%

\text{FIGURE 21-3a}  Assessment summary: anaphylactic reaction.
ANAPHYLACTIC REACTION

1. Establish and maintain an open airway.
2. Suction secretions.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen via reservoir at 10–12 ventilations/minute.
4. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm.
5. If signs and symptoms of moderate or severe (anaphylactic) reaction, including respiratory distress and/or hypotension, administer epinephrine by the patient’s prescribed auto-injector:
   a. Epinephrine is an alpha and beta drug that mimics the sympathetic nervous system and constricts blood vessels, tightens the capillaries, dilates bronchioles, and increases heart rate and contractility.
   b. Epinephrine adult dose: 0.3 mg (over 66 lb)
   c. Epinephrine pediatric dose: 0.15 mg (up to 66 lb)
      a. Obtain order from medical direction.
      b. Check medication.
   d. Press injector firmly against lateral thigh midway between knee and hip.
   e. Hold for 10 seconds.
   f. Dispose of injector in biohazard sharps container.
   g. Record time and reassess patient.
6. Consider calling advanced life support.
7. Expedite transport.
8. Perform a reassessment every 5 minutes.

The body’s response to epinephrine is rapid; within seconds, the patient will begin to feel relief. However, the duration of the drug’s effectiveness is short, only about 10–20 minutes.

Epinephrine comes packaged in a disposable delivery system for self-administration. Common systems prescribed to patients are the EpiPen auto-injector and the Twinject. Each is an auto-injector, which has a spring-activated, concealed needle that is designed to deliver a precise dose of epinephrine when activated. The Twinject contains two doses of epinephrine in one device.

Both epinephrine auto-injectors, the EpiPen and the Twinject, come in two different doses (Figure 21-5 ■). The 0.3 mg dose of epinephrine is for patients weighing 66 pounds or greater. The injector for infants and children up to 66 pounds delivers 0.15 mg of epinephrine. A child who weighs more than 66 pounds may have an adult epinephrine auto-injector. Because a single dose may not completely reverse the effects of an anaphylactic reaction, the physician may prescribe more than one injector or the Twinject device. If the patient does not have the Twinject device, it is important to determine if the patient has more than one injector so you can take it along and be prepared to deliver a second injection. The dose can be repeated in 5 to 15 minutes if the condition is not improving.

Epinephrine Auto-Injector

Epinephrine is the drug of choice for the emergency treatment of a systemic allergic reaction to insect stings or bites, foods, drugs, and other antigens. The drug mimics the responses of the sympathetic nervous system. If you recall from Chapter 7, epinephrine has four properties: alpha₁, alpha₂, beta₁, and beta₂. Alpha₁ causes the vessels to constrict. Alpha₂ regulates the amount of vasoconstriction. Beta₁ increases the heart rate, force of contraction of the heart, and the speed at which the electrical impulses are carried through the heart. Beta₂ causes the bronchiole smooth muscle to dilate.

Recall from earlier in this chapter that three of the major responses to the chemical mediators by the body causing the life-threatening anaphylactic condition are an increase in capillary permeability, vasodilation, and bronchoconstriction and inflammation. Epinephrine’s alpha properties cause vasoconstriction and tighten the capillaries, reversing the vasodilation and increased capillary permeability experienced by the anaphylactic patient. The beta₂ properties cause bronchodilation, reversing the bronchoconstriction. The beta₂ properties will be responsible for side effects from administration. Also, epinephrine has a direct antihistamine effect, reducing the effects of histamine. You can see why epinephrine is the drug of choice in anaphylaxis.
Emergency Care Algorithm

ANAPHYLACTIC REACTION

Mechanism of injury present?

Yes

Consider manual in-line stabilization

Assess mental status

Alert

Administer oxygen

Assess circulation

Secondary assessment

Signs and symptoms of severe allergic or anaphylactic reaction with respiratory distress and/or hypotension?

Yes

Prescribed epinephrine auto-injector?

Yes

Administer epinephrine by auto-injector (0.3 mg adult) (0.15 infant or child)

No

No

Administer epinephrine auto-injector?

Yes

Administer epinephrine by auto-injector (0.3 mg adult) (0.15 infant or child)

No

Transport

Reassessment

Yes

No

Airway open?

Yes

Suction if necessary

Head-tilt, chin-lift or jaw-thrust maneuver

Oro- or nasopharyngeal airway

Assess breathing

Adequate

Inadequate

Administer oxygen

PPV with O₂

Assess circulation

Secondary assessment

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

■ FIGURE 21-4 Emergency care algorithm: anaphylactic reaction.
The auto-injector is simple to use. It is activated by pressing it against the patient’s thigh. The pressure releases a spring-activated plunger, pushing the concealed needle into the thigh muscle and injecting a dose of the drug. If a second dose is needed by the Twinject device, it is necessary to unscrew the gray cap. Hold the blue hub at the needle base and pull the syringe from the barrel. Slide the collar off the plunger. Insert the needle into the thigh and push the plunger all the way down. Remove the needle and dispose of the device in a biohazard puncture-resistant container.

The anterolateral portion of the thigh midway between the hip and knee is preferred because it provides the fastest absorption and the highest peak blood concentration of the medication. Do not inject the epinephrine into a vein or into the buttocks. It is preferable to remove clothing from the site of injection. If it is too difficult to remove the clothing or if the situation requires immediate administration, the injection can be given directly through the clothing.

EMT Skills 21-1 provides an illustration of the process of administering the drug using an EpiPen auto-injector. See EMT Skills 21-2 for the process of administering the drug using the Twinject system. See Figure 21-6 for a detailed summary of the criteria and techniques for administration of epinephrine.

---

**Epinephrine Auto-Injectors**

**Medication Name**
Epinephrine is the generic name. The trade name is Adrenalin. Trade names of epinephrine auto-injectors are EpiPen, EpiPen Jr., and Twinject (adult and child sizes).

**Indications**
All of the following criteria must be met before an EMT administers epinephrine by auto-injector to the patient:
- The patient exhibits signs and symptoms of a moderate-to-severe anaphylactic reaction, including respiratory distress and/or shock (hypoperfusion).
- The medication is prescribed to the patient.
- The EMT has received an order from medical direction for administration, either on-line or off-line.

**Contraindications**
There are no contraindications for the administration of epinephrine in a life-threatening anaphylactic reaction.

**Medication Form**
Epinephrine is a liquid drug contained within an auto-injector that is designed to automatically inject a precise dose when the safety cap is removed and the auto-injector is pressed firmly against the thigh.

**Dosage**
The adult auto-injector delivers a dose of 0.3 mg (for patient >66 lb) of epinephrine. The infant-and-child auto-injector delivers 0.15 mg (for child <66 lb) of epinephrine. A single dose is administered to the patient. It may be necessary in very severe reactions or long transport times to administer a second dose. The EpiPen is capable of delivering only a single dose; however, the Twinject device can deliver a second dose with the same device, if necessary. Consult with medical direction or follow your local protocol for the first dose and before you administer any additional dose beyond the first.

**Administration**
To administer the epinephrine by auto-injector:
1. Obtain an order from medical direction, either on-line or off-line.
2. Obtain the patient’s prescribed auto-injector. Check the medication to be sure that:
   a. The prescription is written for the patient experiencing the anaphylactic reaction. (Medical direction may order administration of epinephrine that is not prescribed to the patient. Some systems carry the EpiPen or Twinject on the EMS unit.)
   b. The medication has not expired, has not become discolored, and does not contain particulates or sediments.

---

**continued**
Epinephrine Auto-Injectors continued

3. Remove the safety cap(s) from the auto-injector.
4. Place the tip of the auto-injector against the lateral aspect of the patient’s thigh midway between the hip and knee.
5. Push the injector firmly against the thigh until the spring-loaded needle is deployed and the medication is injected.
6. Hold the auto-injector in place until all of the medication has been injected.
7. Dispose of the single-dose auto-injector in a biohazard container designed for sharp objects. Be careful not to prick yourself since the needle will now be protruding from the end of the injector. Save the Twinject device and transport it with the patient since it contains a second dose. If a second dose is required from the Twinject device, unscrew and remove the gray cap. Be cautious of the exposed needle. Hold the blue hub at the needle base and pull the syringe from the barrel. Slide the yellow or orange collar off the plunger. Insert the needle into the thigh and push the plunger of the syringe completely down. Remove the needle and syringe and dispose of them in a puncture-resistant biohazard container.
8. Record that epinephrine was administered, the dose, and the time of administration.

Actions

Epinephrine mimics the responses of the sympathetic nervous system. The alpha properties quickly constrict blood vessels to improve blood pressure and reduce the leakage from the capillaries. The beta_2_ properties relax the smooth muscle in the bronchioles to improve breathing and alleviate the wheezing and dyspnea. The beta_1_, which produces side effects, causes an increase in heart rate and contractility. The drug takes effect within seconds, but the duration of its effectiveness is short, about 10–20 minutes.

Side Effects

The patient may complain of side effects following the administration of epinephrine. Possible side effects include the following:

- Increased heart rate
- Pale skin (pallor), especially at the site of injection
- Dizziness
- Chest pain
- Headache
- Nausea and vomiting
- Excitability and anxiousness

Reassessment

Following the administration of epinephrine, it is necessary to reassess the patient. The reassessment should include continued evaluation of the airway, breathing, and circulatory status. Look for the following signs and symptoms that indicate an anaphylactic reaction is worsening:

- Decreasing mental status
- Decreasing blood pressure
- Increased difficulty in breathing and signs of respiratory distress
- Stridor or increased hoarseness

If the condition is worsening, you should consider the following interventions:

- Consult with medical direction about injection of a second dose of epinephrine if a second auto-injector or a Twinject device is available.
- Provide emergency care for shock (hypoperfusion).
- Be prepared to initiate positive pressure ventilation with supplemental oxygen if breathing becomes inadequate.
- Be prepared to initiate CPR and apply the automated external defibrillator (AED) if the patient becomes pulseless.

If the patient’s condition improves following the administration of epinephrine, you should continue to reassess. Be aware that the patient may now complain of side effects from the epinephrine. Continue oxygen therapy with a nonrebreather device and treat for shock, if necessary.

Record and document your interventions and reassessment findings. The baseline vital signs should be checked and recorded every 5 minutes.
Administering an EpiPen Epinephrine Auto-Injector

21-1A  Administer oxygen by nonrebreather mask.

21-1B  Check the EpiPen epinephrine auto-injector to ensure it is prescribed for the patient. Check the expiration date and clarity of the drug.

21-1C  Remove the safety cap from the EpiPen auto-injector.

21-1D  Place the tip of the auto-injector on the anterolateral aspect of the thigh, midway between the hip and knee. Push the injector firmly against the thigh until it activates. Hold it in place until the medication is injected.

21-1E  Properly dispose of the auto-injector. Then record the time of the epinephrine injection.
Administering a Twinject Epinephrine Auto-Injector

21-2A  Administer oxygen and examine the medication.

21-2B  To administer the first dose, remove the green cap from the Twinject device.

21-2C  Remove the red cap from the back of the Twinject.

21-2D  Hold the Twinject with the gray cap against the patient’s lateral thigh midway between hip and knee to inject the first dose.

21-2E  To administer a second dose, remove the gray cap.

21-2F  Remove the yellow or orange tab from the syringe.

21-2G  Inject the second dose into the anterolateral thigh on the leg opposite to the one where the first injection was given.
SUMMARY

An anaphylactic reaction is a severe allergic reaction that is an exaggerated immune response to a foreign substance, known as an antigen. For a true anaphylactic response to take place, the patient must first be sensitized by being exposed at least once to the antigen prior to the anaphylactic reaction. Some drugs and other substances do not require sensitization, but will trigger an anaphylactic reaction on first exposure. This is referred to as an anaphylactoid or non-IgE-mediated reaction, and it produces the same signs and symptoms and requires the same treatment as a true anaphylactic reaction.

In order for an anaphylactic reaction to occur, mast cells and basophils must break down and release chemical mediators, of which histamine is the main mediator. The chemical mediators cause the bronchioles to constrict, the vessels to dilate, and the capillaries to leak. These produce most of the signs and symptoms seen in severe allergic and anaphylactic reactions.

Establishing and maintaining an airway, ventilation, oxygenation, and circulation are the key components of emergency care for an anaphylactic reaction. The drug treatment of choice is epinephrine. Epinephrine’s alpha properties cause the vessels to constrict and the capillaries to tighten, reversing the vasodilation and increased capillary permeability caused by the chemical mediators. The beta 2 properties cause the bronchioles to dilate, reversing the bronchoconstriction.

Scene Size-up

You have been dispatched to a 25-year-old male patient complaining of difficulty in breathing. The patient is located at the Veterans’ Pavilion at Mill Run Park. The Metropark Police have been summoned by a bicyclist who found the patient in distress. The scene is safe, and you find the patient sitting on the grass. The police wave frantically for you to hurry. As you approach the patient, you introduce yourselves and ask the patient his name. He is gasping and can barely get out the name “John Freeman.” He also offers that he feels “real sick.”

Primary Assessment

Your general impression is that the patient, who is dressed in jogging clothes, appears to be having difficulty in breathing. You also note redness and hives that cover his face and neck. The patient is alert and scratching his arms and legs. John responds to questions in one- or two-word phrases with gasps for breath in between. He states, “I—can’t—breathe—and—I itch—all over.” You hear stridor as he inhales. Audible wheezes are heard on inhalation and exhalation. His breathing is labored at a rate of 28 per minute. The patient’s SpO2 reading on room air is 78%, so your partner immediately provides oxygen via a nonrebreather mask at 15 lpm. The radial pulse is barely palpable and is estimated at a rate of approximately 130 per minute. The skin is flushed, dry, and warm to the touch.

Secondary Assessment

You begin your secondary assessment by quickly obtaining a history. You use direct closed-ended questions that require mostly yes and no answers. You determine that John has the following primary symptoms: severe breathing difficulty, itching all over his body, tightness in his throat, and light-headedness. He indicates that he is allergic to yellow-jacket stings. He has a prescribed epinephrine auto-injector in a “fanny pack” around his waist. He suffered a similar reaction about 2 years ago, after which his family physician prescribed the auto-injector. His last reaction was so severe that he had to have an endotracheal tube and spent several days in the hospital. He states that the signs, symptoms, and intensity of this reaction are similar to those of the last one. He last ate at breakfast—a bagel and a cup of coffee.

John states, “I was—jogging on the—trail—when I—felt a sting—in—my left leg. I—ran out of—the woods—to the road. I—felt my—throat—closing and I—began to itch badly.” John estimates that it was about 3 minutes from the sting to the onset of signs and symptoms of the reaction.

Your partner is conducting a rapid secondary assessment as you gather the history. He finds what appears to be the injection site. It is extremely swollen and red, and has a large area of hives surrounding it. Your partner indicates the blood pressure is low at 82/50 mmHg and the radial pulse is extremely weak and at a fast rate...
of 132 beats per minute. The respiratory rate is slightly high at 28 and labored. The skin is warm, dry, and red. Hives are found all over the body. The pulse oximeter only reads 84% while on supplemental oxygen so the nonrebreather mask at 15 lpm is maintained.

You check the epinephrine auto-injector to be sure it is John’s and has not expired. The assessment findings are consistent with a systemic reaction with both hypotension and respiratory distress, so you proceed to administer the epinephrine. You recheck the prescription and expiration date and look for any discoloration or sediment. You explain to John that you are going to place the auto-injector against the outer part of his thigh and that he will feel a pinch when the medication is injected. You then administer the epinephrine.

You and your partner place John in a semisitting position on the stretcher, maintaining oxygen therapy, and begin transport.

**Reassessment**

After about 2 minutes, you reassess the patient and find that the breathing is much less labored and the wheezing has significantly decreased. John says, “Gosh, I feel much better. I can actually breathe now. I feel real nervous though, and my heart is really pounding hard. Is that normal?” You assure him that those are normal side effects from the epinephrine. Your partner indicates that the blood pressure is now up to 124/82 mmHg and that the heart rate has decreased to 98 per minute. The skin looks less red and the hives are beginning to disappear. The SpO₂ reading is 96%, so you switch him to a nasal cannula at 2 lpm and continue to monitor the SpO₂ reading to ensure it is maintained at 94% or greater. You record your treatment, the time of epinephrine administration, and your reassessment findings.

A few minutes later, you again ask John about the symptoms he is currently experiencing. He says his breathing is much easier now, and he no longer feels dizzy or light-headed. He states, “I’m still pretty itchy though!” You find upon reassessment of the vital signs that the blood pressure is now up to 124/82 mmHg and that the heart rate has decreased to 98 per minute. You contact the hospital and report the patient’s condition and give an estimated time of arrival.

Upon arrival at the hospital, you give an oral report to the triage nurse. She says, “Go ahead to Room 9. Dr. Westfield is waiting for you.” There, you report to Dr. Westfield the findings of the assessments before and after the epinephrine injection. As you are leaving the room, the doctor joins you for a moment and says, “You know, you’ve more than likely just saved this guy’s life.”

With a large grin on your face, you walk back to the ambulance, where your partner indicates that the unit is restocked and set for the next run. You complete your prehospital care report and notify dispatch that you are back in service.

---

**Case Study Follow-up continued**

---

**IN REVIEW**

1. List and explain the four life-threatening responses of the body to the release of chemical mediators that produce the signs and symptoms seen in an anaphylactic reaction.
2. Explain the meaning of sensitization in relation to an anaphylactic reaction.
3. List the four routes through which an antigen can be introduced into the body.
4. List the major categories of common causes of anaphylactic reaction and give examples of each category.
5. Describe the airway complications that may occur in anaphylaxis and the appropriate management of them.
6. List the common signs and symptoms and related pathophysiology of anaphylactic reaction in relation to the following body systems/categories: skin, respiratory system, cardiovascular system, central nervous system, gastrointestinal system, genitourinary system, generalized signs and symptoms.
7. Name the two key categories of signs and symptoms of an anaphylactic reaction.
8. Describe the difference in emergency medical treatment for (a) a local allergic reaction, and (b) a systemic anaphylactic reaction.
9. List the indications and contraindications for the epinephrine auto-injector.
10. Describe the method of administration of the epinephrine auto-injector.
11. Describe the actions and possible side effects of the epinephrine auto-injector.
You arrive on the scene and find a 38-year-old female patient at home on the steps of her house. She is sitting upright and appears to be alert; however, she is in obvious severe respiratory distress. She gasps after every word, and you hear obvious stridor on inhalation. Her face, lips, and tongue are severely swollen. You note hives on her face and neck. Her respirations are 38 per minute. Her radial pulse is 142 bpm and is very weak. Her skin is warm, dry, and flushed. Her blood pressure is 78/42 mmHg. Her SpO₂ is 76%. Her husband indicates that she suddenly started to experience respiratory difficulty after taking pain medication that was prescribed to her for dental work that she had done a few hours earlier. She has no known allergies and takes no other medications. She has no significant past medical history. Her last oral intake was about 15 minutes prior to your arrival when she took her pain medication. Her husband states that she was sitting in the recliner when the signs and symptoms suddenly appeared. She has hives on her face, neck, and upper chest. You hear wheezing in all lung fields. Her extremities are flushed, warm, and dry. Her pedal pulses are not palpable.

1. What is causing the airway compromise in the patient?
2. What is causing the respiratory distress?
3. How would you manage the airway and ventilation?
4. What would explain the low blood pressure?
5. What emergency care would you provide to the patient?
6. What criteria would you use to determine the need for the administration of epinephrine?
7. What are side effects of epinephrine?
8. What type of reaction is the patient suffering from?
Toxicologic Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Medicine** (Content Area: Toxicology)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

22-1. Define key terms introduced in this chapter.
22-2. List the primary concerns of the EMT in managing drug and alcohol emergencies.
22-3. Describe each of the four routes by which a poison can enter the body:
   a. Ingestion
   b. Inhalation
   c. Injection
   d. Absorption
22-4. Describe the important steps in managing a poisoning patient, regardless of the specific poison or route of exposure.
22-5. Explain the limited role of specific antidotes in toxicologic emergencies.
22-6. Given a scenario involving a patient who has ingested a poison, describe the steps of assessment-based management.
22-7. Describe the indications, contraindications, mechanism of action, side effects, dosage, and administration of activated charcoal.
22-8. Given a scenario involving a patient who has inhaled a poison, describe the steps of assessment-based management.
22-9. Given a scenario involving a patient who has been exposed to an injected poison, describe the steps of assessment-based management.
22-10. Given a scenario involving a patient who has absorbed a poison, describe the steps of assessment-based management.
22-11. Describe special considerations in assessing and managing patients with each of the following:
   a. Food poisoning
   b. Carbon monoxide poisoning
   c. Cyanide poisoning
   d. Exposure to acid or alkali substances
   e. Exposure to hydrocarbons
   f. Methanol ingestion
   g. Isopropanol ingestion
   h. Ethylene glycol ingestion
   i. Exposure to poisonous plants
22-12. Explain the importance of contacting the poison control center with as complete a patient history as possible, and list specific types of information you should include.
22-13. Given a scenario involving a patient experiencing a drug or alcohol emergency, describe the steps of assessment-based management.
22-14. Describe special considerations in managing violent drug or alcohol abuse patients.
22-15. Describe special considerations in assessing and managing patients experiencing emergencies associated with each of the following:
   a. Drug withdrawal
   b. Alcoholic syndrome
   c. Withdrawal syndrome, including delirium tremens
   d. PCP use
   e. Cocaine use
   f. Amphetamines and methamphetamines
   g. Medication overdose
   h. Huffing
Case Study

Sophie, you ate the leaves of a houseplant and that she is now experiencing bad stomach pains.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for patients suffering from various types of poisonings. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Each year in the United States, thousands of people die or become extremely ill from intentional or accidental poisoning. Most calls to poison control centers involve children, especially toddlers who inadvertently swallow poisonous substances while exploring their environment. Poisonings that occur at home usually involve drugs, cleaning substances, and cosmetics. Poisonings may also result from exposure to industrial chemicals, pesticides, and other substances encountered in the workplace or outdoor environment.

Regardless of the cause, when EMS is promptly called and the appropriate assessment, emergency care, and transport are provided, many instances of poisoning can have a successful outcome.

Drugs and alcohol are abused in a number of ways. In general, the emergency management steps for poisoning are applicable to patients in most alcohol and drug emergencies. However, the EMT needs to be aware of special problems associated with drug and alcohol emergencies. For instance, it is possible that drug or alcohol overdose patients will have injured themselves, so you may be treating them for trauma as well. Patients under the influence of, or withdrawing from, alcohol or drugs can be difficult to manage, behaving in an aggressive or even violent manner and posing threats to your safety.

As an EMT, your primary concern in managing drug and alcohol emergencies will be to protect your own safety, maintain an open airway, treat for life-threatening conditions, and offer calm, nonjudgmental assistance.

POISONS AND POISONINGS

Poisons and Routes of Exposure

A poison is any substance—liquid, solid, or gas—that impairs health or causes death by its chemical action when it enters the body or comes into contact with the skin.

There are more than 1 million poisonings every year in the United States. Although some poisonings are intentional and result in a homicide or suicide, most poisonings are accidental and many involve young children. Most often, the substances involved in unintentional or accidental poisonings are household chemicals.

Toxicology is the study of toxins, antidotes, and the effects of toxins on the body. A toxin is a drug or substance that is poisonous to a human and will cause certain adverse effects that may potentially lead to death. Certain toxins may not be poisonous when used properly, such as prescribed narcotic medications, whereas some toxins are poisonous under all circumstances when in contact with the body, such as sulfuric acid.

Exposure to any harmful substance can be considered a poisoning. However, it is more common for a poisoning to be defined as exposure to a substance other than a drug or medication. The term overdose is
commonly used to describe a poisoning in which the patient has been exposed to an excessive dose of a drug. The drug could be a legally prescribed medication, such as Valium, or it could be an illegal substance such as cocaine. The overdose may be intentional, as in a suicide attempt, or it may be completely accidental. Substance abuse, which can be a form of poisoning, is the inappropriate use of a substance or medication. Substance abuse is addressed later in this chapter.

There are four routes by which a poison can enter the body (EMT Skills 22-1):

- **Ingestion.** A drug or substance can be swallowed with absorption occurring through the gastrointestinal tract (stomach and intestines). This is the most common route of poisoning. A majority of the poison is absorbed from the small intestine and not from the stomach. Thus, it is important to manage the poison before it empties from the stomach into the small intestine. Poisons may remain in the stomach for several hours depending on the circumstances. For example, a larger amount of poison may stay in the stomach longer if it clumps together than if a smaller amount was taken. This will tend to lead to a delayed effect of the poison and signs and symptoms that may not present for several hours.

- **Inhalation.** Breathing a poison, typically a gas, vapor, fume, or aerosol, into the lungs allows for rapid absorption into the body. The poison is transported down the respiratory tract with each inhalation until it reaches the alveoli. Once in the alveoli, the poison can cross the alveolar-capillary membrane and enter the bloodstream, where it is then transported widely throughout the body. This not only produces a more immediate effect than ingestion but also typically causes signs and symptoms to appear earlier with a tendency to be more systemic (throughout the body) in nature. This mechanism produces a variety of signs and symptoms. The inhaled poison can also have direct effects on the pulmonary system by destroying lung tissue. This may lead to pulmonary edema (fluid leaking around and into the alveoli), which inhibits the effective exchange of oxygen and carbon dioxide at the level of the alveoli. Thus, severe respiratory distress in a patient may be an indication of an inhaled poison.

- **Injection.** A poison can be injected under the skin, into the muscle, or directly into a blood vessel. This may result in a local reaction to the poison, which is usually immediate. A local reaction typically causes edema (swelling) at the site of injection, redness, irritation, and sometimes pain. A systemic reaction can occur from injection of a poison, which may be immediate or delayed in its onset, depending on the type of injection and the speed with which it is absorbed and distributed throughout the body. Because of this, a variety of signs and symptoms may occur throughout the body. Injection poisonings may result from drug use, where a person intentionally injects a drug into the body, or from bites and stings. Most insects that can bite or sting are Hymenoptera—an order of insects that includes bees, wasps, hornets, yellow jackets, and fire ants. Other injections may result from spiders, snakes, marine animals, ticks, and scorpions. An anaphylactic reaction, the most severe type of allergic reaction, may result from injection of the venom into the body and its interaction with the immune system. (Review Chapter 21, “Anaphylactic Reactions.”)

- **Absorption.** A poisonous substance can enter the body when it comes in contact with the skin or mucous membranes. The poisonous substance may be a dry powder or a liquid. Severe absorption poisoning results from pesticides and other lethal substances that come in contact with the skin. Absorption-type poisons may cause local irritation or may result in a systemic effect. As an example, organophosphates are commonly found in certain pesticides. Absorption of an organophosphate through the skin may result in a severe systemic reaction, leading to death.

    The signs and symptoms of poisoned patients will depend on the specific poison and the route of entry into the body. One poison may depress the central nervous system, leading to bradycardia, slow, shallow respirations, and hypotension, whereas another poison may stimulate the central nervous system and cause tachycardia, tachypnea, and hypertension. The route of entry may determine how quickly the patient presents with the expected signs and symptoms.

    You must always be prepared to handle the patient who suddenly deteriorates from a suspected poisoning. For example, you arrive on the scene and encounter a patient who says he ingested a large quantity of sedatives because he wants to commit suicide. The patient states that he took around 20 sleeping pills. You assess the patient and find that all of his vital signs are normal with no signs of poisoning. You may question whether the patient actually took the pills or if he is seeking attention by saying he did. However, 20 sleeping pills may take up to several hours to leave the stomach and enter the small intestine for absorption into the body. Not until then will a large amount of the toxic substance be absorbed and the effects begin to be evident. Whatever your suspicions, you must treat the patient as if he truly ingested the poison, contact medical direction for further advice, and constantly monitor the patient’s airway and breathing status.

**ASSESSMENT TIPS**

Even if the patient with a suspected poisoning is currently stable, closely monitor the airway, breathing, circulation, and mental status, because acute deteriorations could occur. A sudden decrease in the mental status may indicate rapid patient deterioration. Burns to the lips and inside the mouth suggest that the patient ingested a corrosive poison. Be as thorough as possible while gathering the history from the patient. This information may not be available later if the patient lapses into unresponsiveness.
Managing the Poisoning Patient

Regardless of the poison or route, a majority of your emergency care will be supportive. You must establish and/or maintain a patent airway, determine whether the breathing is adequate or inadequate, provide positive pressure ventilation for inadequate breathing or maintain adequate oxygenation for adequate breathing, assess the circulation, and continue to reassess the patient.

Keeping in mind that these patients can deteriorate quickly, performing a series of reassessments is necessary. Be sure to closely monitor the breathing status and be prepared to ventilate if necessary. Many persons poisoned by ingestion may vomit, which may further complicate the airway. Place the patient in a lateral recumbent position and closely monitor the airway. Remember that the patient could survive the poisoning but die from aspiration of vomitus into the lungs. You can prevent this through positioning, suctioning, and close monitoring of the airway. Basically, you will provide emergency care for the signs and symptoms that the patient presents with.

Antidotes

An antidote is a substance that will neutralize the effects of the poison or toxic substance. Many people think that antidotes are available for a large number of poisons; however, true antidotes are available for only a small number of poisons. The treatment of poisons is generally geared toward limiting or preventing the absorption of the poison, and then managing any other signs and symptoms that may occur. Oftentimes, the treatment is just to support the airway, breathing, and circulation until the poison is eliminated from the body.

An ALS unit may have medications that reverse the effects of certain drugs that may have been injected, ingested, inhaled, or absorbed. For example, an ALS unit carries the drug naloxone (Narcan), which can reverse the effects of a narcotic overdose. Narcan does not remove the drug from the patient’s body; instead, it blocks the effects of the narcotic at the cell receptor sites. Narcan usually will wear off much sooner than the typical narcotic, and the patient may relapse until another dose of Narcan can be administered.

INGESTED POISONS

An ingested poison is one that is swallowed and enters the gastrointestinal system. The poison will usually remain in the stomach for a period of time before entering the small intestine. The length of time the poison remains in the stomach depends on the amount of poison ingested, the amount of food or liquid in the stomach, and the effect of the poison. A majority of the absorption of the poison occurs in the small intestine and not in the stomach. A quicker onset of the poison’s effects will occur with a faster emptying of the stomach contents into the small intestine. Thus, it is extremely important to determine the length of time since the patient ingested the poison. This may change the treatment the patient receives.

Poisonous substances commonly ingested are:
- Prescription medications
- Over-the-counter medications (aspirin, acetaminophen, cough syrups)
- Illegal drugs (illicit)
- Household products
- Cleaning agents (soaps, detergents, alkalis)
- Foods
- Insecticides
- Petroleum products
- Plants

Many poisonings occur as a result of accidental ingestion. Common causes of accidental ingestion are:
- Taking too much of a medication because of not understanding the directions, particularly in elderly patients
- Combining alcohol with drugs
- Storing poisons in food or drink containers
- Keeping poisonous substances within the reach of children

The ingestion of poisonous plants is a common poisoning emergency, especially in children under the age of 5. Poisonous plants are not necessarily exotic—they include common household and backyard plants, such as morning glory, rhubarb leaves, buttercup, daisy, daffodil, lily of the valley, narcissus, tulip, azalea, English ivy, mistletoe berries, iris, hyacinth, laurel, philodendron, rhododendron, wisteria, and certain parts of the tomato, potato, and petunia plants. A high number of poisonings result from eating wild mushrooms.

Assessment-Based Approach: Ingested Poisons

Scene Size-up

Clues indicating that there has been an ingested poisoning can often be spotted during scene size-up. You may observe overturned or empty medicine bottles, scattered pills or capsules, recently emptied containers, spilled chemicals, spilled cleaning solvents, an overturned plant or pieces of plant, potting soil or dirt on the floor, the remains of food or drink, or vomitus. Look for a possible suicide note.

Primary Assessment

The primary assessment is a vital step in management of the poisoned patient. The mental status may provide a clue as to the length of time since the patient ingested...
the substance. Also, it may indicate the effect on the patient. If the patient is experiencing an altered mental status from the poison, it is evident that the poison is already being absorbed into the bloodstream and is having systemic effects on the body. If the patient is still alert and oriented, it may be an indication that the poison has not yet been absorbed in a large quantity or that a large quantity was not ingested by the patient. It is important to constantly monitor for a decreasing mental status to identify patient deterioration.

If the patient has an altered mental status, it is necessary to open and clear the airway. A poisoned patient may deteriorate rapidly. He may be talking while on the scene and deteriorate to complete unresponsiveness en route to the hospital. As noted earlier, the poisoned patient may vomit, which can lead to aspiration. This will complicate the airway and breathing status of the patient. If the patient has an altered mental status, place him in a lateral recumbent position to reduce the possibility of aspiration. The poison itself may have caused burns to the mouth and airway, leading to swelling and a partially occluded airway. Inspect for burns around the mouth and lips and to the oral mucosa inside the mouth. It may be necessary to insert an oropharyngeal or nasopharyngeal airway to effectively ventilate the patient.

Depending on the poison ingested, the patient may have inadequate breathing. Be sure to assess both the respiratory rate and respiratory quality, paying particular attention to how deeply the patient is breathing. Like the airway, the respirations may suddenly become inadequate from the delayed absorption of the poison. Many poisons depress the respiratory drive. Closely monitor the chest rise and fall and the rate of respiration. If either the rate or depth is inadequate, provide positive pressure ventilation with a bag-valve mask or other ventilation device. If the SpO2 is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO2 is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

**PATHOPHYSIOLOGY PEARLS**

A poison that depresses the central nervous system may cause the respiratory, cardiac, and vasomotor centers to dysfunction or fail, leading to ineffective ventilation, bradycardia, and hypotension.

Assess the circulatory status of the patient. The heart rate and the skin temperature, color, and condition may provide a clue to the type of poison the patient may have ingested. Also, the circulatory status may indicate the systemic effects of the poison. If the pulse is absent, proceed with the cardiopulmonary resuscitation protocol.

**Secondary Assessment**

Most information about an ingested poisoning will be obtained during the secondary assessment. If the patient is a child, other children in the house may have also swallowed the poison, so assess all children carefully. Don’t forget that children often ingest more than one poison at a time—especially if they find several bottles of pills or cleaning supplies kept in one place. Watch for the most common poisons ingested by children: plants, cleaning products kept under the kitchen sink (Figure 22-1), automotive supplies (such as windshield cleaning fluid) kept in the garage, medications (especially liquids), and toiletries (such as cologne, after-shave, and mouthwash).

**PATHOPHYSIOLOGY PEARLS**

An ingested liquid acid is likely to cause more severe tissue damage to the stomach lining than to the esophagus, because the poison will pass down the esophagus quickly but will then sit in the stomach and continue to burn. Ingested alkali substances cause much more severe damage.

**History.** Begin the secondary assessment by obtaining information about the patient. Getting a history from a poisoning patient can be difficult, and the history you do get may not be accurate; the patient may be misinformation, be subject to a drug-induced confusion, or may be deliberately trying to deceive you. Exercise caution with the degree of trust you place in the history gained from a patient who took an intentional overdose. To manage a poisoning patient correctly, however, you need a relevant history. If the patient is unable or unwilling to communicate, you will need to question relatives or bystanders and gather clues from the scene. During the history, ask the following questions:

- **Was any substance ingested?** The answer to this question will help in determining if activated charcoal will be administered. (Remember to ask about over-the-counter medications; these can also be very harmful.)
- **Was any alcohol ingested with the substance?**
• When did the patient ingest the poison? (or) When was the patient exposed to the poison? This will let you determine the span of time between the exposure and the onset of symptoms. Generally, the faster the onset of symptoms, the more serious the condition.

• Over what time period was the substance ingested? (or) Over what time period was the patient exposed to the poisonous substance? This is another indicator of the seriousness of the poisoning.

• How much of the substance was taken? This is sometimes helpful when determining how quickly the substance may empty into the small intestine and how much antidote is needed at the hospital.

• Has anyone attempted to treat the poisoning? Someone may have tried to induce vomiting or give some type of antidote.

• Does the patient have a psychiatric history that may suggest a possible suicide attempt?

• Does the patient have an underlying medical illness, allergy, chronic drug use, or addiction? Not only will this tell you if the patient may have other conditions complicating the poisoning but it may also give a clue as to what drugs may have been ingested with the poison.

• How much does the patient weigh? This is necessary to administer the proper dose of activated charcoal.

• What medications are available in the house? This may provide the source of the poisoning if prescription or over-the-counter medications were ingested.

**Physical Exam.** If the patient was able to provide an adequate history, conduct a physical exam of the areas in which the patient has a complaint, sign, or symptom, and of body systems that might be affected in the poisoning. If in doubt, or if the patient is unresponsive or unable to provide an adequate history, perform a complete secondary assessment. Assess the head, neck, chest, abdomen, pelvis, extremities, and posterior body. Inspect and palpate for any abnormalities. This is especially urgent if the patient may have suffered trauma secondary to the poisoning, or vice versa.

Record the vital signs, but realize that vitals have a limited role in establishing the degree of distress caused by a poisoning. You should use other clinical findings indicative of the seriousness of the condition (e.g., diminished mental status, fast or slow heart rate, seizures).

**Signs and Symptoms.** The signs and symptoms of poisoning by ingestion vary, depending on what was ingested. A seriously poisoned person may have few or no signs or symptoms, so don’t gauge the severity of the emergency on signs and symptoms alone.

The most common signs and symptoms are:

• A history of ingestion
• Swelling of mucosal membranes in the mouth
• Nausea
• Vomiting
• Diarrhea
• Altered mental status
• Abdominal pain, tenderness, distention, and/or cramps

**Emergency Medical Care**

Specific treatment for a patient who is known to have ingested a poison is as follows:

1. **Maintain the airway.** Use gloves to remove any remaining pills, tablets, capsules, or other fragments from the patient’s mouth, taking care not to injure yourself. If the patient is unresponsive, maintain an open airway with an oropharyngeal or nasopharyngeal airway in conjunction with a manual technique for opening the airway. Be sure not to stimulate the gag reflex, which might cause the patient to vomit. Secretions may be profuse following the ingestion of certain poisons, so
be prepared to suction. A poisoning patient’s status can change suddenly. Be prepared to protect the patient from aspiration. If possible, place the patient in the lateral recumbent position in case of vomiting.

2. **Assist ventilations if they are inadequate.** Provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

3. **Maintain oxygenation.** If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≥94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

4. **Prevent further injury.** If a child has handled or been poisoned by a corrosive, protect yourself while washing the child’s hands and fingers and rinsing the child’s mouth and lips to remove traces of the corrosive. Be careful when rinsing the mouth that the patient does not swallow the liquid. **Do not flush the mouth of an unresponsive patient as he may aspirate the fluid.**

5. **During transport, consult medical direction.** If your protocols mandate, contact the regional poison control center. You may be instructed to administer activated charcoal. Follow local protocol. Details on administering activated charcoal are found later in this chapter.

6. **Bring suspected poisons to the receiving facility.** Bring the container and all of its remaining contents, the plant portions or parts that might have been ingested, or other specimens to the receiving facility. Remember to bring all possible containers and labels. Prescription bottles with all remaining pills should be transported because they provide a clue to how much was ingested. If a plant was ingested, bring the remaining roots, leaves, stems, flowers, or fruit. If the patient has vomited, bring a sample of the vomitus in a clean, closed container to the receiving facility. Analysis of this material may help the emergency department staff isolate the type of poison involved.

**Reassessment**

Provide a reassessment with particular attention to the patient’s mental status, airway, and breathing. If the patient is unstable, you should repeat the reassessment every 5 minutes. Be sure to contact the receiving hospital so they can prepare for the patient’s arrival.

**Activated Charcoal**

A medication that is occasionally used in the emergency medical care of ingested poisonings is **activated charcoal**. Even though the literature has suggested that activated charcoal reduces absorption of the ingested poison, there is no evidence that suggests a better patient outcome. Other drawbacks include the ineffectiveness of activated charcoal with certain substances and the risk of aspiration if there is a sudden decrease in mental status. Thus, activated charcoal is rarely administered by emergency medical service personnel in ingested poisons. In some cases of specific medication ingestion that cause a delayed emptying effect, such as opioids, anticholinergic drugs, or medications with a sustained release, medical direction may order the administration of activated charcoal if it is shortly after ingestion. Follow your protocol, medical direction, or the poison control center.

Activated charcoal is a special distilled charcoal that has been treated with superheated steam. It is porous and can adsorb (collect onto its surfaces—or soak up) many times its weight in contaminants. Activated charcoal is produced to have a very small particle size to increase its adsorptive properties. To better illustrate this, consider that a standard 50-gram dose of activated charcoal has roughly the same surface area as ten football fields. The adsorption of the poison by the activated charcoal inhibits the poison from being absorbed into the body. To be effective, it must be administered as early as possible. It should be administered within 1 hour of the ingestion and only in specific cases approved by medical direction.

Some of the trade names of activated charcoal (Figure 22-3) are:

- SuperChar
- InstaChar
- Actidose
- Liqui-Char

Some activated charcoal products contain a laxative agent (cathartic) that helps speed it through the intestinal tract.

**PATHOPHYSIOLOGY PEARLS**

The use of activated charcoal for the ingested poison is intended to limit the amount of poison absorbed by the intestines due to the charcoal’s ability to adsorb the poison while it is still in the stomach or proximal portion of the intestines. However, because of its limited efficacy, it is rarely used and only for specific poisons.

See Figure 22-4 for a detailed summary of the criteria and techniques for administration of activated charcoal. See EMT Skills 22-2 illustrating how to administer activated charcoal to a patient.

**FIGURE 22-3** Several brands and forms of activated charcoal are available.
### Activated Charcoal

#### Medication Name
Activated charcoal is the generic name. Some of the better known trade names of activated charcoal are:
- SuperChar
- InstaChar
- Actidose
- Actidose-Aqua
- Liqui-Char
- Charcoaid

#### Indications
Activated charcoal may be used for a patient who has ingested poison by mouth, upon specific orders from medical direction. It is most effective when administered within 1 hour after the ingestion of the poison and only in very specific cases of poisoning.

#### Contraindications
Activated charcoal should not be administered to a patient who:
- Has an altered mental status (is not fully alert) because it may cause aspiration
- Has swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, or ethyl alcohol)
- Is unable to swallow
- Overdoses on cyanide

#### Medication Form
1. Premixed in water, frequently available in a plastic bottle containing 12.5 grams of activated charcoal
2. Powder—should be avoided in the field

#### Dosage
Unless directed otherwise by medical direction, give both adults and children 1 gram of activated charcoal per kilogram (1g/kg) of body weight. The usual adult dose is 30–100 grams. The usual dose for infants and children is 12.5–25 grams.

#### Administration
To administer activated charcoal:
1. Consult medical direction or the poison control center, according to local protocol, before administering activated charcoal to any patient. Directions that follow are general. Always follow the orders of medical direction or local protocol.
2. Shake the container of activated charcoal thoroughly; if it is too thick to shake well, remove the cap and stir it until well mixed. The activated charcoal settles to the bottom of the bottle and needs to be evenly distributed.

3. Activated charcoal looks like mud. The patient may be more willing to drink it if he can’t see it, such as through a straw from a covered opaque container.
4. If the activated charcoal settles, shake or stir it again before letting the patient finish the dose.
5. Record the time and the patient response.
6. If the patient vomits, notify medical direction to authorize one repeat of the dose.

Once you have given a patient activated charcoal, don’t let the patient have milk, ice cream, or sherbet. These all decrease the effectiveness of activated charcoal.

#### Actions
Activated charcoal adsorbs poisons in the stomach, prevents their absorption by the body, and enhances their elimination from the body. The ability of activated charcoal to adsorb poisons is due to the preparation process that makes it extremely porous. Activated charcoal does not bind to (is not effective for) alcohol, kerosene, gasoline, caustics, or metals, such as iron. It is not routinely used for ingested poisoning. Only administer activated charcoal based on medical direction.

#### Side Effects
The most common side effect is blackening of the stools. Some patients, especially those who are already nauseated, may vomit. If the patient vomits, repeat the dose of activated charcoal once. Be alert for further vomiting, and transport as soon as possible. Other side effects are rare.

#### Reassessment
During administration, ensure that the patient’s airway and mental status are adequate so the patient does not aspirate the medication. Check for abdominal pain or distress upon administration. Watch for possible vomiting after administration, and prevent aspiration by placing the patient in a sitting or lateral recumbent position and being prepared to suction.

---

**FIGURE 22-4** Activated charcoal.
Activated charcoal should be used only for a patient who has ingested poisons by mouth, upon specific orders from medical direction and/or the poison control center. Remember that activated charcoal should not be administered to patients who have an altered mental status because of possible aspiration, to patients who have swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, or isolated ethyl alcohol ingestion), or to patients who are unable to swallow.

In the prehospital environment, use activated charcoal that has been premixed with water. The most common brands contain 12.5 grams of activated charcoal mixed with water in a plastic bottle. Activated charcoal is also available in powder form; however, the powder must be mixed with water before it can be administered to a patient. The use of powdered activated charcoal is discouraged in the field because it is problematic in preparation. Follow local protocol.

**INHALED POISONS**

Thousands of people die each year in the United States from inhaling poisonous vapors and fumes, some of which are present without any sign. Most toxic inhalation occurs as a result of fire. It is critical that care be immediate, because the body absorbs an inhaled poison rapidly. The longer the exposure without treatment, the poorer the prognosis.

Common inhaled poisons include the following:

- Carbon monoxide
- Carbon dioxide from industrial sites, sewers, and wells
- Chlorine gas (common around swimming pools)
- Fumes from liquid chemicals and sprays
- Ammonia
- Sulfur dioxide (used to make ice)
- Anesthetic gases (ether, nitrous oxide, chloroform)
- Solvents used in dry cleaning, degreasing agents, or fire extinguishers
- Industrial gases
- Incomplete combustion of natural gas
- Hydrogen sulfide (sewer gas)
- Nitrogen dioxide from fermented grain

Some poisons are inhaled intentionally in an attempt to “get high.” Patients who inhale paints and propellants are commonly referred to as huffers. The toxins are inhaled in a variety of ways in an attempt to produce certain expected effects. These substances can have many effects as they displace the oxygen content in the alveoli, leading to hypoxia. They can exert actions of their own after crossing over the alveoli into the bloodstream, or they can cause structural damage to the alveolar surface itself, which can also impair gas exchange. Look for paint or other material on the lips or around the nose of the patient during the physical exam. This may be the only indication of toxic inhalation in an unresponsive patient. Commonly abused inhaled poisons are:

- Paints
- Freon
- Gas propellants
- Glue
- Nitrous oxide
- Amyl nitrate
- Butyl nitrate

Keep in mind that inhaled poisons typically have a more immediate onset than injected poisons and may produce more systemic effects. Remember also that inhaled poisons may destroy lung tissue, leading to severe respiratory compromise and significant respiratory distress or failure.

**PATHOPHYSIOLOGY PEARLS**

An inhaled toxin can directly damage the alveoli when inhaled. This will cause fluid to leak into the alveoli and disturb gas exchange, leading to hypoxia.

**ASSESSMENT TIPS**

Inhaled poisons often cause a rapid onset of signs and symptoms because of the rapid absorption of the poison into the lungs and into the circulation. Inhaled poisons frequently cause respiratory signs and symptoms early after the exposure to the poison. As the poison is absorbed into the blood, the patient may begin to exhibit systemic signs and symptoms. Young children and the elderly will typically present with signs and symptoms of carbon monoxide poisoning before any other patients who have been exposed.

**Assessment-Based Approach: Inhaled Poisons**

**Scene Size-up**

During the scene size-up, ensuring your safety is of prime importance. You should be acutely aware of peculiar odors or visible fumes. At the same time, understand that some gases (e.g., carbon monoxide) can be odorless and colorless. The absence of odor does not guarantee safe air for breathing. You need to ensure scene safety so that bystanders and caregivers will not be injured.

If the information given by those present (or their behavior) or the presence of any hazardous materials placards at the scene indicate that toxic fumes may be present, be sure that you are wearing self-contained breathing apparatus before entering the scene. If you are not properly equipped or trained for hazardous materials rescue, call for assistance from those who are. Have those who are properly trained and equipped bring the patient or patients out of the toxic environment (Figure 22-5 ). Do not enter the scene unless they tell you it is safe. As soon
unresponsive, which caused him to inhale the poisonous fumes from the explosion itself.

**History.** Remember to ask the patient or bystanders questions about what was inhaled, when and how long it was inhaled, and what treatments might have been attempted. In addition, you should ask:

- **Does the patient have a history that suggests a possible suicide attempt?** This is more common in apparently intentional carbon monoxide poisonings.
- **Did the exposure occur in an open or a confined space?** A confined space will likely have much higher concentrated amounts of the toxin and may lead to a more severe toxic exposure.
- **How long was the patient exposed?** The severity of the inhaled poisoning is associated with the duration of exposure to the toxin.

Patients who are trapped in a fire are typically exposed to large amounts of toxic substances. Incomplete combustion of products releases toxic fumes, many of which are lethal. Most people who die in a fire do so from inhalation of toxic fumes and not from burns. The second most common cause of death in a fire is from airway injuries secondary to breathing in superheated air. The third most common cause of death in a fire is from trauma.

**Physical Exam.** If the patient is responsive enough to provide you with an adequate history, perform a focused assessment of the areas in which the patient has a complaint, sign, or symptom. If in doubt, or if the patient is unresponsive and unable to provide you with an adequate history, perform a complete physical exam. Obtain and record the patient’s vital signs.

**Signs and Symptoms.** The following are signs and symptoms of inhaled poisoning:

- A history of inhalation of a toxic substance
- Difficulty breathing or shortness of breath
- Chest pain or tightness; a burning sensation in the chest or throat
- Cough, stridor, wheezing, or crackles
- Hoarseness
- Copious secretions
- Oral or pharyngeal burns
- Dizziness
- Headache, often severe
- Confusion
- Seizures
- Altered mental status, possible unresponsiveness
- Cyanosis
- Respiratory rate faster or slower than normal
- Nausea/vomiting (carbon monoxide poisoning)
- Paint on lips, indicating “huffing”
- Other types of material on face or lips (glue, chemical, and so forth)

**Signs of respiratory tract burns include:**

- Singed nasal hairs
- Soot in the sputum
- Soot in the throat

**Primary Assessment**

Of particular importance in the inhaled poison patient is close assessment and management of the patient’s airway and ventilation status. Inhaled poisons may rapidly lead to deterioration in the mental status of the patient, which may in turn compromise the airway. If the patient has an altered mental status, manually open the airway and inspect for any evidence of obstruction. Provide a manual maneuver and insert an oropharyngeal or nasopharyngeal airway, if warranted.

Closely assess the breathing status, determining the rate and depth of respirations. If the rate is inadequate or the tidal volume (depth) is inadequate as evidenced by shallow breaths and poor chest rise on inhalation, immediately begin positive pressure ventilation with a bag-valve mask or other ventilation device. Maximize oxygenation of the patient during ventilation by connecting oxygen to the ventilation device. If the breathing is adequate in both rate and depth, apply a nonrebreather mask at 15 lpm. It is important to maximize oxygenation in the inhaled poisoning patient who is breathing adequately. Monitor this patient closely since he may deteriorate rapidly and begin to breathe inadequately.

Assess the patient’s circulatory status by assessing the pulse and the skin color, temperature, and condition.

**Secondary Assessment**

During the secondary assessment, get a history from the patient or bystanders and as much information as you can about the substance that has been inhaled. Keep in mind that the patient may be a trauma patient. For example, an explosion could have rendered the patient

---

**FIGURE 22-5** Protect yourself. Have trained rescuers remove the patient from the toxic environment.
Emergency Medical Care

Respiratory symptoms are typically the first to appear with inhalation injuries. Specific treatment to include when treating a patient known to have inhaled poisonous gases/fumes is as follows:

1. Protect yourself from exposure to toxic fumes by wearing self-contained breathing apparatus or waiting for a specialized team to make the rescue.
2. Quickly get the patient out of the toxic environment.
3. Place the patient in a supine position or position of comfort. Loosen all tight-fitting clothing, especially around the neck and over the chest.
4. Ensure an open airway.
5. Start positive pressure ventilation with supplemental oxygen immediately if the patient is not breathing or has inadequate breathing.
6. Administer oxygen by nonrebreather mask at 15 lpm (Figure 22-6) initially for all inhaled poisoning patients regardless of the SpO₂ reading.
7. Bring all containers, bottles, labels, or other clues about the poisoning agent to the receiving facility.

Reassessment

Provide a reassessment en route to the hospital with particular attention to the patient’s airway and breathing. Reassess vital signs and treat any respiratory compromise that may develop.

INJECTED POISONS

An injected poison is one that enters the body through a break in the skin, usually by the intentional injection of a drug or by the bite or sting of an animal or insect. Drugs may be injected under the skin, into the muscle, or directly into the bloodstream. Information on specific drug-related emergencies is found later in the chapter. Once the poison is injected into the body, it is usually just a matter of time until it becomes absorbed into the bloodstream and widely distributed throughout the body. Consequently, the findings consistent with an injected poison could be local (at the site of injection), systemic (throughout the body), or a combination of both. Typically with bites and stings, the first signs and symptoms will be at the site of injection.

The most common sources of injected poisons are bites and stings. Most common are stings from bees, wasps, hornets, yellow jackets, and ants; others include the bites of spiders, ticks, marine animals (such as jellyfish, coral, anemones, and stingrays), and snakes (Figure 22-7). Injected poisons generally cause an immediate reaction at the injection site followed by a delayed systemic reaction. Of special note is the threat of anaphylactic shock following the allergic reaction to an insect bite or sting (see Chapter 21, “Anaphylactic Reactions”). More detailed information on bites and stings is found in Chapter 24, “Environmental Emergencies.”

Assessment-Based Approach: Injected Poisons

Scene Size-up

Make note of clues such as discarded syringes or other drug paraphernalia. Consider the possibility of a bite or sting in an outdoor environment (e.g., a sting by a marine life-form at a beach or by an insect at a picnic area). In industrial areas, the patient could also have been accidentally injected by high-pressure equipment with some type of chemical (e.g., paint or an oil-based substance).

Primary Assessment

Carefully assess the patient’s airway and breathing. Open the airway, using a manual maneuver, and insert a mechanical airway device, if necessary. If the breathing is inadequate, immediately begin ventilation. Attach oxygen to the ventilation device as quickly as possible. If the breathing is adequate, administer oxygen based on the SpO₂ reading and the patient’s signs and symptoms. Assess the mental status and determine if the patient is a high priority for transport. Look for indications of an allergic reaction.
**PATHOPHYSIOLOGY PEARLS**

Injected poisons are absorbed into the capillaries. Once the poison enters the blood in the capillaries, it is carried throughout the body, where it can affect many organs.

---

**Secondary Assessment**

During the secondary assessment, get a history from the patient or bystanders and as much information as you can about any substance that may have been injected or about the kind of insect or animal that may have inflicted a bite or sting.

**History.** Ask the patient or bystanders the following questions pertaining to injected poisons:

- Does the patient have a history of drug use? (Bystanders and the patient may be unwilling to answer this.)
- Does the patient have a history of allergic reaction to bites or stings?
- What was the time lapse between the injection and onset of signs and symptoms?
- What type of animal or insect was the patient bitten by?

**Physical Exam.** If the patient is responsive enough to provide you with an adequate history, perform a secondary assessment. Obtain and record the patient’s vital signs.

**Signs and Symptoms.** General signs and symptoms of toxic injection include the following:

- Weakness/lethargy
- Dizziness
- Chills
- Fever
- Nausea/vomiting
- Euphoria
- Sedation
- High or low blood pressure
- Pupillary changes
- Needle tracks
- Pain at the site of injection
- Trouble breathing
- Abnormal skin vitals (color/temperature/condition)
- Possible paralysis
- Swelling and redness at the site of injection

**Emergency Medical Care**

Treatment for a patient known to have suffered a toxic injection is as follows:

1. Maintain the patient’s airway. If appropriate, insert an oropharyngeal airway if the patient does not have a gag reflex. Use a nasopharyngeal airway if the patient has a depressed mental status but will not accept an oropharyngeal airway. Suction vomitus or secretions.

2. Begin positive pressure ventilations with supplemental oxygen if the patient’s respirations are inadequate.

3. Maintain adequate oxygenation. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

4. Be alert for vomiting. Position the patient in a lateral recumbent (coma or recovery) position to help prevent aspiration, and be prepared to suction if necessary.

5. In the case of a bite or sting, protect yourself from injury and protect the patient from repeated injection. Move the patient away from any insects that are still swarming. Bees can sting only once and then lose their stinger—but wasps, hornets, and yellow jackets can sting repeatedly.

6. Bring all containers, bottles, labels, or other evidence of poisonous substances to the receiving facility. If the patient was bitten or stung, try to identify the insect, reptile, or animal that caused the injury (without getting close enough to endanger yourself if it is still alive). If it is dead, bring it to the receiving facility with the patient.

**Reassessment**

Provide a reassessment with particular attention to the airway and breathing. Monitor the patient for possible development of an anaphylactic reaction. Notify the hospital en route so they can prepare for the patient.

---

**ABSORBED POISONS**

An **absorbed poison**—usually a chemical or substance from a poisonous plant that enters through the skin—will generally cause a burn, lesion, or inflammation. The risk of exposure to a hazardous substance is increasing as more chemicals are used in farming and in everyday objects. A dog’s flea collar, for example, could be dangerous to an infant if he put it in his mouth because the chemical in the flea collar could be absorbed by the mucous membranes of the mouth.

---

**PATHOPHYSIOLOGY PEARLS**

Absorbed poisons enter the body through the capillaries in the skin or through the mucous membranes in the eyes, nose, or mouth.
Skin reactions range from mild irritation to severe chemical burns. Absorbed poisons often cause both local and systemic reactions, which can be severe. Exposure of as little as 2.5 percent of the body surface to 100 percent hydrofluoric acid, for example, can cause death.

**Assessment-Based Approach: Absorbed Poisons**

**Scene Size-up**

Make note of any open containers of chemicals or poisonous plants in the environment. Wear gloves and other protective gear as needed to ensure that the harmful substances do not come into contact with your skin. Call for additional help if more than one patient is injured. Patients should be removed from the dangerous area as soon as possible.

**Primary Assessment**

Carefully assess the patient’s airway and breathing. Some types of absorbed poisons can cause muscle paralysis or weakness and compromise the patient’s respiratory status. An altered mental status secondary to the effects of the absorbed poison could cause the jaw and tongue to relax and block the airway. Inspect the patient for any poison that may still be on the person’s body or clothes.

**Secondary Assessment**

**History and Physical Exam.** Get a history from the patient or bystanders and as much information as you can about any substance that may have been absorbed. Perform a physical exam. Obtain and record the patient’s vital signs.

**Signs and Symptoms.** The following are signs and symptoms of an absorbed poison:

- A history of exposure to a poisonous substance
- Traces of liquid or powder on the patient’s skin
- Burns
- Itching and/or irritation
- Redness
- Swelling

Signs and symptoms of contact with a poisonous plant include the following:

- Fluid-filled, oozing blisters
- Itching and burning
- Swelling
- Possible pain
- A rash (If the rash is scratched, secondary infections can occur.)

**Emergency Medical Care**

If poison has been absorbed through the skin, the following specific treatment should be included:

1. **Protecting your hands with gloves, move the patient from the source of the poison and remove the patient’s contaminated clothing and jewelry.**
2. **Carefully monitor the airway and respiratory status.**
3. **Begin positive pressure ventilations with supplemental oxygen** if the patient’s respirations are inadequate.
4. **Maintain oxygenation.** If the SpO₂ is $\geq 94\%$ and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is $\leq 94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of $\geq 94\%$. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.
5. **Brush any dry chemicals or solid toxins from the patient’s skin,** taking extreme care not to abrade the skin or spread the contamination (Figure 22-8). Contact medical direction to determine whether to flush the contaminated area.
6. **If the poison is liquid, irrigate all parts of the body with clean water for at least 20 minutes** (a shower or garden hose is ideal). Carefully check “hidden” areas, such as the nail beds, skin creases, areas between the fingers and toes, and hair. If the patient is wearing any jewelry, removing it prior to flushing will ensure that no toxin remains trapped between the jewelry and skin. Continue irrigation en route to the receiving facility if possible. If the poison is a dry powder, brush off the substance and continue the treatment for other absorbed poisons.

**FIGURE 22-8** Brush dry powder off the patient. Then flush with clean water to remove poison on the surface of the skin.
7. If the poison entered the eye, irrigate the affected eye with clean water for at least 20 minutes (Figure 22-9). Continue irrigation while en route to the receiving facility, if possible. Position the patient so water runs away from the unaffected eye, taking care not to spread the contamination. Further details on treating chemical burns of the eye will be found in Chapter 33, “Eye, Face, and Neck Trauma.”

Reassessment

Provide a reassessment en route to the hospital with particular attention to the status of the patient’s airway and breathing.

Summary: Assessment and Care

To review assessment findings and care for poisoning emergencies, see Figures 22-10 and 22-11.

Assessment Summary

POISONING EMERGENCY

The following findings may be associated with a poisoning emergency.

Scene Size-up

Is the poisoning due to ingestion, inhalation, injection, or absorption (contact)? Look for:
- Mechanism of injury
- Alcohol, drugs, other commonly abused substances
- Empty medicine bottles
- Spilled chemicals, cleaning solvents, other hazardous chemicals
- Pieces of plants
- Position and location of the patient
- Confined spaces
- Peculiar odors
- More than one patient with similar signs and symptoms
- Drug paraphernalia
- Insects, snakes, marine life, other venomous creatures
- Powdered or liquid substance on the skin surface
- Paint or other chemicals on the patient’s lips or around the nose

Primary Assessment

General Impression
- Burns to skin from chemical exposure
- Vomitus or secretions in mouth
- Stings or bites to body with areas of swelling

Mental Status
- Alert to unresponsive
- Confused or disoriented

Airway
- Obstruction from swelling from burns to mouth, tongue, upper airway
- Obstruction by vomitus or secretions
- Stridor or hoarseness
- Excessive salivation
- Singed nasal hairs, soot in sputum and throat (carbon monoxide from fire)

(Insert an oro- or nasopharyngeal airway, if necessary)

Breathing
- Shallow respirations
- Absent respirations
- Wheezing or crackles
- Inadequate or excessive respiratory rates

Circulation
- Heart rate may be increased or decreased
- Skin may be warm, cool, moist, or dry
- Cyanotic, pale, or flushed
- Weak or absent peripheral pulses

Status: Priority Patient

Secondary Assessment

History
- Signs and symptoms vary widely, depending on the substance ingested, inhaled, injected, or absorbed.
- Ask questions regarding the following:
  - What substance was involved?
  - When did the exposure occur?
  - How long was the duration of exposure?
  - How much was ingested, inhaled, or injected?
  - Was any antidote or remedy administered?
  - Any underlying medical history?
  - Any psychiatric history?
  - Does anyone else at the scene have similar signs and symptoms?
Was the patient in a confined space or working with chemicals?
Has the poison control center been consulted?

**Physical Exam**

**Head, neck, and face:**
- Excessive salivation or dry mouth
- Possible cyanosis to mucous membranes and face
- Dilated or constricted pupils
- Swelling
- Flushed, itching, hives
- Burns, discoloration, and swelling to mouth, oral cavity, tongue
- Unusual odors on breath
- Singed nasal hairs
- Soot in mouth and in sputum

**Chest:**
- Wheezing or crackles
- Respiratory distress

**Abdomen:**
- Pain and tenderness on palpation
- Distention
- Cramping
- Vomiting
- Diarrhea

**Extremities:**
- Needle, injection, or bite marks
- Swelling, pain, or irritation at site of injection

**Vital Signs**

- BP: increased, normal, or decreased
- HR: increased, normal, or decreased; may be irregular
- RR: increased, irregular, decreased, or absent
- Skin: warm, cool, moist, or dry
- Pupils: dilated, constricted, sluggish to respond
- \(\text{SPO}_2 \geq 94\%

---

**Emergency Care Protocol**

### POISONING EMERGENCY

1. Protect yourself from potential exposure by taking necessary Standard (body substance isolation) Precautions and safety precautions.
2. Establish and maintain an open airway.
3. Suction secretions as necessary.
4. If the patient is breathing inadequately, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen to maintain an \(\text{SpO}_2\) reading of \(\geq 94\%\). If the poisoning was by inhalation, administer oxygen via a nonrebreather mask at 15 Lpm.
6. Place the patient in a lateral recumbent position.
7. Contact the poison control center and/or medical direction to proceed with treatment:

---

### Inhaled Poison

- Remove the patient from the environment.
- Continue high concentration of oxygen by nonrebreather mask at 15 Lpm or via positive pressure ventilation if the patient has inadequate breathing.

### Injected Poison

- Scrape the stinger from the site.
- Watch for signs and symptoms of severe allergic reaction.

### Absorbed (Contact) Poisoning

- Be sure to wear gloves before touching the patient or his clothing.
- Brush off any dry chemicals or solid toxins from the skin.
- Remove contaminated clothing.
- Flush with large amounts of water for at least 20 minutes.
- Consider advanced life support backup if the patient begins to seize or if status has deteriorated.
- Transport.
- Perform reassessment every 5 minutes.

SPECIFIC TYPES OF POISONING

The following section provides information regarding the treatment and identification of specific poisonings you will be likely to encounter as well as information on the most valuable resource for poison treatment: poison control centers. This information is provided so that you will be better prepared to recognize and manage common forms of poisoning. You are encouraged, however, to learn about any types of poisonings that may be particular to the area in which you are providing prehospital care.

Food Poisoning

A specific kind of ingested poison is food poisoning—caused by ingestion of food that contains bacteria or the toxins (poisons) that bacteria produce. Illness can result from either the bacteria themselves or from the toxins released by the bacteria.

The incidence of food poisoning is increasing dramatically. Each year, millions of Americans develop gastrointestinal disease as a result of food poisoning. One of the most rapidly increasing sources of food poisoning is seafood. Algae ingested by fish create toxins in their tissues, which are then eaten by humans. *Ciguatera*, a commonly reported seafood-related illness in the United States, is caused by eating tainted fish such as dolphin, sturgeon, snapper, grouper, and parrot fish, among others. Unfortunately, the toxins don’t make the fish look, smell, or taste any different—and the toxins can’t be killed by cooking, freezing, smoking, or drying the fish. In some cases of seafood poisoning, symptoms may spontaneously recur for many years. The food products most commonly associated with poisoning emergencies (which are most prevalent in the summer months) include:

- Eggs
- Chicken
- Ready-to-eat foods (cheese, processed meat)
- Untreated water or unpasteurized milk
- Fish

Some types of foodborne illnesses from these and other foods are:

- **Salmonella.** From contaminated food and water, or from undercooked food
- **Campylobacter.** Common poisoning from contaminated poultry, milk, and water
- **Escherichia coli (E. coli).** Severe gastrointestinal poisoning from numerous contaminated foods, undercooked foods, and untreated (contaminated) water
- **Staphylococcus aureus.** Food poisoning from unhygienic food preparation, associated with foods served cold (such as desserts, custards, and salads)

Signs and Symptoms

Because the signs and symptoms vary greatly, food poisoning can be difficult to detect. The symptoms commonly start hours to days after ingestion and may be severe. The pediatric and geriatric populations are especially at risk for severe signs and symptoms from food poisoning. General signs and symptoms include abdominal cramping, nausea and vomiting, gas, diarrhea, and loud or frequent bowel sounds. More severe findings include increased temperature, blood disorders, muscle cramping or muscle paralysis, and passing blood in the stool.

Emergency Medical Care

To care for a patient with food poisoning, follow the general guidelines for any ingested poison. Do not give the patient anything by mouth, and transport as soon as possible.

Carbon Monoxide Poisoning

Of special concern is carbon monoxide (CO) poisoning by inhalation. Carbon monoxide causes thousands of deaths in the United States each year and sends thousands of persons to the hospital. Carbon monoxide poisoning is the leading cause of death among people who inhale smoke from fires.

Carbon monoxide—formed by the incomplete combustion of gasoline, coal, kerosene, plastic, wood, or natural gas—is completely nonirritating, tasteless, colorless, and odorless. It causes a life-threatening lack of oxygen in two ways: First, it reduces the amount of oxygen carried by the bloodstream because the carbon monoxide molecules replace the oxygen molecules on the red blood cells; and second, it inhibits the ability of body cells to utilize what little oxygen is delivered. The brain, spinal cord, and heart sustain the greatest damage. The danger of carbon monoxide poisoning is increased in an enclosed space.

The primary sources of carbon monoxide are home-heating devices (including furnaces and wood-burning fireplaces) and automobile exhaust fumes. Other common sources are tobacco smoke, barbecue grills and charcoal briquettes, kitchen stoves, gas lamps, recreational fires, propane-powered industrial equipment, and faulty water heaters, kerosene heaters, and space heaters.

Signs and Symptoms

The initial symptoms of carbon monoxide poisoning are similar to those of the flu, but there is no accompanying fever, general body aches, or swollen and tender lymph nodes. You should consider carbon monoxide poisoning whenever you encounter unexplained flu symptoms (such as headache, nausea, vomiting, and confusion)—especially if the symptoms are shared by other people in the same environment.

The most common signs and symptoms seen early in carbon monoxide poisoning are:

- Headache
- Tachypnea (rapid respiratory rate)
Cyanide is a poison that can be found in a variety of forms. It can enter the body through inhalation, absorption, injection, and ingestion. Cyanide is found in many household products. Rodent poisons, silver polish, and cherry and apricot pits contain cyanide that can be ingested or absorbed. Cyanide salts and long-term sodium nitroprusside therapy are other cyanide-containing sources. Cyanide is also a by-product of incomplete combustion of many plastics, silk, and synthetic carpets. Thus, inhalation of cyanide can occur in fires when these materials are burning. In some areas, firefighters who are treated for smoke inhalation receive cyanide-poisoning antidotes along with basic inhalation treatment as a standard precaution.

Cyanide is an extremely dangerous poison because it interferes with the use of oxygen at the cellular level. Even though initially there is no destruction of lung tissue or disturbance to respiratory mechanics, cyanide poisoning causes severe hypoxia at the level of the cell.

**PATHOPHYSIOLOGY PEARLS**

Cyanide causes hypoxia at the level of the cell. Oxygen is still being delivered to the cells, but the oxygen cannot be transported and used properly within the cell.

### Signs and Symptoms

Cyanide poisoning in large doses may cause death within a few minutes. The patient may progress quickly from early signs and symptoms to more severe effects. The signs and symptoms of cyanide poisoning are:

#### Early Signs and Symptoms

- Headache
- Confusion
- Agitation or combative behavior
- Burning sensation in the mouth or throat
- Dyspnea
- Hypertension
- Bradycardia or tachycardia
- Smell of bitter almonds

#### Late Signs or Symptoms or Those Seen in Large-Dose Cyanide Poisoning

- Seizures
- Coma
- Hypotension
- Pulmonary edema
- Cardiac dysrhythmias
- Acidosis

### Emergency Medical Care

Scene safety and personal protection are key elements in management of the patient who suffers from cyanide poisoning. It may be necessary to wear self-contained breathing apparatus to remove the patient from the toxic environment.

Provide the following emergency medical care for a cyanide poisoning:

1. Remove the patient from the toxic environment. Ensure that all rescuers are wearing the necessary personal protective equipment.
2. Remove any contaminated clothing and rapidly decontaminate the patient.
3. Open and maintain a patent airway.
4. Assess the breathing status. If the rate and tidal volume are adequate, apply a nonrebreather mask at 15 lpm if cyanide poisoning is suspected, regardless of the SpO₂ reading. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.

5. Consider contacting ALS for administration of a cyanide antidote.

6. Rapidly transport the patient.

**Acids and Alkalis**

Many household products contain strong acids or alkalis. These are commonly referred to as caustic substances. Caustic ingestion poisoning is most common in young children. Strong acids have an extremely low pH. They are commonly found in liquid plumbing drain openers and other bathroom cleaners. Alkalis have an extremely high pH. They are in the form of either a liquid or a solid and are also commonly found around the house in plumbing drain openers.

Acids burn on contact, causing immediate and severe pain. At the burn site, the tissue often dies immediately, producing a protective layer to lessen further burning. If an acid is ingested, a majority of the chemical burn will occur in the stomach and not in the esophagus. The liquid travels down the esophagus quickly, thus allowing very little contact time. Abdominal pain is usually severe and immediate. Bleeding may occur from perforation of the lining of the stomach. Also, the acid may be absorbed by the blood, leading to an acidotic state throughout the body. The patient who has ingested acids may present with burns to and around the mouth. Acids typically burn for only about 1–2 minutes, thereby limiting the damage.

Alkalis also burn on contact; however, it takes longer to recognize the burning sensation. Alkalis have a tendency to burn deeper by continuing to burn through tissue from longer contact times because the burn goes unrecognized for longer periods of time. If ingested, a solid alkali may adhere to the oropharynx or esophagus. This may cause deep burns and possible perforation of the tissue at the site of the burn. Liquid alkalis will most likely injure the stomach tissue, since they pass quickly along the esophagus. The alkali may perforate the stomach and may cause the protective lining to be burned away. Alkalis typically burn for minutes to hours after exposure. Thus, alkalis have a tendency to cause much deeper burns than acids.

**Signs and Symptoms**

General signs and symptoms associated with caustic poisoning are:
- Burns to the mouth and lips, and around the face
- Dysphagia (difficulty swallowing, drooling)
- Pain to the lips, mouth, and throat
- Abdominal pain
- Hoarseness or dysphasia (difficulty speaking)
- Stridor
- Dyspnea (shortness of breath)
- Evidence of shock from perforation of the stomach or esophagus (pale, cool, clammy skin; tachycardia; decreasing blood pressure; decreased mental status)

**Emergency Medical Care**

Rapid management and transportation of the patient is necessary when dealing with a caustic poisoning. Take the necessary precautions to protect yourself from coming in contact with the caustic substance. Activated charcoal is not effective in caustic poisoning; therefore, there is no use in administering it in this situation.

Emergency medical care for a caustic substance ingestion is as follows:

1. Ensure that all rescuers are wearing the necessary personal protective equipment.
2. Remove any contaminated clothing and rapidly decontaminate the patient. Flush the contaminated areas with large amounts of water.
3. Open and maintain a patent airway. The burns may have caused edema (swelling) to the upper airway, making it difficult to establish an airway. Insert an oropharyngeal or nasopharyngeal airway if swelling is preventing you from establishing a patent airway. Contact ALS for more advanced airway care, if necessary.
4. Assess the breathing status. If the rate and tidal volume are adequate, apply a nonrebreather mask at 15 lpm. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.
5. Rapidly transport the patient.

**Hydrocarbons**

Hydrocarbons are substances that are produced from crude oil, coal, or plant sources. They are commonly found in kerosene, naphtha, turpentine, mineral oil, toluene, and benzene. These substances can be found in common household products such as lighter fluid, glues, paints, lubricants, cleaning and polishing agents, spot removers, cosmetics, pesticides, solvents, and aerosol propellants.

The patients who are most commonly poisoned with hydrocarbons are children under 5 years of age. The toxicity of the hydrocarbon varies widely and is somewhat dependent on the viscosity of the substance. The lower the viscosity, the greater the risk of aspiration and the greater the potential side effects. Hydrocarbon poisoning may occur by ingestion, inhalation, or absorption.
**Signs and Symptoms**
The signs and symptoms of hydrocarbon poisoning will vary, depending on the type of hydrocarbon and the route of poisoning. If the patient is not exhibiting any signs or symptoms upon your arrival, it is likely the patient will not suffer a serious consequence of exposure to the hydrocarbon. The signs and symptoms may include the following:

- Coughing, choking, crying
- Burns to mouth or contact area
- Stridor
- Dyspnea
- Wheezing
- Tachypnea
- Cyanosis
- Abdominal pain
- Nausea and vomiting
- Belching
- Fever
- Seizures
- Coma
- Altered mental status
- Headache, dizziness, and dulled reflexes (obtunded)
- Slurred speech
- Cardiac dysrhythmias

**Emergency Medical Care**
Scene safety is of primary importance when treating a patient exposed to a hydrocarbon, especially if the exposure was by inhalation or absorption. Be sure to use the necessary personal protective equipment. Emergency medical care for hydrocarbon poisoning includes the following:

1. Remove the patient from the environment.
2. Remove all contaminated clothing and decontaminate the patient.
3. Open and maintain a patent airway.
4. Assess the breathing status. If the rate and tidal volume are adequate, apply a nonrebreather mask at 15 lpm, regardless of the SpO2 reading if inhalation of the hydrocarbon is suspected. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device.
5. Rapidly transport the patient.

**Methanol (Wood Alcohol)**
Methanol, or wood alcohol, is a poisonous form of alcohol found in a variety of common products such as gasoline, antifreeze, windshield washer fluid, paints, paint removers, Sterno and other canned fuels, and shellac. Methanol is a colorless liquid. It is different from ethyl alcohol (also called ethanol or drinking alcohol), which is the form of alcohol that is designed for consumption. Methanol poisoning may occur from ingestion, inhalation, or absorption. Some patients may deliberately ingest methanol alcohol in an attempt to “get drunk” when ethyl alcohol is not readily available. Chronic alcoholics may ingest methanol alcohol to maintain an inebriated state. Children may ingest substances containing methanol alcohol accidentally. Methanol alcohol, when ingested, will cause the liver to produce massive amounts of acid in the body. The onset of signs and symptoms following ingestion will usually occur 40 minutes to 72 hours after ingestion.

**Signs and Symptoms**
The signs and symptoms are typically related to the central nervous system, gastrointestinal system, and overwhelming acid in the body. Blindness may occur from the ingestion of as little as 4 mL of methanol. The signs and symptoms include the following:

- Altered mental status (confusion, unresponsiveness)
- Seizures
- Nausea and vomiting
- Abdominal pain
- Blurred vision
- Dilated pupils that are sluggish to respond to light
- Visual changes (seeing spots)
- Blindness
- Dyspnea
- Tachypnea

**Emergency Medical Care**
Emergency medical care for methanol poisoning is primarily supportive. Administration of ethyl alcohol (drinking alcohol) will prevent the methanol from being converted to an acid. An antidote, fomepizole, is now available. Until the patient is at the hospital to receive the aforementioned care, the EMT should provide the following:

1. Open and maintain a patent airway.
2. Assess the breathing status. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosis in the body. If breathing is adequate, and the SpO2 is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO2 is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.
3. Rapidly transport the patient.
Isopropanol (Isopropyl Alcohol)

Rubbing alcohol, the most common form of isopropyl alcohol, is found in many households. Isopropyl alcohol can also be found in many household products such as cosmetics, degreasers, disinfectants, solvents, and other cleaning agents. Poisoning most frequently occurs by ingestion, both accidental and intentional. Alcoholics may ingest isopropyl alcohol as a substitute for ethyl (drinking) alcohol. Isopropyl alcohol is more toxic than ethyl alcohol but less toxic than methanol (wood) alcohol. Following ingestion of isopropyl alcohol, the liver creates acetone. This has a major effect on the central nervous system, gastrointestinal system, and kidneys.

Signs and Symptoms

The signs and symptoms of isopropanol poisoning occur rapidly, usually within 30 minutes following ingestion. Isopropanol acts as a central nervous system depressant, causing respiratory depression. Signs of ingestion include:

- Respiratory depression
- Altered mental status
- Slow respirations, shallow tidal volume
- Abdominal pain
- Bloody vomitus (hematemesis)
- Signs of shock

Emergency Medical Care

Administration of ethyl alcohol does not produce the same beneficial effects with isopropyl alcohol as it does in methanol poisoning. The emergency medical care for isopropanol ingestion includes the following:

1. Open and maintain a patent airway.
2. Assess the breathing status. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosis in the body.
3. Maintain adequate oxygenation. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≥94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a non rebreather mask at 15 lpm could be used.
4. Rapidly transport the patient.

Ethylene Glycol

Ethylene glycol is commonly found in detergents, radiator antifreeze, windshield deicers, and coolants. Children are commonly susceptible to accidental ingestion of ethylene glycol. The products usually are colorful and have a sweet taste. Therefore, children will ingest the substance containing ethylene glycol with no reason to believe it is harmful. Also, alcoholic patients who are unable to attain ethyl (drinking) alcohol may abuse ethylene glycol. It is fairly common to hear of teenagers who intentionally drink radiator antifreeze to become intoxicated. Very small amounts can be fatal in an adult or a child.

Ethylene glycol has some of the same effects as ethyl alcohol. Thus, the patient may present as if he is intoxicated. However, like methanol and isopropanol alcohols, the by-products of metabolism of ethylene glycol are extremely harmful, primarily affecting the central nervous system, lungs, heart, vessels, and kidneys.

Signs and Symptoms

The signs and symptoms of ethylene glycol poisoning will commonly occur in three stages. The stages are typically associated with the time from ingestion and affect various body systems. The signs and symptoms include the following:

First Stage: Neurological

This stage occurs 30 minutes to 12 hours after ingestion and primarily affects the central nervous system. These signs and symptoms may be mistaken for a person intoxicated on regular ethyl (drinking) alcohol.

- Uncoordinated movements
- Slurred speech
- Altered mental status
- Nausea and vomiting
- Seizures
- Hallucinations

Second Stage: Cardiopulmonary

This stage usually occurs 12–24 hours after ingestion and primarily affects the central nervous system. These signs and symptoms may be mistaken for a person intoxicated on regular ethyl (drinking) alcohol.

- Tachypnea
- Crackles upon auscultation, indicating pulmonary edema
- Cyanosis
- Dyspnea
- Respiratory distress
- Heart failure

Third Stage: Renal

This stage typically occurs from 24 to 72 hours following ingestion of the ethylene glycol and affects the kidneys.

- Production of very little urine (oliguria) or no urine (anuria)
- Bloody urine (hematuria)
- Pain to the flank areas
4. Routine treatment for this type of absorbed poisoning is first to ensure the airway, breathing, and circulatory status. You should have available any personal protection measures, and decontamination if any plant substance is still on the person's body. You should refer to poison control center officials can also provide information about any available antidote that may be appropriate for a patient. Any treatment recommended by the poison control center officials can also provide information about any available antidote that may be appropriate for a patient.

Emergency Medical Care

The emergency medical care for ethylene glycol poisoning is primarily supportive. However, administration of ethyl (drinking) alcohol may be considered. Be prepared to manage seizures and respiratory arrest. The emergency medical care includes the following:

1. Open and maintain a patent airway.
2. Assess the breathing status. If the respiratory rate or tidal volume is inadequate, immediately provide positive pressure ventilation while maximizing oxygen delivery through the ventilation device. Adequate ventilation is necessary to help reduce the acidosisis in the body.
3. Maintain adequate oxygenation. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.
4. Rapidly transport the patient.

Poisonous Plants

A fairly common type of absorbed poisoning comes from skin contact with a poisonous plant—usually poison ivy, poison sumac, or poison oak. Poison ivy thrives in sun and in light shade. It usually grows in the form of a trailing vine that sends out numerous kinky brown footlets that are slightly thickened at the tips. It can also grow in the form of a bush and grow to heights of 10 feet or more. You don’t need direct contact with the plant to have a reaction from poison ivy; the poisonous element, urushiol, can be carried on animal fur, tools, and clothing. If poison ivy is burned, particles of urushiol are contained in the smoke and can be breathed in or absorbed through the skin. People with an allergy to urushiol—about 75 percent of all Americans—are likely to have severe reactions to contact with poison ivy.

Poison sumac is a tall shrub or slender tree, usually growing along swamps and ponds in wooded areas. Poison oak resembles poison ivy with one important difference: the poison oak leaves have rounded, lobed leaflets instead of leaflets that are jagged. Poison oak is found mostly in the southeastern and western United States.

Other plants that can cause mild to severe dermatitis include stinging nettle, crown of thorns, buttercup, May apple, marsh marigold, candelabra cactus, brown-eyed Susan, Shasta daisy, and chrysanthemum.

Emergency treatment includes scene safety, personal protection measures, and decontamination if any plant substance is still on the person's body. You should first ensure the airway, breathing, and circulatory status. Routine treatment for this type of absorbed poisoning is mainly supportive until arrival at the hospital. You should keep the patient from scratching the site as this may cause a break in the skin, which may allow an infection to set in.

Suicide Bags

Suicide bags, also known as “exit bags” are becoming a very common form of euthanasia worldwide. EMS crews in the United States are beginning to encounter patients using the suicide bag as a less violent method to commit suicide. The suicide bag method is simple, inexpensive, and is made from materials and ingredients that are accessible to the general population.

The suicide bag is composed of a large plastic bag with a drawstring to tighten around the neck; a hose, and a container of gas such as helium or nitrogen. The bag is placed over the head, tightened around the neck and the hose inserted into the bag. The hose is connected to a helium or nitrogen tank. The person turns on the tank while the gas then freely flows into the bag around the head. The helium and nitrogen displace the oxygen in the bag and cause the patient to suffocate to death.

During normal suffocation, the body triggers a strong response from the hypoxia and hypercarbia, which causes the patient to struggle and panic. When helium and nitrogen are used, they do not produce these effects, thereby allowing for a more peaceful death.

This method of suicide does more than create a dangerous toxic environment for the patient. It also puts the EMS crews and other emergency responders at risk. As the helium or nitrogen gas continues to flow freely, the oxygen in the room is displaced, creating a dangerously low-oxygen-content environment. When the first responder or EMS crewmember enters the room, he or she can become asphyxiated with only one to two breaths of the toxic-gas-enriched air.

Scene safety is paramount in any of these suspected situations. If you enter a scene where this type of suicide bag is suspected or recognized, immediately evacuate the room, contact the fire department, and follow their directions. Any person exposed to the helium or nitrogen, whether it is the patient attempting the suicide or an emergency responder entering the scene, must be treated as a toxic-inhalation emergency. Establish and maintain an airway, ventilation, oxygenation, and circulation. In this case, maximize oxygenation by applying a nonrebreather mask at 15 lpm in the patient with adequate breathing.

**POISON CONTROL CENTERS**

Poison control centers have been established across the United States and Canada to assist in the treatment of poison patients. Officials at the center can help you set priorities and formulate an effective treatment plan. Poison center officials can also provide information about any available antidote that may be appropriate for a patient. Any treatment recommended by the poison control center officials can also provide information about any available antidote that may be appropriate for a patient.
control center should be discussed with medical direction before it is administered to the patient.

Calls to poison control centers are toll-free, and most are staffed 24 hours a day to assist prehospital personnel as well as the public. Staffed by experienced professionals, each center is also connected to a network of nationwide consultants with access to trained toxicologists who can answer questions about almost any poison. Information on the poison center’s computer is updated regularly to provide the latest information on treatment options and antidotes. Centers provide follow-up telephone calls, monitoring the patient’s progress and making treatment suggestions until the patient is either hospitalized or no longer has the symptoms.

Be prepared to tell poison center officials the patient’s approximate age and weight. Summarize the patient’s condition, including level of responsiveness, level of activity, skin color, vomiting, and so on. Give as many specifics about the poison as you can. Again, any directions from a poison control center should be verified by your medical direction. Follow local protocol.

### DRUG AND ALCOHOL EMERGENCIES

Drug abuse is defined as the self-administration of drugs (or of a single drug) in a manner that is not in accord with approved medical or social patterns. A drug or alcohol overdose is an emergency that involves poisoning by drugs or alcohol. A patient’s withdrawal from alcohol or drugs—a period of abstinence from the drug or alcohol to which the body has become accustomed—can be as serious an emergency as an overdose.

Most drug overdoses you will see in the field involve habitual drug users, but drug overdose can also be the result of miscalculation, of confusion, of using more drugs that interact with each other in a potentially dangerous way, or of intentional use (usually as a suicide attempt) (Figure 22-12).

Several major medical problems can result from any drug overdose or from sudden withdrawal from a drug. Among the most common findings are altered mental status, respiratory depression, damage to organs such as the kidneys or liver, seizures, cardiac arrest, and hyperthermia or hypothermia. The range of medical problems you may confront in a drug abuse patient is extremely wide and depends on the type of drug taken. For example, stimulants such as cocaine will increase heart rate and blood pressure, while depressants such as barbiturates will lower them.

**PATHOPHYSIOLOGY PEARLS**

Drugs with a stimulant effect elevate the heart rate, blood pressure, and respiratory rate and may create a state of excitation. Drugs with a depressant effect may cause a decrease in the heart rate, blood pressure, and respiratory rate and may depress or deepen depression of the mental status.

Table 22-1 will give you an idea of the variety of consequences of commonly used drugs. As an EMT, you are not expected to remember everything about each of the drug classes, but the table will help you understand the seriousness and complexity of drug and alcohol emergencies. In drug and alcohol emergencies, the goals are to identify and treat the loss of vital functions caused by the drug—especially impairments to the airway, breathing, oxygenation, and circulation—not the specific effects of the drug itself.

As you can see in Table 22-1, alcohol is classified as a type of drug. It is a central nervous system depressant that, in moderate doses, causes an altered mental status. In large doses, it can cause unresponsiveness or death. Alcohol is completely absorbed from the stomach and intestinal tract within 2 hours from the time it is ingested and sometimes as quickly as 30 minutes. Once absorbed from the stomach, it is distributed relatively quickly to all body tissues. It is concentrated, however, in the blood and in the brain.

Habitual alcohol abusers, or alcoholics, are prone to a wide variety of illnesses ranging from cirrhosis of the liver to peritonitis. In addition to causing medical problems, alcohol intoxication is a major cause of automobile crashes. Alcohol ingestion, even in smaller doses, is also a major factor in drug overdoses, homicides, burns, drowning, nonaccidental trauma, and general trauma.

### Assessment-Based Approach: Drug and Alcohol Emergencies

**Scene Size-up**

Conduct a scene size-up. First make sure that the scene is safe, since calls involving drugs or alcohol may involve physical abuse, violent acts, or sudden changes in behavior that may result in violence toward the EMT. In these situations, it may be prudent to call for police backup early so they are on scene with you in case violence erupts. (See “Managing a Violent Drug or Alcohol...

</table>
Abuse Patient” later in this chapter, for specific guidelines on what to do upon encountering a patient who is likely to become aggressive.)

**ASSESSMENT TIPS**

Rapid behavior change may put the EMT at risk. Constantly remain attentive to the dynamics of the scene and the patient. Drug and alcohol emergencies may, at times, erupt in violence that could be directed toward the EMT.

Be very careful to note the presence of any potential weapons and not to get stuck with a drug abuser’s needle, as most people who share needles also share infectious diseases. Make sure you have taken the appropriate Standard Precautions, since alcoholics and drug abusers may have a higher incidence of bloodborne and airborne diseases. Look for a mechanism of injury that could possibly have caused injury to the patient.

In addition, because drug and alcohol emergencies may mimic other medical conditions, especially stroke and hypoglycemia, you should inspect the area immediately around the patient (and carefully check the patient’s pockets) for evidence of drug or alcohol use—empty or partially filled pill bottles or boxes, syringes, empty liquor bottles, prescriptions, hospital discharge orders, or physician’s notes that might help you identify what drug the patient has taken. Also check the patient for any medical ID tag that would give information about chronic conditions such as diabetes. Keep any such evidence with the patient since it will be useful for the staff at the poison control center or the emergency department.

**Primary Assessment**

Begin your primary assessment by forming a general impression. Given the mechanism of injury, take the necessary manual in-line spinal precautions. Quickly scan the patient for any obvious life threats such as gunshot or knife wounds to the chest, major bleeding, or an obstructed airway from vomitus, blood, or other secretions.

The mental status of the drug or alcohol abuse patient can range from extreme excitability to complete unresponsiveness, depending on the substance being abused. If the patient has an altered mental status, open the airway and closely inspect inside the mouth for secretions, vomitus, or other substances that may block the airway or could be aspirated.

Alcohol, narcotics, and other central nervous system (CNS) depressants could easily cause inadequate breathing as a result of slow or absent respiratory rates or decreased inspiratory volume. If the patient is not breathing adequately, as evidenced by either slow breathing (bradypnea), or shallow breathing (hypopnea), provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 per minute. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO2 is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

Assess the circulation by palpating for a radial pulse. The heart rate may be decreased or rapid and weak if CNS depressants are abused, whereas the patient may have significantly increased heart rates when CNS stimulants have been taken. The skin in the CNS depressant abuse patient is usually cool, clammy, and pale because of poor perfusion related to hypotension. Assess for major external bleeding that may have occurred as a result of associated trauma.

The odor of alcohol on the patient’s breath or clothing may provide a clue to alcohol abuse. However, do not confuse the fruity or acetone odor that is related to

a diabetic emergency with the smell of alcohol. In addition, do not automatically decide that an altered mental status or other signs and symptoms are directly related to alcohol ingestion.

**ASSESSMENT TIPS**
The vital signs of a patient who has been abusing drugs may vary widely, based on the type of drug taken. What the EMT may notice, however, is a pattern of signs and symptoms. These patterns may help identify the type of drug, for example, a stimulant or depressant.

Other serious medical conditions may be present and not directly related to or caused by the alcohol. Always be suspicious that a condition other than alcohol intoxication may be the cause of altered mental status and other similar signs and symptoms. As an example, the slurred speech that you assume is due to alcohol ingestion may actually be a result of a stroke or head injury.

**PATHOPHYSIOLOGY PEARLS**
Even though the patient may have taken a drug or ingested alcohol, always consider other possible causes of his condition, such as diabetes, stroke, or even low body core temperature. The EMT should remain suspicious of a wide variety of causes at all times while assessing the patient.

It is necessary to prioritize the patient at the end of the primary assessment. *The following six signs and symptoms indicate a high-priority patient* (Figure 22-13):

- Unresponsiveness
- Inadequate breathing

**DRUG AND ALCOHOL EMERGENCY INDICATORS**

If any of the following six danger signs are present, no matter what caused the crisis, the patient’s life may be threatened and the patient is a high priority for immediate transport.

1. **Unresponsiveness:**
The patient cannot be awakened from what appears to be a deep sleep or coma. If awakened for a short period of time, she almost immediately relapses into unresponsiveness.

2. **Respiratory difficulties:**
The patient’s breathing may be very weak, stong and weak cycles, or may stop altogether. Inhalation or expiration may be noisy. If the patient’s skin is bluish (cyanotic), she is almost certainly not receiving enough oxygen, but the absence of cyanosis does not necessarily mean that respiratory difficulties are not severe.

3. **Fever:**
As a guide it may be stated that any temperature above 100°F or 38°C falls into this category.

4. **Tachycardia or bradycardia, or an irregular pulse:**
Tachycardia, bradycardia or an irregular pulse may be an indication of physiologic instability.

5. **Vomiting with altered mental status:**
If the patient vomits while not alert or unresponsive, the prime danger consists of the possibility that she may occlude her airway or aspirate vomitus into the lungs.

6. **Seizures:**
Muscle rigidity, spasm, or twitching of face, trunk muscles, or extremities may indicate an impending convulsion with a series of violent muscle contractions and jerking movements.

*Figure 22-13* Drug and alcohol emergency indicators.
Fever
- Abnormal heart rate (slow, fast, weak, or irregular)
- Vomiting with an altered mental status
- Seizures

**Secondary Assessment**

In the altered mental status or unresponsive patient, conduct a rapid secondary assessment. Examine the patient for any evidence of trauma.

**Physical Exam.** CNS stimulant drugs typically cause dilated pupils, whereas narcotics cause pinpoint pupils. Inspect the mucous membranes inside the mouth for evidence of cyanosis, excessive salivation, or dryness. The membranes may be swollen if volatile chemicals have been inhaled. As mentioned earlier, “huffers” are patients who inhale paints or propellants in order to “get high” as the poison gets absorbed across the alveolar membrane. These patients are commonly identified by the presence of paint or other material about the mouth and nose. Hallucinogens may cause the face to flush. Jugular venous distention may be found in CNS stimulants or depressant abuse if the patient has suffered heart failure. Auscultate the lungs for abnormal sounds.

**PATHOPHYSIOLOGY PEARLS**

A huffer may experience a euphoric feeling, or “high,” when the paint fumes or gas he inhales displaces the air in his lungs and creates a state of hypoxia.

The muscles in the extremities may appear very relaxed and lack any coordination if narcotics were taken. Peripheral pulses may be very weak, rapid, and irregular, if not absent. The skin may appear cool, clammy, and pale in narcotic drug abuse. Look for needle tracks on the extremities (Figure 22-14).

Obtain a set of vital signs. The blood pressure may be low with CNS depressants and extremely high with CNS stimulants. The pulse will vary, depending on the drug, and may be elevated, slow, or irregular. The skin may be flushed, pale, or cyanotic. Skin condition may be dry, moist, or normal. The temperature may be cool with CNS depressants and warm with CNS stimulants.

Attempt to gather a history from any relatives, friends, or bystanders at the scene. Look for medical alert tags on the patient.

**History.** If the patient is responsive and able to answer your questions and obey your commands, gather a history from the patient before conducting the physical exam and gathering vital signs. During the questioning, attempt to determine what the patient has ingested, injected, inhaled, smoked, or abused in some other manner. Remember, however, that the history may be unreliable because the patient may believe that the EMS provider will get him into trouble with law enforcement. Keep in mind also that patients sometimes abuse more than one substance at a time, using different routes. For example, alcohol is commonly involved with the abuse of other drugs.

The patient may mention pharming or a “pharching party.” This typically refers to adolescents who raid their parents’ or friends’ medicine cabinets for prescription medications or who fake symptoms to obtain prescription medications. The teens then attend a pharming party and trade medications and typically take the medications with alcohol to try to obtain a greater high. Painkillers, CNS depressants, anti-anxiety medications, and stimulants are the most popular medications at pharming parties.

Try to establish the past medical history. Determine what prescription medications the patient is taking since these may interact with the substance being abused and worsen the condition or hide certain characteristic signs. Following the history, conduct a physical exam and obtain a set of vital signs.

**ASSESSMENT TIPS**

Painkillers commonly taken at “pharching” parties are OxyContin, Demerol, Darvon, Dilaudid, Percocet, Vicodin, and Tylenol with Codeine. Many of the stimulants taken are those prescribed for attention-deficit disorders, such as Ritalin, Adderall, and Dexedrine.

**Signs and Symptoms.** The signs and symptoms can vary widely, depending on the substance or drug that was abused. Many times the patient abuses more than one substance or drug. For example, a patient may take a CNS stimulant, drink large amounts of alcohol, and then take a CNS depressant. This would produce a variety of conflicting signs and symptoms. The following are characteristic signs and symptoms based on the most common types of abused drugs and substances (review Table 22-1):

- **CNS stimulants** excite the central nervous system.

**Signs and symptoms:** Excitability, elevated mood, agitation, apprehension, uncooperativeness, tachycardia,
tachypnea, dilated pupils, dry mouth, sweating, increased blood pressure, loss of appetite, lack of sleep.

- **CNS depressants** depress the central nervous system.
  
  **Signs and symptoms:** Euphoria, drowsiness, sleepiness, decreased breathing rates and volumes, bradycardia, hypotension, dilated pupils that are sluggish to respond to light.

- **Narcotics** are CNS depressants that are derived from opium (opiates) or synthetic opium (opioids).
  
  **Signs and symptoms:** Bradycardia, hypotension, inadequate breathing rates and volume, cool, clammy skin, lethargy, constricted pupils, nausea. Respiratory depression or arrest can occur in these patients.

- **Hallucinogens**, sometimes called psychedelic drugs, cause hallucinations.
  
  **Signs and symptoms:** Motor disturbances, paranoia, anxiety, visual or auditory hallucinations, tachycardia, dilated pupils, flushed face, poor perception of time and distance.

- **Volatile inhalants** are substances that are inhaled.
  
  **Signs and symptoms:** Excitement, euphoria, drunkenness, aggressiveness, depression, headache, drowsiness, nausea, swollen mucous membranes of the nose and mouth, glazed eyes, slurred speech, hallucinations, incoordination, erratic pulse and blood pressure, seizures.

### Emergency Medical Care

The emergency care provided to the drug, substance, or alcohol abuse patient is mostly supportive. Scene safety is a priority at many of these scenes. Close monitoring of the patient is necessary, since a rapid change in his condition may occur from the alcohol, drug, or other substance. Calming the patient may be a primary concern, because the mental status of a drug abuser may result in extreme violence or resistance to your care, you may have to restrain him. Never, however, restrain the patient in a prone position, because this makes monitoring the airway and breathing almost impossible. Many protocols require law enforcement presence prior to patient restraint.

1. **Establish and maintain an airway.** If spinal injury is suspected, take manual in-line spinal stabilization. Suction any substance from the mouth. If the patient is unresponsive, consider inserting an oropharyngeal or nasopharyngeal airway.

2. **Establish and maintain adequate ventilation.** If the breathing is inadequate, begin positive pressure ventilation with supplemental oxygen attached to the ventilation device at a rate of 10–12 per minute. Closely monitor the breathing status, since many drugs may cause respiratory depression or arrest. This can occur suddenly in some cases.

3. **Maintain adequate oxygenation.** If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

4. **Position the patient.** The unresponsive patient should be placed in a lateral recumbent position to help protect the airway from aspiration unless a spinal injury is suspected, in which case the patient is positioned supine on a backboard with other spinal precautions taken. If the patient requires ventilation, keep him in a supine position and have suction readily available.

5. **Maintain the body temperature.** Some drugs may cause an increase or decrease in the body temperature. Cover patients with decreased temperatures with a blanket and warm the back of the ambulance. If the patient’s temperature is elevated, remove clothing and passively cool the patient, as described in Chapter 24, “Environmental Emergencies.” If your EMS service has thermometers available, obtaining an actual temperature may be beneficial to treatment. The use of tympanic thermometers is encouraged, because inserting an oral thermometer into the mouth of a patient with an altered mental status is dangerous.

6. **If your local protocol permits, assess the blood glucose level** with a glucose meter to rule out possible hypoglycemia. If the blood glucose level is less than 60 mg/dL, follow your hypoglycemia protocol.

7. **Restrain the patient only if necessary.** Use restraints according to your local protocols. Request assistance from law enforcement, if necessary. Because the mental status of a drug abuser may result in extreme violence or resistance to your care, you may have to restrain him. Never, however, restrain the patient in a prone position, because this makes monitoring the airway and breathing almost impossible. Many protocols require law enforcement presence prior to patient restraint.

### Reassessment

The reassessment is extremely important in drug, substance, or alcohol abuse patients, because their condition can change so rapidly as a result of the influence of the substance. The patient may lose his gag or cough reflex and not be able to maintain his own airway. Closely monitor the airway for vomitus or secretions. The respirations may become inadequate very quickly. The heart rate and blood pressure may fluctuate, either increasing or decreasing excessively. The reassessment should be conducted every 5 minutes to monitor the patient effectively. If the patient is stable, the reassessment may be done at 15-minute intervals, but closely monitor the patient as his condition may rapidly change.

### Summary: Assessment and Care

To review assessment findings that may be associated with drug and alcohol emergencies and emergency care, see Figures 22-15 and 22-16.
**Assessment Summary**

## DRUG OR ALCOHOL EMERGENCY

The following findings may be associated with a drug or alcohol emergency.

### Scene Size-up

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Alcohol, drugs, or other commonly abused substances
- Position and location of the patient
- Needles, syringes, or other drug paraphernalia

### Primary Assessment

#### General Impression

- Vomitus or secretions in mouth
- Paint or chemical stains about mouth and nose
- Gunshot or knife wounds to chest
- Excessively excited patient may indicate CNS stimulant drug abuse
- Excessively depressed patient may indicate CNS depressant drug abuse

#### Mental Status

- Alert to unresponsive
- May appear hyperactive, very nervous or excited, or depressed and lethargic

#### Airway

- Obstruction by tongue
- Obstruction by vomitus or secretions
- Excessive secretions may be present that require suctioning

#### Breathing

- Respirations shallow, slow, or absent
- Hyperventilation

#### Circulation

- Heart rate may be increased, decreased, or normal
- Irregular heart rates may be palpated
- Skin color may be flushed, pale, or cyanotic
- Skin temperature may be cool, normal, or warm
- Skin condition may be wet, dry, or normal

### Status: Priority Patient

### Secondary Assessment

#### General Findings

CNS stimulants:
- Excitability
- Elevated mood

CNS depressants:
- Euphoria
- Drowsiness
- Sleepiness
- Decreased breathing rates and volumes
- Bradycardia
- Hypotension
- Pupils sluggish to respond to light

Narcotics:
- Bradycardia
- Hypotension
- Inadequate breathing
- Cool, clammy skin
- Lethargy
- Constricted pupils
- Nausea

Hallucinogens:
- Motor disturbances
- Paranoia
- Anxiety
- Visual or auditory hallucinations
- Tachycardia
- Dilated pupils
- Flushed face
- Poor perception of time or distance

Volatile inhalants:
- Excitement
- Euphoria
- Drunkenness
- Aggressiveness
- Depression
- Headache
- Drowsiness
- Nausea
- Swollen mucous membranes of nose and mouth
- Glazed eyes
- Slurred speech
- Hallucinations
- Incoordination
- Erratic blood pressure and pulse
- Paint or chemical stains about mouth and nose

*continued*
Managing a Violent Drug or Alcohol Abuse Patient

The unusual, always unpredictable, and sometimes violent behavior of the drug or alcohol abuse patient presents special concerns for the safety of the EMS crew, the patient, and bystanders. For more information on how to interact with and restrain a violent patient (regardless of the reason), see Chapter 26, “Behavioral Emergencies.” The talk-down technique, discussed next, is useful when dealing with a patient who is experiencing a “bad trip.”

The Talk-Down Technique

Emergencies associated with hallucinogens and marijuana are usually more psychological than physical. Such emergencies may present as intense anxiety or panic states (“bad trips”), depressive or paranoid reactions, mood changes, disorientation, or an inability to distinguish between reality and fantasy. Some prolonged psychotic reactions to hallucinogenic drugs have been reported, particularly with persons already psychologically disturbed.
Emergency Care Algorithm

DRUG OR ALCOHOL EMERGENCY

Mechanism of injury present?

Yes

Consider manual in-line stabilization

Assess mental status

Alert

Consider oxygen administration

Assess circulation

Secondary Assessment

Determine the substance, amount, and how long ago it was taken

Any seizure activity?

Yes

Go to seizure protocol

No

Transport

Reassessment

No

Altered

Airway open?

Yes

Suction if necessary

Head-tilt, chin-lift or jaw-thrust maneuver

Oro- or nasopharyngeal airway

Assess breathing

Adequate

Administer oxygen

Assess circulation

Rapid secondary assessment

Inadequate

PPV with O₂

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

FIGURE 22-16 Emergency care algorithm: drug or alcohol emergency.
The talk-down technique can help you reduce the patient’s anxiety, panic, depression, or confusion, as follows:

1. **Make the patient feel welcome.** Remain relaxed and sympathetic. Because a patient can become suddenly hostile, have a companion with you. Be calm, but be authoritative and firm.

2. **Identify yourself clearly.** Tell the patient who you are and what you are doing to help. Be careful not to invade the patient’s “personal space” until you have established rapport. Try to stay approximately 8–10 feet away until you sense that the patient has some trust in you. Never touch the patient until he gives you permission (Figure 22-17 ■) or unless the patient suddenly poses a threat to safety (the patient’s or someone else’s). Leave yourself a way to safely exit the scene should the patient become violent.

3. **Reassure the patient that his condition is caused by the drug and will not last forever.**

4. **Help the patient verbalize what is happening to him.** Review what is going on. Ask questions. Outline the probable time schedule of events.

5. **Reiterate simple and concrete statements.** Repeat and confirm what the patient says. Orient the patient to time and place. Be absolutely clear in letting the patient know where he is, what is happening, and who is present. Help the patient identify surrounding objects that should be familiar, for example a picture, a person, or maybe even the room or home he is in. This is a process that helps with self-identification.

6. **Forewarn the patient about what will happen as the drug begins to wear off.** There may be confusion one minute, mental clarity the next. Again, help the patient understand that this is due to the drug, not to mental illness.

7. **Once the patient has been calmed, transport.**

Never use the talk-down technique for patients who you know have used the hallucinogen phencyclidine (PCP), because it may further agitate them. (See additional information on PCP patients later in the chapter.)

---

**SPECIFIC SUBSTANCE ABUSE CONSIDERATIONS**

The drug and alcohol emergencies you encounter may be due to the effect of recently consumed alcohol or drugs, or they may be the result of the cumulative effects of years of alcohol abuse. While it will not be necessary for you to diagnose the type of alcohol or drug emergency on the scene, it may help to become familiar with various conditions that are caused by consumption of too much alcohol or drugs or by habitual abuse. For instance, the patient who has abused alcohol steadily for years may need treatment not only for acute intoxication but also for medical conditions that have been caused by alcoholism.

What follows are signs and symptoms and special considerations for managing some of the most common types of alcohol and drug emergencies.

---

**FIGURE 22-17** Explain who you are and maintain a nonjudgmental attitude. (© Craig Jackson/In the Dark Photography)
**Drug Withdrawal**

A habitual drug user may develop a *tolerance* to a drug, in which larger doses are required to produce the same desired effects. This quite often leads to a physical or psychological *dependence*, in which the patient experiences a strong need to use the drug repeatedly.

The psychologically dependent person is completely preoccupied with the procurement of the drug. His behavior may be compulsive or neurotic and is geared toward acquiring another dose of the drug. There are, however, no physiological consequences of drug withdrawal for this patient. The physically dependent drug user, on the other hand, undergoes physiological changes within the body that require the drug to be present in his system to prevent withdrawal consequences from occurring. Drugs that commonly produce physical drug dependence are narcotics, sedatives, hypnotics, barbiturates, cocaine, and marijuana.

The following signs and symptoms of drug withdrawal usually begin to occur at about the time when the next drug dose is required, and they usually peak at 48 to 72 hours after the person has stopped taking the drug:

- Anxiety and agitation
- Confusion
- Tremors
- Profuse sweating
- Elevated heart rate and blood pressure

**The Alcoholic Syndrome**

Alcohol emergencies are related to the alcoholic syndrome. The alcoholic syndrome usually consists of problem drinking (during which alcohol is used frequently to relieve tensions or other emotional difficulties) and true addiction (in which abstinence from drinking causes physical withdrawal symptoms).

The kind of alcohol used is irrelevant; the heavy beer or wine drinker is as much an alcoholic as the person who drinks too much hard liquor. Alcoholics may abuse alcohol in many forms: Sterno, moonshine, grain alcohol, mouthwash, antifreeze, and rubbing alcohol, to name a few. Frequently, alcoholics are dependent on other drugs as well, especially those in the sedative, barbiturate, and tranquilizer categories. Some alcoholics have underlying psychiatric disorders (especially schizophrenia).

**ALCOHOL EMERGENCIES**

**CAUTION:** Do not immediately decide that a patient with apparent alcohol on the breath is drunk. The signs may indicate an illness or injury such as epilepsy, diabetes, or head injury.

**SIGNS OF INTOXICATION**

- Odor of alcohol on the breath
- Swaying and unsteadiness
- Slurred speech
- Nausea and vomiting
- Flushed face
- Drowsiness
- Violent, destructive, or erratic behavior
- Self-injury, usually without realizing it

**EFFECTS**

- Alcohol is a depressant. It affects judgment, vision, reaction time, and coordination.
- When taken with other depressants, the result can be greater than the combined effects of the two drugs.
- In very large quantities, alcohol can paralyze the respiratory center of the brain and cause death.

**MANAGEMENT**

- Give the same attention as you would to any patient with an illness or injury.
- Monitor the patient’s vital signs constantly. Provide life support when necessary.
- Position the patient to avoid aspiration of vomit.
- Protect the patient from hurting him- or herself.

**FIGURE 22-18** Alcohol emergencies.
The alcoholic usually begins drinking early in the day, is more prone to drink alone or secretly, and may periodically go on prolonged binges characterized by loss of memory (“blackout periods”). Abstinence from alcohol is likely to produce withdrawal symptoms, such as tremulousness, anxiety, seizures, or delirium tremens (DTs). (See the special segment on delirium tremens later in this chapter.)

As the alcoholic becomes more dependent on alcohol, his performance at work and relationships with friends and family are likely to deteriorate. Absences from work, emotional disturbances, and reckless driving become more frequent.

Be aware that the signs and symptoms of disorders or injuries unrelated to alcohol—such as hypoxia, hypoglycemia, hypothermia, recent seizure activity, or head trauma—can easily be confused with the signs and symptoms of intoxication.

Also be aware that alcoholics are prone to injuries and medical conditions brought about by or related to their alcoholism. For example, alcoholics fall down often and are prone to chronic subdural hematomas. Always assess and treat an alcoholic’s injuries and medical problems first, before assuming his only problem is “just being drunk.”

One of the most serious disorders associated with alcoholism is Wernicke-Korsakoff syndrome, a chronic brain syndrome resulting from the toxic effect of alcohol on the central nervous system combined with malnutrition, which is common among alcoholics. Common signs and symptoms of the syndrome include paralysis of the eyes, dementia, hypothermia, the inability to sort signs and symptoms of the syndrome include paralysis of the eyes, dementia, hypothermia, the inability to sort signs and symptoms of the syndrome include paralysis of the eyes, dementia, hypothermia, the inability to sort signs

Alcoholics often do not eat right, and their health deteriorates. They are more prone to the following illnesses:

- Hypertension
- Altered mental status due to liver malfunction
- Cirrhosis of the liver
- Liver failure (the liver degenerates to fatty material)
- Pancreatitis (including inflammation, abscesses, and necrosis)
- Cardiomyopathy or heart muscle disease
- Peritonitis (inflammation of the abdominal lining)
- Chronic gastric ulcer
- Suppression of the bone marrow’s ability to produce red and white blood cells and platelets
- Upper gastrointestinal hemorrhage due to varicose veins in the esophagus, a common cause of death among alcoholics
- Seizures
- Subdural hematoma
- Fractures of the ribs and extremities due to repeated falls
- Hypoglycemia (low blood sugar)
- Pruritus (extreme itching)

The Withdrawal Syndrome

Withdrawal syndrome occurs after a period of abstinence from the drug or alcohol to which a person’s body has become accustomed. However, it does not require that the alcoholic or drug abuser stop drinking or taking the drug completely. The withdrawal syndrome can also occur when an alcoholic’s alcohol intake falls below the amount usually ingested.

Alcohol withdrawal is dose dependent: The more the alcoholic was drinking, the more severe the syndrome will be. Alcohol withdrawal syndrome (Figure 22-19 ■), which can mimic a number of psychiatric disorders, is characterized by the following signs and symptoms:

- Insomnia (inability to sleep)
- Muscular weakness
- Fever
- Seizures or tremors
- Disorientation, confusion, and thought process disorders
- Transient visual, tactile, or auditory hallucinations
- Anorexia (a life-threatening loss of appetite)
- Nausea and vomiting
- Hyperthermia (elevated body temperature)
- Sweating
- Hypertension
- Rapid heartbeat

There are four general stages of alcohol withdrawal:

- Stage 1, which occurs within about 8 hours, is characterized by nausea, insomnia, sweating, and tremors.
- Stage 2, which occurs within 8 to 72 hours, is characterized by a worsening of stage 1 symptoms plus hallucinations.
- Stage 3, which can occur as early as 48 hours following the last alcoholic beverage, is characterized by major seizures.
- Stage 4 is characterized by delirium tremens (see the next section).

Delirium Tremens

The last stage of alcohol withdrawal, delirium tremens (DTs), is a severe, life-threatening condition with a mortality rate of approximately 5 to 15 percent. DTs can occur between 1 and 14 days after the patient’s last drink, most commonly within 2 to 5 days. A single episode of DTs lasts between 1 and 3 days. Multiple episodes can last as long as a month. DTs should be suspected in any patient with delirium (mental confusion) of unknown cause. Signs and symptoms of DTs are:

- Severe confusion
- Loss of memory
- Tremors
- Restlessness and irritability
ALCOHOL WITHDRAWAL SYNDROME

Delirium tremens constitutes the most extreme form of alcohol withdrawal syndrome. Less severe forms include alcoholic tremulousness, alcoholic hallucinosis, and withdrawal seizures, which generally (but not always) precede delirium tremens.

Stage 1
Alcoholic tremulousness
Difficulty concentrating
Restlessness
Irritability
Insomnia
Sweating
Nausea
Tremors

Stage 2
Alcoholic hallucinosis
Visual, auditory, and/or tactile hallucinations

Stage 3
Withdrawal seizures
These are characterized by muscle rigidity and relaxation that usually alternate rhythmically in rapid succession and in groups of 2–6.

Stage 4
Delirium tremens
Confusion
Inattentiveness
Disorientation
Fever
Nausea, vomiting
Incoherence
Hyperirritability
Relentless insomnia

FIGURE 22-19  Alcohol withdrawal.

- Extremely high fever
- Dilated pupils
- Profuse sweating
- Insomnia
- Elevated blood pressure
- Tachycardia
- Nausea and vomiting
- Diarrhea
- Hallucinations, mostly of a frightening nature (such as delusions of snakes, spiders, or rats)
Seizures are common in alcoholic withdrawal, but not in DTs. However, approximately a third of all those who have seizures in early withdrawal will progress to DTs if left untreated or if treated inadequately. The treatment goals for a patient who is experiencing DTs include psychological as well as physical support (DTs can be a frightening experience).

**PCP, Cocaine, Amphetamines, Methamphetamines, and PABS**

The emergency consequences of commonly abused drugs were discussed in Table 22-1. Because of the unique effects of PCP and cocaine, their use requires special considerations in emergency care.

**PCP**

One of the most dangerous hallucinogens is phencyclidine (PCP). Known by at least 46 names, it is also called angel dust, killer weed, supergrass, crystal cyclone, hog, elephant tranquilizer, PeaCe Pill, embalming fluid, horse tranquilizer, mintweed, mist, monkey dust, rocket fuel, goon, surfer, KW, or scuffle.

Nothing has so bewildered and amazed researchers as PCP, a drug that is cheap, easy to make and easy to take, and produces horrible psychological effects (some of which can last for years). PCP is stored in body fat. If a user suddenly loses weight, the drug can be released into the bloodstream and can cause a reaction even if the drug has not been recently taken.

**Cocaine**

Another drug that deserves special mention is cocaine—partly because of its common use, and partly because of the devastating medical complications of its use.

Cocaine is inhaled through the nose, injected into the veins, and injected into the muscles. An almost-pure form of cocaine known as “crack” is smoked. Another special form of cocaine is heated and inhaled (“free based”). Cocaine is highly addictive, and an overdose can be fatal.

**Amphetamines and Methamphetamines**

Amphetamines and methamphetamines are abused in a number of forms including tablets, capsules, powders, impregnated in paper, and gelatin. The drug is commonly referred to on the street as “crank” or “go.” A crystalline form, referred to as “ice” or “crystal,” is smoked, injected, or snorted. Hallucinogenic amphetamines are typically ingested but may be injected or snorted. Street names for hallucinogenic amphetamines include Adam, ecstasy, Eve, essence, harmony, love, tranquility, peace, serenity, and golden eagle.

Amphetamines and methamphetamines stimulate the central nervous system, excite the cardiovascular system, and can produce hallucinations. Hyperthermia, muscle rigidity, or severe excitation may occur, leading to long periods of an awake and excited state. The resulting hypertension, hyperthermia, and increased muscle tone may be life threatening. Methamphetamine use is associated with the sensation of ants or bugs crawling under the skin. The patient often picks at his skin or mutilates himself. Panic attacks and visual and auditory hallucinations may also occur.

**PABS (Bath Salts)**

EMS is seeing an increase in the frequency of use of the illegal drug psychoactive “bath salts” (PABS). These “bath salts” have no ingredients related to hygiene, however; they are a synthetic designer drug with properties that inhibit the reuptake of norepinephrine and dopamine in the body. As a result, the drug acts as a central nervous system stimulant. The effect of the drug is similar to methamphetamine and cocaine and produces similar signs and symptoms. A long-term user can build up a tolerance and the cessation of use can trigger withdrawal and intense cravings.

The drug is often purchased online under names such as Ivory Wave, Vanilla Sky, Bliss, Blue Silk, Cloud Nine, Drone, Energy-1, Lunar Wave, Meow Meow, Stardust, Snow Leopard, and many others. It is a white, off-white, or slightly yellow-colored powder packaged in small plastic bags. The drug also comes in a tablet or capsule form. Users will ingest, snort, inject, smoke, or use a rectal route of administration.

A patient who has taken a PABS can experience extreme sympathetic stimulation and altered mental status. The sympathetic effects include:

- Tachycardia
- Hypertension
- Hyperthermia
- Seizures

The altered mental status presents as severe paranoia, panic attacks, agitation, hallucinations, and violent behavior. The PABS have been reported to produce effects that are worse than LSD, PCP, ecstasy, cocaine, or methamphetamine.

**Signs and Symptoms of PCP, Cocaine, Amphetamines, Methamphetamines, or PABS**

Physical signs and symptoms of PCP, cocaine, amphetamines, methamphetamines, or PABS are somewhat similar. However, the EMT should remember that emergency management is supportive and not geared toward figuring out exactly what drug was used if the history is unclear. Signs may include:
Emergency Medical Care

You will treat an amphetamine, methamphetamine, cocaine, PCP, or PABS overdose as you would any other drug emergency, with the following special considerations.

Your first priority in providing emergency medical care for the patient under the influence of PCP, amphetamine, methamphetamine, cocaine, or PABS is to protect yourself and your crew, since the patient may be combative and require restraint. Keep the patient in a quiet, nonstimulating environment.

Check quickly to determine whether there are any injuries that need attention. If there are, administer emergency medical care for those injuries as you would for any trauma patient (ensuring the airway, providing oxygen and ventilations if required, and supporting the circulatory system) before continuing with psychological care. Monitor vital signs regularly and transport the patient as quickly as possible.

Medication Overdose

Another common source of drug overdose is prescription and over-the-counter medications. The overdose may be intentional, where the patient is trying to commit suicide or achieve some type of effect that is not intended for that medication, or it may be accidental. Accidental overdose typically occurs when the patient does not understand the prescription instructions and takes too much of the drug or the patient is forgetful and mistakenly takes the drug more often than is needed. Patients who are on many different medications may suffer synergistic drug interactions when adding a new or an over-the-counter medication. Medications that are commonly involved in overdose are:

- Cardiac medications such as calcium channel blockers, beta blockers, cardioactive steroids, angiotensin-converting enzyme (ACE) inhibitors, and antidysrhythmics
- Psychiatric medications such as benzodiazepines, tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and lithium
- Over-the-counter pain relief drugs such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and aspirin
- Antihistamines
- Herbal remedies
- Dietary supplements

Signs and symptoms of medical overdose vary depending on the substance ingested. For example, if beta blockers or calcium channel blockers were involved in the overdose, the heart rate would be bradycardic and the patient would likely be hypotensive; whereas, overdose on acetaminophen will initially not produce any signs or symptoms.

Emergency care for medication overdose focuses on establishing and maintaining an adequate airway, ventilation, and oxygenation. Transport and continuously reassess the patient for changes in his condition. The effects of the medication may continue to increase and cause the patient to deteriorate. This may require you to become more aggressive in your management of the airway, ventilation, and oxygenation.

Huffing

Some poisons are inhaled intentionally in an attempt to “get high.” As noted earlier, patients who inhale paints and propellants for this purpose are commonly referred to as “huffers.” (See Figure 22-20.) The chemical toluene, the agent most commonly used for huffing, is
easily found in paints, glues, industrial chemicals, and household chemicals. The toxins are inhaled in a variety of ways in an attempt to produce certain expected effects. Many of the chemicals used for huffing accumulate in the regions of the brain responsible for feelings of pleasure and reward. After time, they migrate to other regions where they can cause abnormal muscle coordination and alterations in mental status. These substances can also have effects as they displace the oxygen content in the alveoli, leading to hypoxia, or they can cause structural damage to the alveolar surface itself, which can also impair gas exchange. Look for paint or other material on the lips or around the nose of the patient during the physical exam. This may be the only indication of toxic inhalation in an unresponsive patient. Poisons that are commonly used by huffers include:

- Chemicals that contain toluene
- Paints
- Freon
- Gas propellants
- Glue

Keep in mind that inhaled poisons typically have a more immediate onset of effects than injected poisons and may produce more systemic effects. Remember also that inhaled poisons may destroy lung tissue, leading to severe respiratory compromise and significant respiratory distress or failure. Treatment is geared toward removing the patient from the exposure, assessing and treating any loss of vital function caused by the drug (such as airway, breathing, oxygenation, or circulatory deficits), and providing rapid transport to the emergency department.

FIGURE 22-20  A “huffer” inhales poisons deliberately to “get high.”
Routes of Exposure

- **22-1A** Ingestion.
- **22-1B** Absorption.
- **22-1C** Inhalation.
- **22-1D** Injection.
Administering Activated Charcoal

• 22-2A Obtain an order from medical direction.

• 22-2B Place the activated charcoal in a cup with a lid. A straw may also help to improve the patient’s willingness to drink the charcoal.

• 22-2C Observe the patient drinking the charcoal.

• 22-2D Record the dose and time the charcoal was administered.

SUMMARY

Each year in the United States, thousands of people die or become extremely ill from poisonings that occur either accidentally or through some type of intentional act. The greatest number of poisoning emergency patients are children, especially toddlers who swallow some type of poisonous substance as they are exploring their environment. Poisonings often involve prescription or illicit drugs, cleaning substances, and cosmetics. Many other types of poisonings exist. For example, poisonings may result from exposure to industrial chemicals, pesticides, and other substances encountered in the workplace or outdoor environment.

Poisons can gain access to the body by four different routes. Through ingestion, the poison is swallowed and gets absorbed into the bloodstream through the gastrointestinal tract. With inhalation, a poisonous gas or fume becomes absorbed into the bloodstream by way of the alveoli of the lungs. With injections, such as insect stings or injection of illegal drugs, the poison is forcefully inserted through the skin.
into the tissues. Absorption, typically the slowest route of poisoning, occurs when a poison on the surface of the skin gets absorbed into the tissues.

Regardless of the mechanism, an EMT summoned to a poisoning emergency should approach the situation with a specific process in mind. The first thing to consider is scene safety and ensuring that whatever poison the patient was subjected to will not be a risk to the care providers. After ensuring scene safety, the EMT should complete a primary assessment and ensure that any life threats to the airway, breathing, oxygenation, or circulation are immediately managed. Contact with the poison control center should be made as early as possible, and any treatment recommendations they provide should also be approved by medical direction. The use of activated charcoal for treatment recommendations they provide should also be approved by medical direction prior to administration. So long as the EMT follows these steps when approaching the patient in a poisoning emergency, many patient outcomes can be successful.

Drugs and alcohol are abused by a variety of people in a number of ways, and the EMT needs to be aware of special problems that are associated with specific drug and alcohol emergencies. For instance, it is possible that drug and alcohol overdose patients will have injured themselves, so you may be treating them for trauma as well as medical consequences. You will also note that patients under the influence of, or withdrawing from, alcohol or drugs can be difficult to manage, oftentimes behaving in an aggressive or even violent manner and posing threats to your safety as well as their own.

While it will not be necessary for you to diagnose the type of alcohol or drug emergency on the scene, it may help for you to become familiar with various conditions or presentation patterns that are caused by consumption of too much alcohol (or drugs) or by habitual abuse. For example, if a patient were to abuse a stimulatory drug, there are usually consistent findings of tachycardia, elevated blood pressure, anxiety, tremors, diaphoresis, and mood elevation. A patient who has abused a depressant drug often presents with a collection of symptoms that includes a decrease in heart rate and blood pressure, cool skin, and a depressed mental status. Patients who are suffering withdrawal symptoms from drug abuse commonly have anxiety and agitation, hallucinations (visual, auditory, or tactile), tremors, sweating, nausea, vomiting, and muscle cramping.

As an EMT, your primary concern in managing drug and alcohol emergencies will be to protect your own safety and, for the patient, to maintain an open airway, treat for life-threatening conditions, and offer calm, nonjudgmental assistance.

---

**Case Study Follow-up**

**Scene Size-up**

You have been dispatched to a 3-year-old patient with abdominal pain. As you approach the patient’s residence, you can scan the scene, but note no safety hazards. The patient’s mother runs out the door, holding the patient, and pulls on your sleeve, saying, “Help! I think my daughter Sophie was eating a plant, and I don’t know what to do!” You reassure the mother that you will do all you can to help. As you walk into the living room, you see an overturned plant with dirt and leaves scattered around it. Your partner gathers up some of the leaves, stems, roots, and dirt to keep with the patient and transport to the receiving facility. You have Sophie sit on her mother’s lap on the couch.

**Primary Assessment**

You assess Sophie while she is on her mother’s lap so as not to frighten her. Sophie is hugging her stomach and crying, so your general impression is of a child in pain with an open airway and adequate respirations. She responds appropriately to your simple questions and commands. Using gloves you sweep Sophie’s mouth and remove some tiny fragments of the houseplant as well as bits of dirt. You do this to help ensure that Sophie’s airway remains open as well as to find evidence of what she has taken into her mouth.

As you examine her oral cavity, you notice that the mucous membranes are beginning to swell and there is some irritation in her throat. Because of the swelling, you will continue to closely monitor her airway patency. The SpO2 reading is 97% on room air and she is exhibiting no signs or symptoms of respiratory distress, hypoxia, hypoxemia, poor perfusion, or heart failure, so you decide not to apply oxygen.

Sophie’s mother gets frightened and starts to cry, blaming herself for the poisoning. “If I would have only watched her better she’d be OK.” You reassure Mrs. Horowitz that she did the right thing by calling 911, that breathing the extra oxygen through the mask will help Sophie a lot, and that it’s best for her to remain calm so that Sophie will not become frightened and so that you can treat her quickly.

**Secondary Assessment**

You obtain a history from the mother and determine that she was in the kitchen washing dishes when her daughter toddled off to the living room. About 10 minutes later she heard a crash and her daughter’s scream. She ran into the living room and saw the big philodendron overturned and Sophie clutching a handful of leaves. At first she thought Sophie was hurt from the plant tipping over, but when the intensity of Sophie’s crying and her complaints of “my tummy hurts” increased over the course of a half hour, she called 911. You ask if she did anything to treat Sophie and she answers that she had Sophie drink some water and spit it out into a basin to rinse her mouth. However, she adds, Sophie did not vomit.

Since the plant that overturned was in a heavy pot, you begin a secondary assessment, checking for any evidence of injury. You don’t see any sign of trauma; however, Sophie cringes in pain when you feel for tenderness in her abdomen. You place her on her side on the stretcher, in case of vomiting, while your partner records her vitals. She has a radial pulse rate of 96 continued
bpm. Her respiratory rate is 32 per minute. Her BP is 102/66 mmHg, and her skin is warm and dry. Her pulse oximeter reading remains at 97% on room air.

You let the mother ride in the ambulance with Sophie, and during transport you contact the poison control center as your protocol indicates for any further orders.

**Reassessment**
You reassess Sophie’s airway, breathing, and circulation and find them adequate. You also check the swelling in the oral cavity and see that the condition of the mucous membranes is not worsening. You reassess her mental status every 5 minutes without noting any change. You reassess her abdominal pain, asking if her tummy hurts more or less or is the same. She nods when you say “same.”

You arrive at the emergency department without any further change in Sophie’s condition and transfer her to the staff. You and your partner complete a prehospital care report and prepare the ambulance for another call.

---

**Case Study Follow-up continued**

---

**IN REVIEW**

1. Explain why children are frequent victims of poisoning.
2. List the four ways poisons enter the body.
3. Describe the relationship between poisoning and airway management.
4. Describe the main ways of determining if a poisoning has taken place.
5. Describe the general emergency medical care steps for a poisoning or overdose patient.
6. Give the indications, contraindications, dosage, and administration steps for the administration of activated charcoal.
7. List the general emergency care steps for an ingested poison.
8. List the general emergency care steps for inhaled poisons.
9. List the general emergency care steps for injected poisons.
10. List the general emergency care steps for absorbed poisons (a) to the skin; (b) to the eye.
11. Describe how you can determine whether a patient’s condition is alcohol or drug related.
12. Outline the special safety precautions you need to take for a drug or alcohol emergency.
13. List the six indicators that a drug or alcohol patient is a high priority for transport.
14. Explain why the signs and symptoms of alcohol- and drug-related emergencies vary so widely.
15. List the emergency care steps for an alcohol or drug emergency.

**CRITICAL THINKING**

You are summoned to a residential address for an unknown medical emergency at 1930 hours one cold winter evening. Upon your arrival, you are greeted by the fire and police departments as well as by a middle-aged man who states he is the son of the elderly man inside the home. The son says that he had not been able to reach his father by phone all yesterday or today and was afraid something happened to him. After finding the doors and windows locked, the son has given his permission for the fire and police department to use force in gaining entry into the residence. While you wait outside on the porch, the fire department personnel are first to enter with the police, but they both quickly retreat because of a strong smell of fumes inside the house.

The firefighters then don their self-contained breathing apparatus and reenter the house. Shortly thereafter, they emerge with an unresponsive elderly male who is wearing pajama bottoms but no shirt. The firefighters report that there was a kerosene heater in the living room and all the burners on the gas stove top and oven were ignited to help heat the downstairs. The son tells you that his father told him a week earlier that his furnace had stopped working and he had to wait until his Social Security check arrived to hire a repairman. You conclude that the patient succumbed to the noxious fumes of the burning gas and kerosene as well as any carbon monoxide that may be present.

The patient responds to painful stimuli with nonpurposeful motion. His pupils are dilated, the airway is patent, breathing is shallow at 38 times per minute, and the peripheral pulses are weak. Blood pressure is 102/88, the pulse oximeter reads 94%, lungs are clear, and the skin is ashen in color. The son is unclear as to what the medical history or medications are for his father, so the fire department is going to reenter the home in an attempt to find any medication or other clues to his history.

1. Why was it a good idea to allow the fire department to access the home first?
2. What is the underlying mechanism for poisoning in this patient?
3. What is the single greatest intervention you could provide for this patient?
4. Given this type of poisoning, why is the pulse oximeter of little use?
5. What would be the basic tenets of care the patient should receive?
Chapter 23
Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • Medicine (Content Areas: Abdominal and Gastrointestinal Disorders; Gynecology; Genitourinary/Renal)

COMPETENCY • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES • After reading this chapter, you should be able to:

23-1. Define key terms introduced in this chapter.
23-2. Describe the anatomy and physiology of the structures of the abdominal cavity, including:
   a. Boundaries of the abdominal cavity
   b. Visceral and parietal peritoneum
   c. Intra- and retroperitoneal organs
   d. Relationship between the topographic anatomy of the four abdominal quadrants and nine abdominal regions to the location of the organs corresponding to them
23-3. Compare and contrast the general characteristics of hollow and solid organs and vascular structures found in the abdominal cavity.
23-4. List the general mechanisms and types of abdominal pain.
23-5. Describe the pathophysiology and the signs and symptoms associated with common causes of acute abdomen, including:
   a. Peritonitis
   b. Appendicitis
   c. Pancreatitis
   d. Cholecystitis
   e. Gastrointestinal bleeding
   f. Esophageal varices
   g. Gastroenteritis
   h. Ulcers
   i. Intestinal obstruction
   j. Hernia
   k. Abdominal aortic aneurysm
23-6. Describe the pathophysiology and the signs and symptoms associated with hematologic emergencies, including:
   a. Anemia
   b. Sickle cell anemia/sickle cell crisis
   c. Hemophilia
   d. Sickle cell
   e. Hemophilia
   f. AIDS
23-7. Explain the assessment-based approach to acute abdomen, including assessment and appropriate medical care.
23-8. Describe the basic anatomy and physiology of the female reproductive system.
23-9. Describe the pathophysiology and the signs and symptoms associated with common gynecologic conditions, including:
   a. Sexual assault
   b. Nontraumatic vaginal bleeding
   c. Menstrual pain
   d. Ovarian cyst
   e. Endometritis
   f. Endometriosis
   g. Pelvic inflammatory disease
   h. Sexually transmitted diseases
23-10. Explain the assessment-based approach to acute gynecologic emergencies, including assessment and appropriate medical care.
23-11. Describe genitourinary/renal structures and functions.
23-12. Describe the pathophysiology and the signs and symptoms associated with common genitourinary/renal conditions, including:
   a. Urinary tract infection
   b. Kidney stones
   c. Kidney failure
   d. Renal failure
   e. Renal tubular acidosis
23-13. Describe the purpose of dialysis, how dialysis works, and dialysis emergency management.
23-14. Describe the purposes and types of urinary catheters and urinary catheter management.
23-15. Explain the assessment-based approach to genitourinary/renal emergencies, including assessment and appropriate medical care.
**Abdominal Structures and Functions**

The abdomen, or **abdominal cavity**, is located below the diaphragm and extends to the top of the pelvis. The abdominal cavity is lined with the **peritoneum**. Like the thoracic pleura, the abdominal peritoneum has two layers: the **visceral peritoneum** and the **parietal peritoneum**. The visceral peritoneum is the innermost layer and is in contact with the abdominal organs, whereas the parietal peritoneum is the outer layer. The two layers are separated by a space that contains serous fluid that acts as a lubricant.

The abdominal cavity contains many vital organs (Figure 23-1 ■). The majority of the abdominal organs—including the stomach, spleen, liver, gallbladder, pancreas, small intestine, and part of the large intestine—are enclosed by the visceral peritoneum. Hence they are termed **intraperitoneal**. However, some organs or portions of organs are located behind the peritoneal space. This area is referred to as the **retroperitoneal space**. The kidneys, ureters, pancreas, and **abdominal aorta** are located in the retroperitoneal space.

---

**Case Study**

**The Dispatch**

Medic 58—respond to 323 Leslie Place, a single-family dwelling, for a 16-year-old male complaining of “stomach” pain—time out is 0945 hours.

**Upon Arrival**

Upon arrival at the address you notice a well-kept, single-floor ranch house. There are no apparent safety hazards or signs of trauma. You knock on the door and are greeted by a woman who states, “It’s my son, Parker. He’s had a fever for the last couple of days. I thought it was the flu or something. But this morning he woke up with a bad pain in his stomach.”

**How would you proceed with this patient?**

This chapter will describe the assessment and emergency medical care for the patient suffering from acute abdominal pain. Later we will return to this case and apply what you have learned.

---

**INTRODUCTION**

Acute abdominopelvic pain is an emergency you are sure to encounter during your EMS career. It can have any number of causes and may often signal a very serious medical condition. No matter what the cause, in all cases of abdominopelvic pain it is important to assess for life-threatening conditions, make the patient as comfortable as possible, administer oxygen, and get the patient to the hospital quickly.

**ACUTE ABDOMEN**

Acute abdominal pain, sometimes called **acute abdomen**, or **acute abdominal distress**, is a common condition. It may be severe, and it can have any number of causes. Some causes of acute abdominal pain are obvious, but most causes are not that apparent. Medical texts cite approximately 100 different causes of abdominal pain. Acute abdominal pain may arise from the cardiac, pulmonary, gastrointestinal, hematologic, genital, urinary, reproductive, or other body systems.
Chapter 23 • Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies

Most vital organs of the body, such as the heart, lungs, and brain, are contained within body cavities that are protected by bones. However, just the upper portion of the abdomen is protected by the lower rib cage, while the remainder of the abdomen is protected only by the muscular layer of the abdominal cavity. When looking at mechanisms of injury, it is easy to see why injuries to the abdomen can be very serious. Trauma to the abdomen is discussed in Chapter 34, “Chest Trauma.”

Abdominal Quadrants and Regions

Because you can’t use bones as reference points when assessing the abdomen, it is helpful to reference the abdomen by dividing it into quarters, or quadrants, using the navel, or umbilicus, as the central reference point (Figure 23-2a). In naming the quadrants, right and left are the patient’s right and left.

- **Left upper quadrant (LUQ).** Contains most of the stomach, the spleen, the pancreas, and part of the large intestine. The left kidney is behind the abdominal lining.
- **Right upper quadrant (RUQ).** Contains most of the liver, the gallbladder, and part of the large intestine. The right kidney is behind the abdominal lining.
- **Right lower quadrant (RLQ).** Contains the appendix (a worm-shaped structure extending from the beginning of the large intestine), part of the large intestine, and the female reproductive organs.
- **Left lower quadrant (LLQ).** Contains part of the large intestine and the female reproductive organs.

Another way to describe the abdomen is by using a system of nine regions. This is done by drawing four imaginary lines, much akin to a tic-tac-toe board, on the abdomen with the umbilicus in the center of the middle box (Figure 23-2b). The regions are (from the patient’s right to left, from the top row down):

- Right hypochondriac, epigastric, left hypochondriac
- Right lumbar, umbilical, left lumbar
- Right iliac, hypogastric, left iliac

Types of Abdominal Structures

The abdominal cavity contains three types of structures: hollow organs, solid organs, and vascular structures (Table 23-1). Hollow organs contain some type of substance that may leak into the abdominal cavity if the organ is perforated or injured. When a hollow organ is perforated or injured, any substance that leaks into the abdominal cavity may lead to chemical or bacterial peritonitis. Hollow organs typically do not have the same amount of blood supply as solid organs; therefore, they tend not to bleed as much as solid organs.

Solid organs are very vascular (contain a large amount of vessels and blood). Some are covered by a thick fibrous capsule (liver and spleen). When a solid organ is ruptured or injured, it tends to bleed, potentially leading to severe shock.

Vascular structures are the large blood vessels found in the abdominal cavity. Portions of the descending aorta and the inferior vena cava are located in the abdominal cavity. Rupture or injury to either vessel will result in major bleeding, rapid blood loss, and death.

The function of most of the organs contained in the abdomen has to do with digestion of food, absorption of nutrients into the body, and excretion of wastes. Table 23-2 provides a brief list of the organs and their functions. As an EMT, you should not focus on determining which organ or specific illness may be causing a patient’s abdominal pain. Your priority is to recognize potential life threats related to acute abdominal pain and provide appropriate emergency medical care.
The rapid distention of an organ will cause a rapid onset of abdominal pain. For example, a patient who is experiencing gas will have a sudden onset of abdominal pain caused by the distention of the intestine. Once the gas is dissipated, the organ is no longer stretched and the pain is eliminated. Therefore, rapid onset of abdominal pain is usually a red flag indicating an acute onset of an abdominal disorder. If the distention of the organ is gradual, as in cirrhosis of the liver where the liver can distend to twice its size, the patient experiences little pain. Thus, pain would not be an early indicator of that condition.

Stretching of the peritoneum will also cause pain. This may be due to distention of an organ that tugs on the peritoneum, adhesions (scar tissue) from surgery or a previous injury, or forceful movement of the small intestine associated with a bowel obstruction. The exception to this is the pregnant patient in her third trimester (last 3 months) of pregnancy. The peritoneum is stretched so far that it is no longer sensitive to stretching. This could be dangerous in a pregnant patient experiencing a condition that would normally cause pain and alert the patient to a problem earlier. The abdominal organs in the pediatric patient are closer together than in an adult. Pain from stretching a solid organ is usually a steady type of pain. Inflammation of a hollow organ may irritate the lining of the walls of the organ, causing a crampy (colicky) type of pain. Pain associated with ischemia (hypoxia) to an abdominal organ will be steady and severe and will continue to worsen as the organ becomes more hypoxic.

### Types of Abdominal Pain

Abdominal pain can be classified as visceral pain, parietal (somatic) pain, or referred pain. The characteristic of pain varies depending on what organ is involved. **Visceral pain** occurs when the organ itself is involved. Most organs do not have a large number of...
Visceral pain is produced by ischemia, inflammation, infection, or mechanical obstruction of an organ.

Stimulation of visceral nerve fibers in an organ typically produces pain that is aching, dull, less severe, intermittent, and poorly localized.

Parietal pain, also called somatic pain, is associated with irritation of the peritoneal lining. Remember, the peritoneum has a larger amount of highly sensitized nerve endings. Thus, one would expect the pain to be more severe and more localized (easier to point to with one finger). Parietal pain is more localized, intense, usually found on one side or the other, sharp, and typically constant. You will typically find the patient lying supine with the knees flexed up toward the chest. This reduces the stretch of the abdominal muscles and puts less pressure on the peritoneum. The patient is usually lying still and breathing shallowly. When the patient breathes deeply, the diaphragm moves lower and pushes on the peritoneum and abdominal organs, causing more pain.

**PATHOPHYSIOLOGY PEARLS**

Parietal (somatic) pain is associated with irritation and inflammation of the peritoneal lining of the abdomen.

**ASSESSMENT TIPS**

Parietal (somatic) nerve fiber stimulation typically produces sharp, knifelike, intense, constant pain that is highly localized (can be pinpointed).

Referred pain is actually visceral pain (pain from the organ itself) that is felt elsewhere in the body. It is usually poorly localized but is felt consistently in the part of the body it is referred to. Referred pain occurs when organs share a nerve pathway with a skin sensory nerve. The brain becomes confused in the interpretation of the impulse and causes the patient to feel pain at a location that may be totally unrelated to the organ involved. As an example, a patient who is experiencing inflammation of the gallbladder (cholecystitis) will typically feel referred pain in his right shoulder and scapular (shoulder blade) area. See Figure 23-3.
Conditions That May Cause Acute Abdominal Pain

This section is an overview of some of the most common causes of acute abdominal pain or distress. (See Table 23-3.) Definitive care for almost all of these conditions is hospitalization and possibly surgical intervention. These conditions can result in life-threatening complications if left untreated. You should never spend extended time at the scene trying to determine the exact cause of acute abdominal pain.

Peritonitis

Irritation and inflammation of the peritoneum is called peritonitis. Peritonitis occurs when blood, pus, bacteria, or chemical substances leak into the peritoneal cavity. The onset and type of the abdominal pain a patient experiences is somewhat dependent on the type of substance leaking into the peritoneum. For example, the duodenum contains highly acidic digestive material that usually causes pain that is immediate, severe, sharp, intense, and constant. However, the ileum contains digestive material with a neutral pH (not acidic and not alkalotic). If the ileum is perforated, the material may leak out, but the pain may be delayed for several hours, may be intermittent, or may be not as severe because the material's pH is neutral. Because critical abdominal conditions may present in a variety of ways, it is important to maintain a high index of suspicion when dealing with an acute abdomen. The type or degree of pain often does not indicate the severity of the problem.

**PATHOPHYSIOLOGY PEARLS**

Abdominal contents that are acidic or alkaline that leak into the abdominal cavity and irritate the peritoneum will produce a sudden onset of severe, sharp, constant abdominal pain.

**TABLE 23-3 Some Conditions That May Cause an Acute Abdomen**

- Peritonitis
- Appendicitis
- Pancreatitis
- Cholecystitis
- Gastrointestinal bleeding
- Gastroenteritis
- Ulcerative diseases
- Intestinal obstruction
- Hernia
- Abdominal aortic aneurysm

**Common Signs and Symptoms of Peritonitis**

- Abdominal pain or tenderness
- Nausea, vomiting, or diarrhea
- Fever and chills
- Lack of appetite (anorexia)
- Positive Markle (heel drop or heel jar) test

**The Markle “Heel Drop” or “Heel Jar” Test.** An examination technique called “rebound tenderness” has been used to assess a patient with abdominal pain like that caused by peritonitis and appendicitis. The EMT would push slowly down on a quadrant of the abdomen to slightly compress the tissues beneath and then suddenly release the pressure. When the abdominal contents reassumed their original location, it would make the peritoneal surfaces rub together. If there was inflammation to the peritoneal linings, it would elicit pain in the patient. This technique, however, has fallen into disfavor because the patient with abdominal pain could be either over-obliging to the test or extremely frightened of someone pushing on his abdomen, and in either case fail to be objective.
Appendicitis

Appendicitis is an inflammation of the appendix that commonly causes an acute abdomen. Appendicitis is usually caused by a blockage in the intestines and results in inflammation and irritation. If left untreated, the inflammation may cause the tissue to die and rupture. This may result in abscess formation (local pus collection), peritonitis, or shock. Appendicitis is common in children because their appendix wall is thinner. This is also true for elderly patients who are prone to perforation. Definitive care for this condition is surgical intervention, ideally before rupture of the appendix contents into the peritoneal cavity.

Common Signs and Symptoms of Appendicitis

- Abdominal pain or cramping—Initially this may be dull, diffuse, and located around the umbilicus. Later this pain is usually localized to the right lower quadrant medial to the iliac crest (pelvic wing), also called the McBurney point.
- Nausea and vomiting
- Low-grade fever and chills
- Lack of appetite (anorexia)
- Abdominal guarding
- Positive Markle (heel drop or heel jar) test

Pancreatitis

Pancreatitis, or inflammation of the pancreas, may cause severe pain in the middle of the upper quadrants (epigastic area) of the abdomen. This abdominal pain sometimes radiates to the back. Pancreatitis may be triggered by a variety of causes including ingestion of alcohol, gallstones, or infection. Complications that may result from pancreatitis include abscesses, sepsis, hemorrhage, tissue death, hypoglycemia or hyperglycemia, and organ failure.

Common Signs and Symptoms of Pancreatitis

- Abdominal pain
- Nausea and vomiting
- Abdominal tenderness and distention
- Mild jaundice (depending on cause)
- Severe abdominal pain with radiation from the umbilicus (navel) to the back and shoulders
- Fever, rapid pulse, and signs of shock (in extreme cases)

Cholecystitis

Cholecystitis, or inflammation of the gallbladder, is commonly associated with the presence of gallstones. This condition is more common in women than men and frequently occurs between the ages of 30 and 50. It rarely occurs in children. In some cases of cholecystitis, the gallstones may actually block the opening of the gallbladder to the small intestine. This blockage causes an increase in pressure inside the gallbladder, which can cause severe pain. Definitive care for this condition is hospitalization and sometimes surgical intervention to remove the gallbladder, stones, or blockage. If left untreated, tissue death, perforation, or pancreatitis may occur.

Common Signs and Symptoms of Cholecystitis

- Sudden onset of abdominal pain located from the middle of the upper quadrants (epigastic area) to RUQ areas (Pain is present more commonly at night and associated with ingestion of fatty foods. Pain may also be referred to the right scapula.)
- Tenderness upon palpation of the RUQ
- Belching or heartburn
- Nausea and vomiting (contents may be greenish)

Gastrointestinal Bleeding

Gastrointestinal bleeding can occur anywhere within the gastrointestinal tract and can be attributed to numerous causes. Gastrointestinal bleeds are usually classified as upper or lower, based on the location of the bleeding. Upper gastrointestinal bleeds are frequently caused by peptic ulcers, gastric erosion, and varices. They are more prevalent in adult males. Lower gastrointestinal bleeds are frequently caused by diverticulosis and occur more in women. Gastrointestinal bleeding most commonly affects people in their 40s to 70s, but children and younger adults may experience it too. Most deaths resulting from gastrointestinal bleeding occur in patients over 60 years of age.
Common Signs and Symptoms of Gastrointestinal Bleeding

- Abdominal pain or tenderness
- Hematemesis (vomiting blood, which can be bright red or look like coffee grounds)
- Hematochezia (bright red blood in the stool normally signifying a rapid onset)
- Melena (dark tarry stools containing decomposing blood normally from the upper gastrointestinal system)
- Altered mental status, weakness, or syncope
- Tachycardia
- Signs of shock

Esophageal Varices

Esophageal varices are a bulging, engorgement, or weakening of the blood vessels in the lining of the lower part of the esophagus. These abnormalities are common to heavy alcohol drinkers or patients with liver disease and are caused by increased pressure in the venous blood supply system of the liver, stomach, and esophagus (Figures 23-4a and 23-4b). Esophageal varices are usually identified with painless bleeding in the digestive tract. Bleeding can be profuse, leading to shock. Emergency medical care is the same as for any other abdominal pain or distress; however, airway and breathing management may be more challenging.

Common Signs and Symptoms of Esophageal Varices

- Large amounts of bright red hematemesis (vomiting of blood)
- Absence of pain or tenderness in the abdomen
- Rapid pulse
- Breathing difficulty

- Pale, cool, clammy skin
- Other signs and symptoms of shock
- Jaundice (yellowing) of the skin or sclerae of the eyes from liver disease (may be seen in some cases) (Figure 23-5)

Gastroenteritis

Gastroenteritis, or inflammation of the stomach and small intestines, is commonly associated with the presence of abdominopelvic pain. This condition can be chronic or acute. Chronic gastroenteritis is most commonly a result of an infection. Acute gastroenteritis is normally caused by viruses and bacteria and is commonly diagnosed in children. If left untreated, it may result in the breakdown of the mucosal layers in the gastrointestinal tract. This breakdown can lead to

![Figure 23-4](a) Esophageal varices are common to heavy alcohol drinkers or patients with liver disease. (b) Endoscopic view of an esophageal varix. (© Dr. Bryan E. Bledsoe)

![Figure 23-5](Jaundiced sclera of the eyes from liver disease may be seen in some cases of esophageal varices. (© 2008 Vincent Zuber/Custom Medical Stock Photo, All Rights Reserved)
dehydration, hemorrhage, ulceration, and perforation. Hematemesis, hematochezia, or melena may be present in severe acute cases. In these severe cases, signs and symptoms of shock will be present.

**Common Signs and Symptoms of Gastroenteritis**
- Abdominal pain or cramping
- Nausea, vomiting, and diarrhea
- Abdominal tenderness
- Fever and dehydration
- In severe cases, signs and symptoms of shock and hemorrhage may be present

**Ulcers**

Approximately 4 million patients a year are affected by an ulcerative disease. Ulcers are open wounds or sores within the digestive tract, usually in the stomach or the beginning of the small intestine (Figures 23-6a and 23-6b). Ulcers are associated with a breakdown of the lining that normally protects the intestine from the digestive fluids contained inside the digestive tract. This breakdown can cause damage to the stomach or intestine and, in some instances, massive bleeding or perforation. This can result in hematemesis, hematochezia, or melena depending on the location and severity of the bleed. The type of abdominal pain is also affected by the location and severity of the ulcer. Patients with severe ulcerative disease can develop signs and symptoms of shock and signs of peritonitis from erosion through the stomach or duodenum that are life threatening. Most patients are usually aware of their ulcers and will provide you with this information during the history. In some cases, the patient will take over-the-counter antacids or prescribed medications for this condition.

**Common Signs and Symptoms of Ulcers**
- Sudden onset of abdominal pain normally in the LUQ and epigastric area, usually described as a burning- or gnawing-type pain before meals or during stressful events
- Nausea and vomiting
- Hematemesis, hematochezia, or melena or coffee-ground emesis in some cases
- Signs or symptoms of shock in cases of massive bleeding
- Peritonitis with a rigid abdomen in cases of perforation

**Intestinal Obstruction**

An intestinal obstruction is a blockage that interrupts the normal flow of the intestinal contents within the intestines. This condition can occur in both the small and the large intestines and can be either partial or complete.
Blockages occurring in the small intestine are usually the result of adhesions (a sticking together of the sides of the intestines), gallstones, or a hernia. Blockages of the large intestine are commonly caused by tumors, fecal impaction, or overloading. If left untreated, intestinal obstructions may lead to sepsis, perforation, intestinal infarction, and peritonitis. Patients over the age of 50 are at increased risk for having an intestinal obstruction. This condition is likely to reoccur in patients who have a history of a previous bowel obstruction.

**Common Signs and Symptoms of Intestinal Obstruction**

- Abdominal pain, moderate to severe, depending on location of obstruction—typically described as crampy and colicky
- Nausea and vomiting
- Constipation (difficulty in moving bowels)
- Abdominal distention and tenderness
- Abnormally prominent, high-pitched bowel sounds with auscultation in early stages (Bowel sounds may be diminished or absent in some later cases.)

**ASSESSMENT TIPS**

The patient with an intestinal obstruction may want to continue to walk and move, whereas the patient with peritonitis will want to lie very still and not be moved or touched.

**Hernia**

A hernia is a protrusion or thrusting forward of a portion of the intestine through an opening or weakness in the abdominal wall. Hernias are most commonly associated with increased pressure in the abdominal cavity during heavy lifting or straining, causing the peritoneum to be pushed into the weakness or opening. Others are caused by previous surgical incisions or at the umbilicus. Most hernias are not life threatening and can be easily treated. In some cases, however, they may become incarcerated or strangulated, causing the portion of the intestine to be pinched or cut off, producing obstruction.

**Common Signs and Symptoms of Hernia**

- Sudden onset of abdominal pain (usually after heavy lifting or straining)
- Fever
- Rapid pulse
- Tender mass at point of hernia
- Others similar to intestinal obstruction

**Abdominal Aortic Aneurysm**

An abdominal aortic aneurysm (AAA) is a weakened, ballooned, and enlarged area of the wall of the abdominal aorta. The aneurysm may eventually rupture (Figure 23-7a ■) and is one of the most lethal causes of abdominal pain. Although it can happen at any age, this condition, which generally results from atherosclerosis, is most common in men over the age of 60. Another condition involving the aorta is an aortic dissection or a dissecting aorta, which begins with a small tear of the inner vessel structure, which allows blood to leak between the walls of the aorta (Figure 23-7b ■). The process of dissection continues with increasing pressure until, finally, the outer wall is damaged and blood leaks out behind the peritoneum or into the abdominal cavity.

**Common Signs and Symptoms of AAA**

- Gradual onset of lower lumbar, groin, and abdominal pain
- Rupture associated with sudden onset of severe, constant abdominal pain. May radiate to lower back, flank, or pelvis. May be described as a “tearing” pain.
- Testicular pain in the male patient
- Possible nausea and vomiting
- Mottled or spotty abdominal skin
- Pale, cool, clammy, and possibly cyanotic skin in legs from decreased blood and perfusion
• Absent or decreased femoral or pedal pulses
• If the abdomen is soft, a pulsating abdominal mass may be felt. If the aneurysm has burst, the abdomen will be rigid and tender.
• If the aortic aneurysm is starting to rupture, the skin below the waistline may become cyanotic, cold, and mottled. This is from a significant drop in blood flow to the extremities.

If you suspect a patient has an abdominal aortic aneurysm, palpate the abdomen very gently. Pressure or excessive movement may aggravate the aneurysm, causing it to leak or rupture. Assessment for shock is crucial. Transport without delay. If the rupture is in the process of occurring, this is a true emergency.

**Vomiting/Diarrhea/Constipation**

Vomiting, constipation, and diarrhea are symptoms of many of the conditions previously discussed. In themselves, diarrhea, vomiting, and constipation are rarely medical emergencies but can cause abdominal pain in pediatric and adult patients. The EMT should be concerned when the vomiting or diarrhea has persisted for days (or hours in the case of vomiting) and the patient has become dehydrated. The vomiting mechanism in children is still not fully understood, but the pediatric patient can decompensate very quickly with fluid loss. Infants or children who continue to vomit over a period of 1 day and adults who continue to vomit for several days may lose significant fluid volume and develop an electrolyte imbalance that is serious enough to cause shock, cardiac dysrhythmias, or other conditions.

**Assessment-Based Approach:**

**Acute Abdomen**

As previously stated, it is not important that you try to isolate the exact cause of abdominal pain or distress in the prehospital setting. Rather, you should correctly assess and identify that the patient is suffering abdominal pain and provide suitable emergency medical care based on that symptom.

All patients with abdominal pain should be considered to have a life-threatening condition until proven otherwise. Associated signs of low blood pressure, syncope (fainting), or pale, cool, and clammy skin, coinciding with abdominal pain, are considered very serious and high priority.

Severe abdominal pain is not only very distressing to the patient; it needs to be treated as an emergency. This is especially true if the pain lasts for 6 hours or longer, regardless of its intensity.

**Scene Size-up**

Begin by looking out for any potential threats to you, the patient, or other personnel. As you approach the scene, make sure you take Standard Precautions. Use face and eye protection if the patient is vomiting and splash or splatter is anticipated.

Look for any mechanism of injury to rule out trauma as the cause of the abdominal distress. Be alert to any talk or evidence of knives, guns, or other items that could cause penetrating wounds to the abdomen. Also be alert to signs of blunt trauma to the abdomen—for example, any mechanism of injury indicating a fall or auto collision.

Use all your senses to size up the scene. For instance, certain types of bleeding from gastrointestinal causes will have a distinct smell and can be determined as you arrive on the scene. Location of patients may offer clues to their condition. Many EMTs have found that patients who are experiencing abdominal bleeding may faint, and many do so in the bathroom. If you find the patient in the bathroom, you might begin to suspect gastrointestinal bleeding. Look for waste baskets or garbage cans used to catch emesis near the location of the patient. Make sure you note the color and quantity of any vomitus you may see. Remember that blood that has been present in the stomach for any time looks more like coffee grounds than frank blood.

Look for over-the-counter medications that may have been used to help alleviate abdominal pain before you arrived.

**Primary Assessment**

As you approach the patient, form a general impression. Stabilize the spine if injury is suspected. A person with an acute abdomen generally appears very ill and will assume a **guarded position** with his knees drawn up and his hands clenched over his abdomen (Figure 23-8). Start by ensuring that the patient has a patent airway with adequate breathing. Be alert for vomiting and possible aspiration and suction if needed. Apply high-concentration oxygen therapy and assist the patient’s ventilations if they are absent or decreased femoral or pedal pulses.

If the abdomen is soft, a pulsating abdominal mass may be felt. If the aneurysm has burst, the abdomen will be rigid and tender.

If the aortic aneurysm is starting to rupture, the skin below the waistline may become cyanotic, cold, and mottled. This is from a significant drop in blood flow to the extremities.

If you suspect a patient has an abdominal aortic aneurysm, palpate the abdomen very gently. Pressure or excessive movement may aggravate the aneurysm, causing it to leak or rupture. Assessment for shock is crucial. Transport without delay. If the rupture is in the process of occurring, this is a true emergency.

**Vomiting/Diarrhea/Constipation**

Vomiting, constipation, and diarrhea are symptoms of many of the conditions previously discussed. In themselves, diarrhea, vomiting, and constipation are rarely medical emergencies but can cause abdominal pain in pediatric and adult patients. The EMT should be concerned when the vomiting or diarrhea has persisted for days (or hours in the case of vomiting) and the patient has become dehydrated. The vomiting mechanism in children is still not fully understood, but the pediatric patient can decompensate very quickly with fluid loss. Infants or children who continue to vomit over a period of 1 day and adults who continue to vomit for several days may lose significant fluid volume and develop an electrolyte imbalance that is serious enough to cause shock, cardiac dysrhythmias, or other conditions.

**Assessment-Based Approach:**

**Acute Abdomen**

As previously stated, it is not important that you try to isolate the exact cause of abdominal pain or distress in the prehospital setting. Rather, you should correctly assess and identify that the patient is suffering abdominal pain and provide suitable emergency medical care based on that symptom.

All patients with abdominal pain should be considered to have a life-threatening condition until proven otherwise. Associated signs of low blood pressure, syncope (fainting), or pale, cool, and clammy skin, coinciding with abdominal pain, are considered very serious and high priority.

Severe abdominal pain is not only very distressing to the patient; it needs to be treated as an emergency. This is especially true if the pain lasts for 6 hours or longer, regardless of its intensity.

**Scene Size-up**

Begin by looking out for any potential threats to you, the patient, or other personnel. As you approach the scene, make sure you take Standard Precautions. Use face and eye protection if the patient is vomiting and splash or splatter is anticipated.

Look for any mechanism of injury to rule out trauma as the cause of the abdominal distress. Be alert to any talk or evidence of knives, guns, or other items that could cause penetrating wounds to the abdomen. Also be alert to signs of blunt trauma to the abdomen—for example, any mechanism of injury indicating a fall or auto collision.

Use all your senses to size up the scene. For instance, certain types of bleeding from gastrointestinal causes will have a distinct smell and can be determined as you arrive on the scene. Location of patients may offer clues to their condition. Many EMTs have found that patients who are experiencing abdominal bleeding may faint, and many do so in the bathroom. If you find the patient in the bathroom, you might begin to suspect gastrointestinal bleeding. Look for waste baskets or garbage cans used to catch emesis near the location of the patient. Make sure you note the color and quantity of any vomitus you may see. Remember that blood that has been present in the stomach for any time looks more like coffee grounds than frank blood.

Look for over-the-counter medications that may have been used to help alleviate abdominal pain before you arrived.

**Primary Assessment**

As you approach the patient, form a general impression. Stabilize the spine if injury is suspected. A person with an acute abdomen generally appears very ill and will assume a **guarded position** with his knees drawn up and his hands clenched over his abdomen (Figure 23-8). Start by ensuring that the patient has a patent airway with adequate breathing. Be alert for vomiting and possible aspiration and suction if needed. Apply high-concentration oxygen therapy and assist the patient’s ventilations if they are absent or decreased femoral or pedal pulses.

If the abdomen is soft, a pulsating abdominal mass may be felt. If the aneurysm has burst, the abdomen will be rigid and tender.

If the aortic aneurysm is starting to rupture, the skin below the waistline may become cyanotic, cold, and mottled. This is from a significant drop in blood flow to the extremities.

If you suspect a patient has an abdominal aortic aneurysm, palpate the abdomen very gently. Pressure or excessive movement may aggravate the aneurysm, causing it to leak or rupture. Assessment for shock is crucial. Transport without delay. If the rupture is in the process of occurring, this is a true emergency.

**Vomiting/Diarrhea/Constipation**

Vomiting, constipation, and diarrhea are symptoms of many of the conditions previously discussed. In themselves, diarrhea, vomiting, and constipation are rarely medical emergencies but can cause abdominal pain in pediatric and adult patients. The EMT should be concerned when the vomiting or diarrhea has persisted for days (or hours in the case of vomiting) and the patient has become dehydrated. The vomiting mechanism in children is still not fully understood, but the pediatric patient can decompensate very quickly with fluid loss. Infants or children who continue to vomit over a period of 1 day and adults who continue to vomit for several days may lose significant fluid volume and develop an electrolyte imbalance that is serious enough to cause shock, cardiac dysrhythmias, or other conditions.

**Assessment-Based Approach:**

**Acute Abdomen**

As previously stated, it is not important that you try to isolate the exact cause of abdominal pain or distress in the prehospital setting. Rather, you should correctly assess and identify that the patient is suffering abdominal pain and provide suitable emergency medical care based on that symptom.

All patients with abdominal pain should be considered to have a life-threatening condition until proven otherwise. Associated signs of low blood pressure, syncope (fainting), or pale, cool, and clammy skin, coinciding with abdominal pain, are considered very serious and high priority.

Severe abdominal pain is not only very distressing to the patient; it needs to be treated as an emergency. This is especially true if the pain lasts for 6 hours or longer, regardless of its intensity.

**Scene Size-up**

Begin by looking out for any potential threats to you, the patient, or other personnel. As you approach the
inadequate. Assess circulation by checking the pulse for rate and regularity; checking for obvious or major bleeding; and noting skin color, temperature, and condition.

Look for signs of shock (hypoperfusion): rapid, thready pulse; restlessness; cool, clammy skin; and as a late sign, falling blood pressure. Internal bleeding, peritonitis, and excessive vomiting or diarrhea often lead to considerable fluid loss or shock.

Shock is only one indicator that this is a serious medical emergency. The patient with an acute abdomen should be categorized as a priority for transport if he meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Shock (hypoperfusion)
- Severe pain

Secondary Assessment

In any of the circumstances just discussed, immediately begin transport following the secondary assessment. If the patient is responsive, first conduct the history. If the patient is unresponsive, conduct the history after the physical exam and vitals, gathering information from the family or bystanders. If more than one EMT is on the scene, the physical exam can be conducted and baseline vital signs can be obtained by one EMT while the other EMT collects the history.

History. The following are pertinent questions to ask.

- Ask the OPQRST questions (onset, provocation/palliation, quality, radiation, severity, time) to get a full description of the pain, from the pain’s onset and what provokes it to its severity and duration or what, if anything, makes it better. When questioning the patient about onset, note if it was sudden and abrupt. If so, it’s likely that the patient has a serious medical emergency.
- Does the patient have any known allergies to medications, food, or other substances? Is there any medical alert identification tag or information present?
- Is the patient currently taking any medications, either over-the-counter or physician prescribed? If so, when was the last time the medications were taken?
- Does the patient have any pertinent past medical history regarding the abdominal pain or distress? Has this ever happened to the patient prior to this event and has the patient ever been hospitalized for the same type of abdominal pain? Has the patient had any abdominal surgeries or trauma? Has the patient seen his physician for this pain?
- When was the last time the patient had anything to eat or drink? Did the patient ingest large quantities of alcohol or eat very spicy or fatty food? Ask if anyone sharing a meal with the patient is also experiencing abdominal pain.
- Has the patient’s appetite changed? Is he anorexic? Has there been any weight loss?
- Has the patient been nauseated? Ask if he has experienced belching or flatulence. Has he had a fever?
- Did the patient vomit, and if so, what was the color and appearance of the vomitus? Ask if vomitus looked like coffee grounds (contains partially digested blood), or if it contained undigested red blood, which indicates a bleeding in the upper gastrointestinal tract. Ask how many times the vomiting has occurred.
- What was the color of the patient’s last stools? Dark and tarry stools or bright red stools are indicators of gastrointestinal bleeding. Ask how many bowel movements the patient has had. Ask if he has had a change in bowel habits. Ask if he has been constipated or if he has had diarrhea. If he has, ask for its time of onset and frequency.
- Has the patient had difficulty urinating? Ask if he has had pain or any changes in the color, frequency, or odor of the urine.
- Was the patient doing anything prior to the onset that led to the abdominal pain or distress? Any heavy lifting? Was the patient at rest? Is the patient having any concurrent chest pain?

Physical Exam. The physical exam will focus on the abdomen. However, you should still assess the rest of the body for associated signs and symptoms. Remember that some abdominal complaints can be associated with cardiac or pulmonary conditions, especially in diabetics, women, and geriatric patients. Other systems can also cause abdominal pain. Perfusion should be assessed in all four extremities.

Perform the physical examination of the abdomen carefully and gently, since the abdomen may be tender. Even the slightest palpation may further aggravate existing pain and make the patient less willing to allow you to examine him. Begin by inspecting the abdomen. Look for any scars indicating previous surgeries. When beginning the exam always ask the patient to point to the area that is the most painful and then palpate each quadrant (Figure 23-9 ■), beginning with the area of the abdomen that is the least painful and farthest from the site of pain.

- Determine if the patient is restless or quiet and whether pain is increased upon movement.
- Inspect the abdomen to determine if it is distended (enlarged). Ask the patient if this is normal.
- Gently palpate the abdomen using the quadrants as landmarks. Start with the least painful area first and examine the quadrant with specific pain last.
- Assess if the abdomen feels soft or rigid. Normally, the abdomen should be soft and nontender. If the abdomen is rigid, determine if the patient can relax the abdominal muscles upon request. Note any involuntary guarding, an abdominal wall muscle contraction that the patient cannot control, resulting from inflammation of the peritoneum. Involuntary guarding is also referred to as rigidity. In contrast, voluntary guarding is when the patient contracts the abdominal muscles, usually in anticipation of pain or...
an unpleasant sensation. Clinically it is important to recognize the contracted abdominal muscles (guarding or rigidity) and proceed as if an acute abdomen is suspected.

**PATHOPHYSIOLOGY PEARLS**

Rigidity is an involuntary reflex that causes the abdominal muscles to contract and produce a rigid (boardlike) abdomen. The patient has no control over the muscle contraction. Abdominal guarding is when the patient voluntarily contracts his abdominal muscles. He may relax the muscles after your examination of the abdomen.

• Assess if the abdomen is tender or nontender when touched.
• When palpating the abdomen, note any masses that may be present. Are they pulsating?
• Ask the patient if he has any pain in other body areas.
• Document the quadrant in which any pain is located.

Obtain and document the patient’s baseline vitals. Expect to find an increased respiratory rate and shallow breathing in patients with acute abdominal pain. Pay attention to blood pressure and heart rate. Decreased blood pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

**Signs and Symptoms.** The following signs and symptoms may be associated with acute abdominal pain:

• Pain or tenderness—Can be diffuse (widespread) or localized; pain can also be crampy, sharp, aching, or knifelike.
• Anxiety and fear—Very often the patient is anxious and does not want to move for fear of aggravating or creating unbearable pain.
• Position—A patient will draw the feet up to the abdomen (guarded position) while lying on the side in order to relax the abdominal muscles. However, some patients may move about, attempting to find comfort.
• Rapid and shallow breathing—Usually to reduce movement of the diaphragm, which causes more pain.
• Rapid pulse—May be from pain or shock
• Blood pressure changes—Sometimes elevated in severe pain but may be low as a late sign of shock
• Nausea, vomiting, and/or diarrhea—Is it excessive?
• Rigid abdomen or guarding—Can this be relaxed upon command?
• Distended abdomen
• Fever or chills
• Belching or flatulence
• Changes in bowel habits or urination—note the frequency, color, odor, and if they have associated pain
• Other signs and symptoms associated with shock
• Signs of internal bleeding—vomiting blood (hematemesis or like coffee grounds), blood in the stool (bright red or dark and tarry; also very distinct smell)

**PATHOPHYSIOLOGY PEARLS**

Severe abdominal pain activates the sympathetic nervous system. This causes an increase in heart rate, respiratory rate, and blood pressure and may cause the skin to become pale, cool, and clammy. These responses can be mistakenly interpreted as indications of hypovolemia.

**ASSESSMENT TIPS**

When assessing blood pressure in the abdominal pain patient, consider the pulse pressure (difference between the systolic and diastolic blood pressure). If it is narrow—along with tachycardia, and pale, cool, clammy skin—it can be a sign of internal bleeding. Inspect inside the mouth of the patient complaining of acute abdominal pain. Pale oral mucosa may indicate the patient has been bleeding over a long period of time.

In infants and children, suspect an acute abdominal emergency if tenderness or guarding upon palpation is present. Do not waste time with extensive exams or palpation prior to initiating transport. Excessive palpation can worsen the pain and aggravate the cause of the abdominal pain or distress.
Emergency Medical Care

Follow these emergency care steps:

1. Keep the airway patent. Always be alert for vomiting and the potential for aspiration. It may be necessary to place the patient in the left lateral recumbent position to protect the airway. Be prepared to suction.

2. Place the patient in the position of comfort. If the patient is vomiting or has an altered mental status, place him in a lateral recumbent position.

3. If breathing is adequate, maintain oxygenation. If the SpO2 is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO2 is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

4. NEVER GIVE ANYTHING BY MOUTH.

5. Calm and reassure the patient. Provide emotional support.

6. If signs and symptoms of hypoperfusion are present, treat for shock. (See Chapter 15, “Shock and Resuscitation.”)

7. Initiate a quick and efficient transport. Consider ALS intercept based on your protocols.

Reassessment

Perform reassessment during transport. Document and record all vital signs. Communicate all findings to the receiving facility.

Summary: Assessment and Care

To review assessment findings that may be associated with acute abdominal pain and emergency care for acute abdominal pain, see Figures 23-10 and 23-11.

HEMATOLOGIC EMERGENCIES

The Nature of Hematologic Emergencies

Hematologic emergencies involve the blood and its components. There are some hematologic disorders that you might encounter more frequently in the prehospital environment. Three common hematologic conditions that you may encounter in the prehospital environment are anemia, sickle cell disease, and hemophilia.

Anemia

Anemia is basically a reduction of the number of red blood cells in the circulating blood volume. It is unlikely that a patient will call EMS for anemia unless it is the result of acute blood loss; however, the anemia may worsen other conditions the patient is experiencing.

Acute anemia may result from a sudden decrease in red blood cells resulting from a source of bleeding. Chronic anemia results from a slow source of blood loss, such as a gastrointestinal bleed, lack of production or maturity of red blood cells, or issues with the structure of the hemoglobin on the surface of the red blood cell. The patient with chronic anemia often appears pale, fatigues easily, and experiences shortness of breath on exertion. In both acute and chronic anemia, the lack of the availability of red blood cells and hemoglobin to carry oxygen in the blood leads to a faster onset of hypoxia. However, because the hemoglobin is not available to change the color of the skin, cyanosis is often a very late sign of hypoxia associated with anemia.

Sickle Cell Anemia

Sickle cell anemia is a hereditary blood disorder most often affecting African Americans and black Africans but also those of Mediterranean, South and Central American, Caribbean, and Middle Eastern origin.

In sickle cell anemia, some red blood cells have abnormal hemoglobin that does not carry adequate oxygen. As a result, the cells take on a crescent (sickle) shape and become fragile, stiff, and rigid. The sickled cells begin to stack up, blocking capillary blood flow. Cells and tissues become ischemic and may die. Patients with this disease often suffer infections from damaged red blood cells blocking the spleen.

Sickle Cell Crisis. Almost all patients with sickle cell disease suffer painful episodes known as sickle cell crisis. There are four common patterns of acute sickle cell crisis:

- **Bone crisis** typically involves the large long bones in the arm (humerus) and leg (femur and tibia), causing sudden severe pain.

- **Acute chest syndrome** involves a sudden onset of chest pain, possibly with dyspnea, hypoxia, and cough, which may be nonproductive, or the patient may cough up blood. A low-grade fever may be present.

- **Abdominal crisis** causes sudden, constant abdominal pain that may be general or localized. There may or may not also be nausea, vomiting, and diarrhea.

- **Joint crisis** presents with an acute onset of one or more painful, stiff joints.
Assessment Summary

**ACUTE ABDOMINAL PAIN**

The following findings may be associated with acute abdominal pain.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Poisonous substances, especially corrosives
- Position of the patient, typically “guarded,” or lying very still with knees drawn up to chest
- Vomitus containing blood or displaying a coffee-ground appearance
- Dark, tarry stool or stool with blood in it
- Location, especially if the patient is found in the bathroom

**Primary Assessment**

**General Impression**
- Vomitus or secretions in mouth
- Patient appears ill

**Mental Status**
- Alert to altered mental status

**Airway**
- Vomitus may cause obstruction

**Breathing**
- Shallow and fast respirations

**Circulation**
- Heart rate is usually increased
- Skin color may be pale, cool, and clammy

**Status: Priority Patient**

**History and Secondary Assessment**

**History**
- Signs and symptoms:
  - Pain or tenderness to abdomen (crampy, sharp, aching, or knifelike)

**Emergency Care Protocol**

**ACUTE ABDOMINAL PAIN**

1. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. If breathing is adequate, administer oxygen to maintain an SpO₂ of ≥94%.
5. Place the patient in a position of comfort, usually with knees flexed. If the patient is vomiting, place in a left lateral recumbent position only if no spinal injury is suspected.
6. Transport according to the patient’s condition.
7. Perform a reassessment every 5 minutes.
Mechanism of injury present?
- Yes
  - Consider manual in-line stabilization
  - Assess mental status
    - Alert and able to obey commands
      - Consider oxygen administration
    - Altered
      - Airway open?
        - No
          - Suction if necessary
          - Head-tilt, chin-lift, or jaw-thrust maneuver
        - Yes
          - Oro- or nasopharyngeal airway
          - Assess breathing
          - Adequate
            - Administer oxygen
            - Assess circulation
            - Rapid secondary assessment
            - Lateral recumbent position (no spinal injury)
          - Inadequate
            - PPV with $O_2$
            - Transport
            - Reassessment

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

FIGURE 23-11 Emergency care algorithm: acute abdominal pain.
Other consequences may include pneumonia, joint infections, stroke, vision disturbances, and detached retina. Almost all sickle cell patients develop kidney damage. Infections occur at higher rates especially in the kidney, lung, bone, and central nervous system. Anemia may cause shortness of breath, light-headedness and fatigue. Men may have priapism (involuntary and constant erection).

**Common Signs and Symptoms of Sickle Cell Crisis.** Severe abdominal pain is a frequent complaint leading to EMS response. Other signs and symptoms include:

- Bone pain
- Joint pain
- Fever
- Chest pain
- Shortness of breath
- Fatigue
- Pale skin
- Tachycardia
- Jaundice (yellowed sclera and skin)
- Ulcers on the lower legs
- Excessive thirst
- Priapism
- Frequent urination
- Sudden blindness in one eye

**Emergency Care for Sickle Cell Crisis.** The emergency care is supportive. Ensure an adequate airway, ventilation, oxygenation, and circulation.

**Hemophilia**

Hemophilia is a blood disorder that affects clotting. When a person with hemophilia is injured, it takes longer for the bleeding to stop because clots are unable to form properly. Bleeding that would be considered minor for a nonhemophiliac, such as a nosebleed, is a major emergency for the hemophiliac. Normal bleeding control procedures should be applied to the hemophiliac; however, stopping the blood loss will be more difficult and your attempts to do so less effective.

**GYNECOLOGIC EMERGENCIES**

Gynecology is the branch of medicine that studies health of the female patient and her reproductive system. Female patients who experience gynecologic problems often complain of abdominal pain and vaginal bleeding or abnormal discharge. This pain, bleeding, or discharge may be attributed to various conditions that can be life threatening. Conditions causing abdominal pain in pregnant patients will be discussed in Chapter 37, “Obstetrics and Care of the Newborn.”

**Female Reproductive Structures and Functions**

The female reproductive system (Figure 23-12 ■) is composed of the external genitalia and internal organs and structures. The female external genitalia, also called the vulva, consist of vascular tissues called the perineum, mons pubis, labia, and clitoris. The vulva provides accessory functions to the internal organs that are used primarily for reproduction. The internal organs of the female reproductive system are the vagina, uterus, ovaries, and fallopian tubes. The vagina functions as the birth canal during childbirth, receives the penis during sexual intercourse, and serves as a passageway for menstrual flow. The ovaries are the primary sex glands located on each side of the uterus. They excrete hormones and develop and release eggs that are needed for reproduction. The fallopian tubes extend from near each of the ovaries to the uterus. Fertilization of the egg normally occurs here. The uterus is the pear-shaped muscular organ that provides an appropriate site for egg implantation and fetal development during pregnancy. The uterus is lined by the endometrium, which is sloughed off during menses, or the menstrual period.

**Gynecologic Conditions**

This section presents an overview of some of the most common gynecologic conditions that may cause abdominopelvic pain or bleeding. (See Table 23-4.) These conditions can have either medical or traumatic causes. Gynecologic conditions can result in life-threatening complications if left untreated. Remember that you should never spend extended time at the scene trying to determine the exact cause for acute abdominopelvic pain.

**Sexual Assault**

Sexual assault is an act of violence and a crime that is defined differently by each state. Most definitions include sexual intercourse or other sexual activities that are performed without consent. Anyone can be a victim of a sexual assault; however, women are victims more frequently than men. Most victims of sexual assaults
It is important to provide emergency care that addresses both the physical and the emotional needs of the patient. It is also very important that the victims of sexual assaults are evaluated at the hospital and that any evidence related to the crime is preserved to the extent possible. The following guidelines can be applied by the EMT when a sexual assault has occurred:

- Do not allow the patient to change clothes, bathe, comb, or clean any part of her body. If the clothing was changed, collect it, bag it separately, and take it with you.
- Do not cut through any holes or tears in the patient's clothing. Handle the clothing as little as possible.
- Do not touch or change anything at the crime scene unless it impedes emergency medical care.
- Do not clean wounds, if possible. Treat wounds as you would other soft tissue injuries.
- Do not examine the genital area unless there is a life-threatening hemorrhage. Minor bleeding can be absorbed by a pad. Make sure all bloody articles are collected and transported with the patient.

When caring for a patient who has been sexually assaulted, it is important to remain nonjudgmental and objective. Provide a safe environment for the patient. Always maintain patient confidentiality and ask only questions that are pertinent to assessment and emergency medical care. When interviewing the patient, it is not necessary to question her about the specific details of the crime, because your treatment will be based on your assessment findings and your patient's current presentation. Do not touch the patient without her consent or unnecessarily. Respect your patient's wishes and privacy. Obtain vitals and evaluate any other associated injuries that may have occurred. Document all findings objectively and accurately.
Vaginal Bleeding (Nontraumatic)

Vaginal bleeding in female patients may be caused by cancerous lesions, pelvic inflammatory disease, hormonal imbalances, spontaneous abortion (miscarriage), ectopic pregnancy, or labor. Vaginal bleeding in female patients occurs naturally with normal menstruation; however, the EMT should not assume any bleeding is occurring from menses. In girls age 10 or older, menarche, or the onset of menses, could be the cause of bleeding.

The most common cause of nontraumatic vaginal bleeding other than menses is a spontaneous abortion or miscarriage. Women of childbearing age, of course, are most at risk for a spontaneous abortion. However, menopausal women can also become pregnant and experience spontaneous abortions. More than 20 percent of women who are less than 20 weeks pregnant will have vaginal bleeding. More than 50 percent of these pregnant women with vaginal bleeding will be having or have had a spontaneous abortion. Regardless of the cause, vaginal hemorrhage can be life threatening and should be treated as such.

Common Signs and Symptoms of a Spontaneous Abortion

- Lower abdominal or pelvic pain
- Abdominal tenderness
- Vaginal bleeding
- Rapid pulse
- Signs and symptoms of shock

Menstrual Pain

When the endometrial lining of the uterus is sloughed off during menses, it can be accompanied by strong uterine cramps that cause the severe pain during menstruation called dysmenorrhea. Dysmenorrhea is normally caused by hormonal imbalances or other gynecologic conditions. Occasionally, a patient may experience abdominopelvic pain in the middle of her menstrual cycle. This pain is called mittelschmerz (German for “middle pain”). It is caused by irritation of the peritoneum by the small amount of bleeding associated with the rupture of ovarian tissue that occurs with release of the mature ovum. Remember that abdominopelvic pain, regardless of the cause, should be treated as an emergency.

Ovarian Cyst

An ovarian cyst is a fluid-filled sac that forms inside or on an ovary. It is formed during ovulation when a follicle containing the egg fails to open as it is supposed to. Ovarian cysts can cause abdominopelvic pain if they rupture, twist, or break open and leak their contents into the abdomen; however, most ovarian cysts are asymptomatic (have no symptoms).

Common Signs and Symptoms of an Ovarian Cyst

- Unilateral abdominopelvic pain that may radiate to the back
- Abdominal tenderness
- Vaginal bleeding that may be irregular or abnormal
- Pain during sexual intercourse or bowel movements

Endometritis

Endometritis is an inflammation of the endometrium. It is most commonly caused by an infection; however, it may also occur from childbirth, abortions, gynecologic procedures, or intrauterine devices. If left untreated, endometritis may lead to peritonitis, abscess formation, septicemia, shock, and infertility.

Common Signs and Symptoms of Endometritis

- Abdominopelvic pain or tenderness
- Fever
- Abdominal distention
- Vaginal bleeding or discharge
- Discomfort during a bowel movement

Endometriosis

Endometriosis is a condition in which endometrial tissue grows outside the uterus. The most common sites for endometrial tissue implantation are the abdomen and pelvis, but the tissue can be implanted anywhere in the body. This endometrial tissue can bleed into the surrounding area and may result in inflammation, scarring, pain, and adhesions. Endometriosis is most commonly diagnosed in women who are 25 to 35 years of age.

Common Signs and Symptoms of Endometriosis

- Abdominopelvic pain or tenderness that may be dull or cramping
- Dysmenorrhea
- Vaginal bleeding
- Pain during sexual intercourse or a bowel movement

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infection of the female reproductive tract. Pelvic infections are caused by bacteria, fungi, or viruses. The majority of these infections are caused by the same bacteria that lead to sexually transmitted diseases. Approximately one million women will develop PID each year. Although this condition is spread most often during sex, it can also result from a gynecologic procedure, insertion of an intrauterine device, childbirth, or an abortion.
Risk factors associated with PID include sexual activity during adolescence, multiple sexual partners, unsafe sexual practices, a recent gynecologic procedure, insertion of an intrauterine device, and a history of sexually transmitted diseases or pelvic inflammatory disease. If left untreated, PID can lead to scarring, infertility, or sepsis (Figure 23-13 ■). Although some patients may be asymptomatic, most patients with PID will have abdominopelvic pain.

**Common Signs and Symptoms of Pelvic Inflammatory Disease**
- Abdominopelvic pain or tenderness
- Vaginal discharge with an abnormal color, consistency, or odor
- Fever and chills
- Anorexia
- Nausea or vomiting
- Irregular vaginal bleeding or cramping
- Pain during sexual intercourse

**Sexually Transmitted Diseases**
Sexually transmitted diseases (STDs) are infectious diseases that are transmitted through sexual contact. Over 300 million new cases of treatable STDs are diagnosed each year.

Most sexually transmitted diseases are caused by bacteria, viruses, parasites, or fungi. Chlamydia and gonorrhea are the most commonly reported STDs. Some of the most frequent sexually transmitted diseases and their causes are listed in Table 23-5. The treatment for an STD is normally based on the type of organism that causes the infection.

Patients most at risk for developing STDs are those who have multiple sexual partners, do not use condoms, or have had a history of previous STDs or PID.

Although most sexually transmitted diseases are asymptomatic in females, especially gonorrhea and chlamydia, some patients may complain of abdominopelvic pain and other symptoms. If left untreated, some STDs may lead to sepsis, infertility, abscesses, peritonitis, or other systemic illnesses. It is important to note that the patient and the patient’s sexual partners should receive treatment for these conditions.

**Common Signs and Symptoms of Sexually Transmitted Diseases**
- Abdominopelvic pain or tenderness
- Vaginal discharge with an abnormal color, consistency, or odor
- Fever and chills
- Nausea or vomiting
- Irregular vaginal bleeding or cramping
Assessment-Based Approach: Gynecologic Emergencies

Scene Size-up
Do a scene size-up and ensure that the scene is safe for you, your partner, and others. Make sure you take all Standard Precautions. Based on the dispatch information and a scan of the scene, determine if the patient has been injured or is suffering from a medical illness. Many gynecologic complaints are called in to dispatch as abdominopelvic pain or vaginal bleeding. If the call appears to be a crime scene, like that encountered from a sexual assault, make sure to call the proper authorities. As you approach the patient, inspect the scene for a mechanism of injury that would be significant enough to cause a possible spinal injury. If no mechanism of injury is apparent, you would then suspect that the gynecologic complaint is a result of medical illness. Remember that patients experiencing a gynecologic emergency may fall or suffer trauma separately from or as a result of their condition.

Primary Assessment
Form a general impression of your patient. If an injury is possible, stabilize the spine. Determine if the patient is alert and oriented or if she has an alteration in her mental status. Because some conditions can result in shock, it is possible for a patient with a gynecologic emergency to be unresponsive. Ensure that your patient has an open and clear airway and use a mechanical airway device if necessary. It may be necessary to suction the airway if vomitus or secretions are present. Determine if the rate, rhythm, and quality of the patient’s breathing are adequate.

If breathing is adequate, administer oxygen based on the SpO₂ reading and signs of hypoxia, poor perfusion, or respiratory distress. If breathing is inadequate, provide bag-valve-mask ventilations at 10–12 times a minute with supplemental high-concentration oxygen. Pay particular attention to the patient’s perfusion status. Internal and external bleeding that may occur in a gynecologic emergency can easily result in shock. Check the patient’s pulse and skin. Look for signs of shock. Identify any major bleeding. If the major bleeding is coming from the vagina, attempt to control the bleeding by placing a pad over the external genitalia to absorb the blood flow. Never pack the patient’s vagina.

ASSessment Tips
If the patient has vaginal bleeding, absorb the blood flow with pads and never pack the patient’s vagina.

Shock is only one indicator that this is a serious medical emergency. The patient with acute abdominal pain or vaginal bleeding as a result of a possible gynecologic emergency should be categorized as a priority for transport if she meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Severe pain
- Shock (hypoperfusion)

Secondary Assessment
Make sure you protect the patient’s privacy and modesty. It will be necessary to ask questions involving personal issues that some patients may be hesitant or embarrassed to answer. Be patient, compassionate, and professional when communicating with the patient. If the patient is responsive, your partner may take baseline vital signs as you begin gathering information and a history from her. If the patient is unresponsive, perform the physical exam first and then obtain a history and vitals.

History. During your history, ask the following questions:

- What are the signs and symptoms the patient is complaining of?
- Did the signs and symptoms seem to get progressively worse or better?
- How long has the patient been sick or suffering from these signs and symptoms?
- Was the onset of signs and symptoms gradual or sudden?
- What was the patient doing prior to the onset of the complaint?
- Does the patient have any known allergies to medications, food, or other substances?
- When did the patient last have something to eat or drink? What did she eat or drink?
- What medications, prescription and nonprescription, is the patient taking? Is she taking birth control pills or other contraceptives?
- What is the patient’s past medical history? When was the last time she has seen a doctor for her medical condition? Has she had any surgeries?
- When was the patient’s last menstrual period? Is her cycle regular?
- Does the patient have any vaginal bleeding? If so, how much and for how long? How many pads has she saturated?
- Is there a possibility that she is pregnant? (Note that this history may be unreliable.) Has she been pregnant before? If so, how many children does she have?
- Does she have any vaginal discharge? If so, what is the color, consistency, and odor like?
- Has the patient had any nausea or vomiting? If so, when and how much?
- Does the patient have any pain associated with urination, defecation, or sexual intercourse?
**ASSESSMENT TIPS**
Remember to take the blood pressure of a dialysis patient on the arm without the shunt or access site.

*Signs and Symptoms.* The signs and symptoms associated with a gynecologic emergency will vary depending on the cause. Abdominopelvic pain and vaginal bleeding are two of the most common signs and symptoms associated with a gynecologic emergency. Others include:

- Vaginal discharge with an abnormal color, consistency, or odor
- Abdominopelvic pain or tenderness
- Nausea and vomiting
- Fever or chills
- Syncope
- Irregular vaginal bleeding or cramping
- Pain during sexual intercourse, urination, or a bowel movement
- Irregular vaginal bleeding or cramping
- Vaginal pain
- Genital itching, redness, or swelling
- Signs of shock

*Physical Exam.* The physical exam will focus on the gynecologic complaint, which normally involves abdominopelvic pain or vaginal bleeding. However, you should still assess the rest of the body for associated signs and symptoms. You do not need to determine the exact cause of the abdominopelvic pain that may be from a gynecologic condition, but the pain may be from another system. Therefore, all systems should be assessed.

Perform the physical examination of the abdomen carefully and gently, since the abdomen may be tender. You should consider the possibility that the patient may be pregnant or may have a sexually transmitted disease. Be aware that even the slightest palpation may further aggravate existing pain and make the patient less willing to allow you to examine her.

Begin by inspecting and palpating the abdomen. Ask the patient to point to the area that is the most painful first and then palpate each of the other quadrants before that one. Determine if there is any vaginal bleeding, clots, or tissues. If there is vaginal bleeding, use a pad to absorb the blood and take any tissues with you to the hospital. Document the number of pads that the patient saturates. Obtain and document the patient’s baseline vitals. Pay attention to blood pressure and heart rate. Decreased blood pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

*Emergency Medical Care*

As previously stated, it is not important that you try to isolate the exact cause of abdominopelvic pain or vaginal bleeding relating to a gynecologic condition in the prehospital setting. Rather, you should correctly assess and identify the pain or bleeding and provide suitable emergency medical care based on the signs and symptoms.

1. **Maintain manual spinal stabilization** if trauma is suspected.
2. **Keep the airway patent.** Always be alert for vomiting and the potential for aspiration. It may be necessary to place the patient in the left lateral recumbent position to protect the airway. Be prepared to suction.
3. **Maintain adequate oxygenation.** If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is <94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.
4. **Control any major vaginal bleeding if present,** if not already started during your primary assessment. Use a pad to absorb the flow and do not pack the vagina.
5. **Place the patient in the position of comfort if no trauma is suspected.** If spinal stabilization is required, fully immobilize the patient on a backboard.
6. **Calm and reassure the patient.** Be supportive and nonjudgmental.
7. **Initiate a quick and efficient transport.** Consider ALS intercept based on your protocols.

*Reassessment*

Continuously monitor the patient for changes in her mental status, airway, breathing, and circulation. For a patient with an altered mental status or signs of shock, repeat the reassessment every 5 minutes. Record the vital signs and communicate your findings to the receiving medical facility.

**GENITOURINARY/RENAL EMERGENCIES**

*Urology* is the branch of medicine that studies the urinary system in females and the genitourinary system in males. The organs of the female reproductive system are separate from those in the female urinary system; however, in males, some of the structures are shared. Because of this, the term genitourinary system is referred to in males. Patients with genitourinary or renal conditions frequently experience abdominopelvic pain.

**Genitourinary/Renal Structures and Functions**

The urinary system is composed of the kidneys, ureters, urinary bladder, and urethra (Figures 23-14, 23-15a, and Functions.
The first part of the male’s urethra. The penis is the male organ used for sexual intercourse and urination.

**Genitourinary/Renal Conditions**

This section presents an overview of some of the most common genitourinary/renal conditions (Table 23-6). It also discusses dialysis and catheter management. Genitourinary or renal conditions can result in life-threatening complications if left untreated. These conditions require the EMT to perform an accurate patient assessment, provide prompt emergency care, and transport the patient.

**Urinary Tract Infections**

Urinary tract infections (UTIs) can affect the urethra, bladder, ureters, and kidneys. They can also affect the prostate in men. They are most frequently caused by bacteria that enter the urinary system via the urethra. Women, especially those who are pregnant, elderly patients, immobile patients, catheterized patients, and diabetics are prone to urinary tract infections; however, anyone can contract a UTI.

**Common Signs and Symptoms of Urinary Tract Infections**

- Abdominopelvic pain or tenderness
- Blood in the urine (*hematuria*).
- Urine with cloudiness or a foul or strong odor
- Pain or burning with urination or sexual intercourse
- Frequent or urgent need to urinate
- Genital or flank pain

**TABLE 23-6 Common Genitourinary/Renal Conditions**

- Urinary tract infections
- Kidney stones
- Kidney failure

The urinary system produces, stores, and eliminates urine from the body. The kidneys are bean-shaped organs located in the retroperitoneal space. The kidneys filter the blood and excrete waste products in the urine. They also play a role in homeostasis by regulating the body’s pH (acid/base levels) and electrolytes, controlling the blood volume, and regulating the blood pressure. The ureters are the tubes that carry urine from the kidneys to the urinary bladder. The urinary bladder houses the urine until it is eliminated from the body via a duct called the urethra. In women, the urethral opening is anterior to the vagina and excretes urine; however, in men the urethra is located at the tip of the penis and eliminates both urine and male reproductive fluid.

The organs of the male reproductive system include the testes, epididymis, vas deferens, prostate gland, and penis. The testes are the primary male reproductive organs. They produce sperm cells, which are necessary for reproduction and are stored in a small sac called the epididymis. In order for the sperm to leave the body, it passes through the two ducts called the vas deferens. The sperm then mixes with fluid from the prostate gland before it can be ejaculated from the body. The prostate gland surrounds the male urinary bladder and houses...
Kidney Stones

Kidney stones, or renal calculi, are crystals of substances such as calcium, uric acid, struvite, and crystals that are formed from metabolic abnormalities. They most frequently occur in men between the ages of 20 and 50. Other risk factors associated with renal calculi include family history, hyperparathyroidism, recurrent UTIs, sedentary lifestyle, dehydration, and obesity. Renal calculi are believed to originate in the kidneys and must pass through the rest of the urinary system to be eliminated from the body. Severe pain can occur with renal calculi, especially if the stone is large and is passing through a ureter. If left untreated, renal calculi can lead to loss of kidney function, obstruction of the urinary tract, or kidney damage. The recollection of kidney stones is common and can occur in up to 50 percent of patients who have had them. Older patients with kidney stones present similarly to an acute abdominal aneurysm, and the latter should always be suspected.

Common Signs and Symptoms of Kidney Stones
- Abdominopelvic pain or tenderness
- Flank or back pain that is colicky and severe
- Groin pain
- Abnormal urine color
- Pain with urination
- Frequent or urgent need to urinate
- Fever or chills
- Nausea or vomiting

Kidney Failure

Kidney failure, or renal failure, occurs when the kidneys fail to function adequately. During this condition, the kidneys are not able to filter the wastes and maintain homeostasis as they normally would. Kidney failure is normally classified as either acute or chronic. Acute renal failure (ARF) normally occurs over a period of days and often results from a significant decrease in urine elimination. Some causes of acute renal failure are decreased blood flow to the kidneys, trauma, cardiac failure, surgery, shock, sepsis, and urinary tract obstruction. This condition is sometimes reversible, but many patients will require dialysis.

Chronic renal failure (CRF) normally occurs over a period of years, and the symptoms range from mild at first to severe kidney failure. The causes of chronic renal failure are numerous; however, diabetes and hypertension are linked to a majority of the cases. Chronic renal failure results in an accumulation of waste products and fluids that can affect almost every organ system in the body. This condition is permanent and life threatening. Patients with this type of kidney failure ultimately will require dialysis or a kidney transplant for survival.

Some complications that may result from kidney failure are:
- Pulmonary edema
- Cardiac tamponade or pericarditis
- Electrolyte and other metabolic abnormalities
- Cardiac dysrhythmias
- Congestive heart failure
- Hypertension
- Infections
- Hemorrhage
- Liver failure
- Altered mental status
- Seizures
- Uremia

Common Signs and Symptoms of Kidney Failure
- Blood in the urine or stools
- Altered mental status
- Edema of the feet, ankles, and legs
- Decreased urine output or cessation of urination
- Hypertension
- Swelling or easy bruising
- Anorexia
- Tachycardia

Dialysis

Dialysis is an artificial process used to remove water and waste substances from the blood when the kidneys fail to function properly. It generally works through osmosis and filtration of fluid across a semipermeable membrane. In general, the blood containing waste products passes on one side of the membrane while a dialysate (special fluid used for dialysis) passes on the other side. When this occurs, the water and waste products travel from the blood across the membrane and into the dialysate thus removing the waste from the patient.

There are two major types of dialysis: hemodialysis and peritoneal dialysis. In hemodialysis, a dialysis machine containing the dialysate is connected to an access site on the patient. The access site may be a shunt, fistula, port, or graft (Figure 23-16 ▪). The patient’s blood, which is heparinized, is pumped through the access site and into the machine to have the waste removed. The access site should be treated with care because dialysis cannot occur without it. The EMT should not take the blood pressure of a dialysis patient on the side of the patient’s access site. Hemodialysis is commonly performed at an outpatient dialysis facility, but can be performed in other locations.

In peritoneal dialysis, the dialysate is run through a tube into the patient’s abdomen (Figure 23-17 ▪). The peritoneal membrane functions as the semipermeable membrane during peritoneal dialysis. The fluid remains in the abdomen for several hours so it can absorb the
wastes and then is drained out of the body through a different tube. Peritoneal dialysis is commonly performed at home and is often performed while the patient is sleeping at night. This form of dialysis has fallen into disfavor and is less commonly seen.

Other peritoneal techniques can be used during the day.

Although dialysis provides a necessary treatment for patients with kidney failure, it has risks that can result in adverse effects and life-threatening complications such as:

- Hypotension
- Muscle cramps
- Peritonitis (especially in peritoneal dialysis)
- Nausea and vomiting
- Hemorrhage (especially from the access site)
- Infection at the access site
- Irregular pulse or cardiac arrest
- Difficulty breathing

In addition to these risks, patients may experience life-threatening problems if they miss their dialysis treatments. The most common problems are weakness and pulmonary edema.

**Dialysis Emergency Management.** Management of a patient with a dialysis emergency involves the following:

1. Maintain the airway, breathing, and circulation.
2. Support ventilation as needed.
3. Provide high-concentration oxygen.
4. Stop any bleeding from the shunt or access site as needed.
5. Position the patient. If the patient has signs of shock, place him in a supine position. If the patient has pulmonary edema, place him upright.
6. Transport.

**Urinary Catheters**

As an EMT, you may encounter patients who have urinary catheters. There are various types of catheters that serve to collect urine when patients are not capable of eliminating it themselves. Foley or indwelling catheters
as abdominopelvic pain. As you approach the patient, inspect the scene for a mechanism of injury that would be significant enough to cause a possible spinal injury. If no mechanism of injury is apparent, you would then suspect that the complaint is a result of a medical illness. Remember that patients experiencing genitourinary or renal emergencies may fall or suffer other trauma as a result of their condition.

**Primary Assessment**

Form a general impression of your patient. Does he appear to be in major distress? If an injury is possible, stabilize the spine. Determine if the patient is alert and oriented or if he has an alteration in his mental status. Because a genitourinary or renal emergency can have many complications, the patient may be disoriented or unresponsive. Ensure that your patient has an open and clear airway and use a mechanical airway device if necessary. It may be necessary to suction the airway if vomitus or secretions are present. Determine if the rate, rhythm, and quality of the patient’s breathing are adequate. If breathing is adequate, apply oxygen based on the SpO₂ reading and signs of respiratory distress, poor perfusion, and hypoxia. If breathing is inadequate, provide bag-valve-mask ventilations at 10–12 times a minute with supplemental high concentrations of oxygen. Assess the perfusion status of the patient. Remember that complications from genitourinary or renal emergencies can result in shock. Check the patient’s pulse and skin. Look for signs of shock. Identify and control any major bleeding. If the major bleeding is coming from a dialysis shunt, it should also be controlled.
Shock is only one indicator of a serious medical emergency. The patient having a genitourinary or renal emergency should be categorized as a priority for transport if he meets any of the following criteria:

- Poor general appearance
- Unresponsive
- Responsive, not following commands
- Severe pain
- Shock (hypoperfusion)

**Secondary Assessment**

Protect the patient’s privacy and modesty. It will be necessary to ask questions involving personal issues that some patients may be hesitant or embarrassed to answer. Be patient, compassionate, and professional when communicating with them. Your partner may take baseline vital signs as you begin gathering information and a history from the patient if he is responsive. If the patient is unresponsive, perform your physical exam first and then obtain a history and vitals.

**History.** During your history, ask the following questions:

- What are the signs and symptoms the patient is complaining of?
- Did the signs and symptoms seem to get progressively worse or better?
- How long has the patient been sick or suffering from these signs and symptoms?
- Was the onset of signs and symptoms gradual or sudden?
- What was the patient doing prior to the onset of the complaint?
- Does the patient have any known allergies to medications, food, or other substances?
- When did the patient last have something to eat or drink? What did he eat or drink?
- What medications, prescription and nonprescription, is the patient taking?
- What is the patient’s past medical history? When was the last time he has seen a doctor for his medical condition? Has he had any surgeries?
- When was the patient’s last menstrual period? Is her cycle regular? Does she have any vaginal bleeding or discharge? Could she be pregnant?
- Is there any genital pain or discharge? If so, what is the color, consistency, and odor like?
- Is there a change in urine? If so, what is the color and odor like?
- Does the patient receive dialysis? If so, when was the last treatment received? When is the next treatment due?
- Does the patient have any abdominopelvic or flank pain?
- Has the patient had any nausea or vomiting? If so, when and how much?
- Does the patient have any pain associated with urination, defecation, or sexual intercourse?

**Signs and Symptoms.** The signs and symptoms associated with a genitourinary or renal emergency will vary depending on the cause. They may include the following:

- Urine with an abnormal color, consistency, or odor
- Abdominopelvic pain or tenderness
- Nausea and vomiting
- Fever or chills
- Syncope or altered mental status
- Pain or burning during sexual intercourse, urination, or a bowel movement
- Flank, groin, or back pain
- Frequent or urgent need to urinate or decreased urine output
- Blood in the urine (hematuria)
- Edema of the feet, ankles, and legs
- Hypertension
- Anorexia
- Tachycardia
- Signs of shock

**Physical Exam.** The physical exam will primarily focus on the genitourinary or renal complaint and will normally involve the abdominopelvic area. Genitourinary and renal conditions can affect other body systems; therefore, you must assess related body systems, such as the cardiovascular and respiratory systems, for associated signs and symptoms.

Perform the physical examination of the abdomen carefully and gently. If the patient is a female, you should consider the possibility that she may be pregnant. Begin by inspecting and palpating the abdomen. Remember to ask the patient to point to the area that is the most painful first and then palpate each of the other quadrants before that one. Determine if there is any bleeding, pain, or tenderness. You should also note if the patient has a catheter. If a catheter is present, you should document the amount of urine, color, and odor before emptying it. Remember to keep the catheter free from anything it could get caught on. Obtain and document the patient’s vital signs. Remember: Do not obtain a blood pressure in the arm with the fistula or shunt. Pay attention to blood pressure and heart rate. Decreased blood pressure, increased heart rate, and pale, cool, moist skin are indicators of shock.

**Emergency Medical Care**

As previously stated, it is not important that you try to isolate the exact cause of abdominopelvic pain or a genitourinary or renal condition in the prehospital setting. Rather, you should correctly assess and identify the signs and symptoms and provide the proper emergency medical care as follows:

1. **Maintain manual spinal stabilization** if trauma is suspected.
2. **Keep the airway patent.** Always be alert for vomiting and the potential for aspiration. It may be necessary
to place the patient in the left lateral recumbent position to protect the airway if the patient has an altered mental status. Be prepared to suction.

3. **Maintain adequate oxygenation.** If the SpO$_2$ is $\geq 94\%$ and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO$_2$ is $\leq 94\%$ or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO$_2$ reading of $\geq 94\%$. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

4. **Control any major bleeding if present.** Recheck the access site for bleeding in a dialysis patient.

5. **Place the patient in the position of comfort if no trauma is suspected.** If spinal stabilization is required, fully immobilize the patient on a backboard. If signs or symptoms of shock are present, then place in a supine position. If pulmonary edema is suspected, place the patient in an upright position.

6. **Calm and reassure the patient.** Be supportive and nonjudgmental.

7. **Initiate a quick and efficient transport.** Consider ALS intercept based on your protocols.

**Reassessment**

Continuously monitor the patient for changes in mental status, airway, breathing, and circulation. For a patient with an altered mental status or signs of shock, repeat the reassessment every 5 minutes. Record the vital signs and communicate your findings to the receiving medical facility.

---

**SUMMARY**

The primary goal in the assessment and management of the patient experiencing acute abdominopelvic pain is to manage any life threats to the airway, breathing, oxygenation, and circulation. Patients with gynecologic, genitourinary, or renal complaints may also complain of pain or bleeding that may be associated with an acute abdomen. It is not the responsibility of the EMT to attempt to determine what the exact condition is or what organ is causing the complaint; however, it is important to recognize the signs and symptoms associated with an acute abdomen, since it can be associated with life-threatening bleeding and hypovolemic shock. Your emergency care for an acute abdominopelvic patient is primarily supportive.

---

**Case Study Follow-up**

**Scene Size-up**

You have been dispatched to a 16-year-old male complaining of “stomach” pain. As you approach the home, you scan the scene for any hazards or signs of trauma but find everything in order. You are greeted at the door by the boy’s mother. She tells you that her son, Parker, has had a fever for the last couple of days and that he woke up this morning saying his “stomach hurt real bad.”

**Primary Assessment**

You follow the mother into the boy’s bedroom. You note that the patient is lying on his left side, curled up, and holding his stomach. Your general impression is that Parker appears ill. He speaks clearly—confirming a severe pain in his stomach—so you know that he is alert and his airway is open. His breathing is slightly rapid and his skin is flushed. His radial pulse is strong and rapid.

You tell your partner to go ahead and get the stretcher. His SpO$_2$ is 97% on room air and there are no signs of hypoxia and poor perfusion, so you decide not to administer oxygen.

**Secondary Assessment**

You visually inspect the patient quickly from head to toe as you begin to ask him and his mother some questions. Using the OPQRST mnemonic, you find out the following: The pain began this morning around 5:00; nothing makes the pain better, but lying flat makes it worse; the pain is a dull cramping and is located around the navel, radiating down to the RLQ; Parker says it is “the worst continued”
stomach pain” he has ever had; and it has been constant since early this morning.

The history reveals the following: Parker does not have any known allergies; his mother gave him some cold medicine before bed last night; he does not have any significant medical history; he last drank some fluid around 5:30 this morning but vomited shortly thereafter; nothing seems to have led to this condition; his mother states he has not eaten since lunch yesterday; and he has had some nausea with one episode of vomiting. The vomitus was not abnormal and did not contain any blood.

While you are still asking the history questions, you begin the physical exam. You determine that the patient’s abdomen is soft but tender to palpation in the RLQ with some guarding after performing the Markle test. Meanwhile, you talk to him about how the football season has been going to help keep his mind off the pain.

You arrive on the scene and find a 26-year-old patient who is suffering abdominal pain as a priority for transport. You explain to Parker that he needs to go to the hospital. You move him onto the stretcher and allow him to lie in a position that is comfortable for him. His mother elects to drive her own car to the hospital. Once in the ambulance, you prepare for suction in case Parker vomits. Meanwhile, you talk to him about how the football season has been going to help keep his mind off the pain.

Reassessment

While en route to the hospital you continually reassess Parker for any signs of shock, repeat his vital signs, and check to make sure the oxygen is working. Once at the hospital, you give a detailed report regarding Parker’s condition to the triage nurse and finish writing your pre-hospital care report as your partner readies the ambulance for the next call.

Later, while you are at the hospital on another call, you find out that Parker has had successful surgery to remove his inflamed appendix.

**Case Study Follow-up continued**

**IN REVIEW**

1. List the organs contained within the abdominal cavity.
2. Using the umbilicus as a reference point, name the quadrants of the abdominal cavity and the organs you would expect to find in each quadrant.
3. List the signs and symptoms of acute abdomen.
4. List the factors that would make you consider a patient who is suffering abdominal pain as a priority for transport.
5. Describe the general guidelines for conducting a physical examination of a patient with acute abdominal pain.
6. Outline the steps for emergency medical care of a patient with acute abdominal pain.
7. List the organs of the female reproductive system.
8. List common gynecologic emergencies that can cause abdominopelvic pain.
9. Describe the guidelines for managing a victim of a sexual assault.
10. List the organs of the renal system.
12. Describe how to manage a patient who has a catheter.
13. Describe hemodialysis and peritoneal dialysis.

**CRITICAL THINKING**

You arrive on the scene and find a 26-year-old patient who is complaining of vomiting up blood. He tells you that he is an alcoholic and has been drinking for a week or so. He is alert but sluggish in responding to your questions. His respirations are 22 per minute with good tidal volume. His radial pulse is 132 bpm and is very weak. His skin is extremely pale, cool, and clammy. His blood pressure is 108/60 mmHg. His skin is warm, dry, and flushed.

You continue to assess the patient in the ambulance. He is complaining of abdominal pain in the RLQ with some guarding after performing the Markle test. Meanwhile, your partner, who has returned with the stretcher, obtains and documents Parker’s baseline vitals. His breathing is adequate but somewhat rapid and shallow with a rate of 28; his radial pulse is strong, regular, and rapid with a rate of 130. His blood pressure is 108/60 mmHg. His skin is warm, dry, and flushed.

You explain to Parker that he needs to go to the hospital. You move him onto the stretcher and allow him to lie in a position that is comfortable for him. His mother elects to drive her own car to the hospital. Once in the ambulance, you prepare for suction in case Parker vomits. Meanwhile, you talk to him about how the football season has been going to help keep his mind off the pain.
CHAPTER 24

Environmental Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Trauma (Content Area: Environmental Emergencies)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

24-1. Define key terms introduced in this chapter.
24-2. Explain the importance of being able to recognize and provide emergency medical care for patients with environmental emergencies.
24-3. Describe the process by which the body maintains normal temperature.
24-4. Explain the mechanisms by which the body loses heat.
24-5. Explain the mechanisms by which the body gains heat.
24-6. Describe the pathophysiology of generalized hypothermia.
24-7. Recognize factors that contribute to a patient’s risk for hypothermia, (including immersion hypothermia, urban hypothermia, and myxedema coma or hypothyroidism).
24-8. Describe the pathophysiology of local cold injury, including the stages of local cold injury.
24-9. Discuss the assessment-based approach to cold-related emergencies.
24-10. Describe the emergency medical care for generalized hypothermia.
24-11. Describe the emergency medical care for immersion hypothermia.
24-12. Describe the emergency medical care for local cold injury.
24-13. Describe the pathophysiology of heat-related emergencies.
24-14. Recognize factors that contribute to a patient’s risk for hyperthermia.
24-15. Discuss the assessment-based approach to heat-related emergencies.
24-16. Describe the emergency medical care for a heat emergency patient with moist, pale, normal-to-cool skin.
24-17. Describe the emergency medical care for a heat emergency patient with hot skin that is moist or dry.
24-18. Describe the emergency medical care for heat cramps.
24-19. Describe the characteristics of common venomous snakes and factors that affect the severity of a snakebite.
24-20. Recognize the signs, symptoms, and patient history associated with bites or stings of the following:
   a. Black widow spiders
   b. Brown recluse spiders
   c. Scorpions
   d. Fire ants
   e. Ticks
24-21. Discuss the assessment-based approach to bites and stings.
24-22. Describe the signs and symptoms and the emergency medical care for anaphylactic shock resulting from a bite or sting.
24-23. Describe the signs and symptoms and the emergency medical care for a bite or sting.
24-24. Recognize the signs, symptoms, and patient history associated with the bite or sting of a marine animal and the emergency medical care for marine life poisoning.
24-25. Explain the pathophysiology of lightning strike injuries.
24-26. Given a scenario with a patient who has been struck by lightning, predict findings and complications associated with the mechanism of injury.
24-27. Describe the emergency medical care for a patient who has been struck by lightning.
24-28. Describe the signs, symptoms, and patient history associated with acute mountain sicknesses and emergency medical care for acute mountain sickness.
24-29. Describe the signs, symptoms, and patient history associated with high altitude pulmonary edema and emergency medical care for high altitude pulmonary edema.
24-30. Describe the signs, symptoms, and patient history associated with high altitude cerebral edema and emergency medical care for high altitude cerebral edema.
INTRODUCTION

You will face situations as an EMT that are termed environmental emergencies. These are caused when there is a significant disruption in normal physiological activities of the body as a response to a change in some element (or combination of elements) in the patient’s natural surroundings. Such emergencies can arise from interaction with the climate, as in exposure to excessive cold or heat. They can also be brought on by contact with creatures living in the environment, as in the bites or stings of snakes or spiders. In addition, going into a high altitude can cause emergencies that would not occur at sea level. These and other causes of environmental emergencies are discussed in this chapter.

Although environmental emergencies happen in large metropolitan areas, they also occur in isolated areas that do not have ready access to an emergency department. Therefore, it is important for the EMT to learn how to assess and provide on-scene or en route emergency medical care for patients affected by environmental emergencies.

HEAT AND COLD EMERGENCIES

To understand how exposure to heat or cold can create life-threatening situations, you should have a basic understanding of how the body regulates its temperature.

Regulation of Temperature

The human body stubbornly defends its constant core temperature of approximately 98.6°F (37°C). In order to do this, the body must constantly monitor its temperature and balance the amount of heat production and heat loss.

The body temperature is monitored and controlled primarily by the hypothalamus in the brain. The hypothalamus contains a temperature control center called the thermoregulatory center. This center receives input from two different receptors: (1) the central thermoreceptors, which are located on or near the anterior hypothalamus; and (2) the peripheral thermoreceptors, found in the skin and the mucous membranes. A thermoreceptor (thermo refers to temperature; receptor is a sensory nerve ending that receives various types of stimuli)
is responsible for sending nerve impulses to the hypothalamus indicating the temperature of the body. The central thermoreceptors measure the core body temperature by monitoring the temperature of the blood, and the peripheral thermoreceptors monitor the body temperature found in the skin and extremities.

When understanding body temperature, the concept of a thermal gradient (transfer of heat or cold) applies. The thermal gradient operates by warmer temperatures moving toward cooler temperatures. In other words, the transfer of heat will always be from hot to cold. As an example, the body skin temperature is normally about 90°F. If the outside temperature is 95°F, heat will be transferred from the outside air to the skin of the body. This causes the body to take on a greater heat load, thereby making the person feel warmer. The heat in this situation is moving down the thermal gradient from the warmer air to the cooler body. If the outside temperature is 65°F, the heat will be transferred from the warmer skin of the body to the cooler outside air. In this instance the thermal gradient is causing the movement of heat down a temperature gradient from the body to the ambient air. If the rate of heat loss starts to exceed the body’s heat production, the skin will begin to cool excessively, and the peripheral thermoreceptors will pick up the drop in temperature. In response, the patient begins to feel cool and may try to generate heat by shivering, moving about, or adding clothes.

The body must maintain an optimum body temperature so that the cells can continue to function normally. In order to do so, the amount of heat lost by the body must equal the amount of heat gained by the body. If the amount of heat lost exceeds the amount of heat gained, the patient’s body core temperature will begin to decrease. Likewise, the amount of heat gained must equal the amount of heat lost. If the amount of heat gained exceeds the ability of the body to lose heat, the body core temperature may begin to increase. The body continuously produces and conserves heat in order to balance heat production and heat loss.

**PATHOPHYSIOLOGY PEARLS**

The body must maintain an optimum body temperature so that cellular function can continue normally. If at any time the body cannot compensate for the amount of heat that is either gained or lost, resulting cellular and organ damage may lead to an environmental emergency.

How is heat produced? The body produces heat mainly through processes of metabolism, including digestion of food. The body also produces heat, increasing it by up to 400 percent, through shivering, which is nothing more than skeletal muscle movement. skeletal muscle movement is an effective way to produce heat, which is why patients who are losing heat will frequently pace or otherwise move about and jump up and down in place. Keep in mind, though, that shivering will cease when the body core temperature drops to below 90°F (32°C). This is an ominous sign, since cooling occurs very rapidly once shivering has stopped. Hormones such as thyroxin from the thyroid gland and epinephrine from the adrenal gland will increase the metabolic rate of the body and produce heat as a by-product.

How is heat conserved? In a cool or cold environment, the body conserves heat by constricting blood vessels (vasoconstriction) and sending warm blood from the surface of the skin to internal organs. Hair on the skin surface erects (piloerection), thickening the layer of warm air that is trapped immediately next to the skin. (However, piloerection has been shown to have little effect in conserving heat in humans, especially when there is a breeze blowing.) Little or no perspiration is released to the skin surface, preventing cooling by evaporation. The patient may attempt to reduce heat loss by decreasing the surface area of the body through folding his arms across his chest, adding more clothing, or drawing his body up close in a fetal position.

The body also has an elaborate system for cooling itself. There are three organ systems primarily responsible for cooling the body and reducing the body core temperature: (1) the skin, (2) the cardiovascular system, and (3) the respiratory system. As the core temperature rises, the warmed blood travels to the periphery, and blood vessels near the skin’s surface dilate. An increased flow of warmed blood near the skin helps dissipate excess heat through radiation and convection (see the later explanation). However, this cooling system works only if the ambient air is cooler than the skin temperature. If the outside air is as warm as, or warmer than, the temperature of the skin, the body relies on dissipation of the heat through the evaporation of sweat from the skin surface. The cardiovascular system responds to increasing heat loads by elevating the heart rate and increasing the strength of contractions so that more blood can move to the surface of the skin to be cooled. Also, the increase in cardiac output maintains the blood pressure as the peripheral vessels dilate. Finally, the respiratory system contributes to the cooling of the body by eliminating heat through evaporation during exhalation.

**PATHOPHYSIOLOGY PEARLS**

The body relies on three body systems—skin, cardiovascular, and respiratory—to help maintain a normal temperature when the body becomes too warm.

**When Heat Lost Exceeds Heat Gained**

When the body loses more heat than it gains or produces, the result is hypothermia, or low body temperature (<95°F or 35°C). As mentioned earlier, heat loss occurs through five mechanisms: radiation, convection, conduction, evaporation, and respiration (Figure 24-1). As an EMT, you must be aware of the ways in which heat is lost so that you can be alert to a situation in which a patient may be suffering from hypothermia, and so that you can protect the hypothermic patient from further heat loss.
Radiation. The most significant mechanism of heat loss is **radiation**, which involves the transfer of heat from the surface of one object to the surface of another without physical contact. Most heat loss through radiation is from the head, hands, and feet. This is why it is so important to cover a newborn’s head after birth.

The amount of heat a person loses through radiation depends also on environmental conditions. In a temperate climate and under normal conditions, a person loses about 55–65 percent of his heat production by radiation. At a temperature of 90°F, however, radiation loss will probably drop to zero. In subzero temperatures, it will drastically increase as body heat is transferred to the atmosphere.

**Convection.** The process of **convection** causes cold air molecules that are in immediate contact with the skin to be warmed. The heated air molecules move away, and cooler ones take their place. Those in turn are warmed, and the process starts all over again. Anything that speeds movement of the air, such as the wind, also speeds the cooling process. That is where the concept of **wind chill** comes into understanding and predicting hypothermia (Figure 24-2 ■).

A unit of wind chill is the amount of heat that would be lost in an hour from a square meter of exposed skin surface with a normal temperature of 91.4°F. In essence, the wind-chill factor combines the effects of the wind speed and environmental temperature into a number that indicates the danger of exposure. For example, on a windless day, exposed flesh will normally freeze in less than 1 minute at a temperature of –70°F. Because of the wind-chill factor, the same results will occur at a temperature of –20°F if there is a wind speed of between 20 and 25 mph.

**Conduction.** The mechanism of **conduction** causes body heat to be lost through direct contact. Water conducts heat 240 times faster than air, and conduction is the method of heat loss in **water chill**. This means that water and wet clothing will conduct heat away from the body at a much higher rate than air and dry clothing and much more rapidly than the body can produce it. This is an important factor in drowning, in which cold water temperatures can lead to a dramatic change in body temperature. Conduction and convection combined produce about 15 percent of heat loss.

**Evaporation.** The process in which a liquid or solid changes to a vapor is called **evaporation**. Evaporation has a cooling effect. When body heat causes the body to perspire and the perspiration evaporates, the heat that has been absorbed by the sweat is dissipated into the air, and the body surface is cooled. When air temperature equals or exceeds skin temperature, evaporation is the only way the body has of losing heat. Heat loss through evaporation is also affected by the relative humidity of
the air. A relative humidity of 75 percent will significantly reduce the effectiveness of evaporation, whereas a relative humidity of 90 percent will cause evaporation to become essentially ineffective. This is evident on humid days when sweat seems to accumulate on the surface of the skin without drying.

The sweating mechanism has its limits. The normal adult can sweat only about 1 liter per hour and can sweat at that rate for only a few hours at a time. In addition, sweating only cools the body effectively if the relative humidity of the air is low. As just mentioned, when the air humidity is high, the water vapor contained in the air inhibits the evaporation of moisture from the skin surface. During intense exercise, about 85 percent of heat loss occurs through sweating. Under normal conditions, however, evaporation combined with heat loss through respiration comprises approximately 20–30 percent of heat loss.

**Respiration.** Breathing, or respiration, also produces heat loss. A person breathes in cold air from the atmosphere and breathes out air that has been warmed and humidified inside the lungs and the airway. Some of the body’s heat is carried away with the exhalation of this warm, humidified air. Respiration alone comprises about 10–20 percent of heat loss under normal circumstances.

**PATHOPHYSIOLOGY PEARLS**

Heat loss leading to hypothermia can be from conduction, convection, radiation, evaporation, and/or respiration.

**When Heat Gained Exceeds Heat Lost**

When the amount of heat the body produces or gains exceeds the amount the body loses through the processes just described, the result is hyperthermia, or high body temperature. At times, the body may produce more heat than needed even at moderate air temperatures, or may fail to cool the body when needed by not recognizing an increasing core temperature (from certain medical conditions or as a response to certain medications). However, in most cases, hyperthermia occurs in a hot environment. Hyperthermia is most common in situations in which the air temperature is high, the humidity is high, and there is little or no breeze.

**PATHOPHYSIOLOGY PEARLS**

Hyperthermia, or a high body temperature, occurs when the body is unable to cool itself effectively.

**EXPOSURE TO COLD**

Exposure to cold can cause two kinds of emergencies. One is generalized hypothermia, also called a generalized cold emergency, which is an overall reduction in body temperature affecting the entire body. The other is local cold injury, or damage to body tissues in a specific (local) part or parts of the body.

**Generalized Hypothermia**

Generalized hypothermia results from an increase in the body’s heat loss, a decrease in the body’s heat production, or both. It is the most life-threatening cold injury because it affects the entire body. Mortality (death) from generalized hypothermia can be as high as 87 percent.

Hypothermia can have a sudden onset, as when someone falls through ice, or a gradual onset, as from prolonged exposure to wind, cold air, or cool water.
Pathophysiology of Generalized Hypothermia

In general, thermal control (the ability of the body to regulate its temperature) is lost once the body temperature is lowered to 95°F (35°C). Coma (deep unresponsiveness, severely depressed vital signs) occurs when the body's core temperature reaches approximately 79°F (26°C). Death can occur within 2 hours of the first signs and symptoms of generalized hypothermia (Figure 24-3). The most important phase of management with hypothermic patients is the first 30 minutes following rescue and during the transport time to the hospital.

Predisposing Factors

Risk factors for generalized hypothermia include:

- **Ambient temperature, wind chill, and moisture.** Extremely low temperatures are not necessary for hypothermia to occur. It can occur in temperatures as high as 65°F, depending on the wind-chill factor. Wetness, either from perspiration or immersion in water (or rain), always compounds the problem and increases the risk of hypothermia (Figure 24-1).

- **Age.** People who are at the extremes of age, such as infants (especially newborns) and toddlers and the elderly, are at increased risk of hypothermia. Infants and young children have a large surface area in relation to their overall size, increasing both the amount and speed of heat loss. The ability to shiver (a heat-producing mechanism) is not well developed in children and does not exist in infants because of their small muscle mass. Both the very young and very old tend to have less body fat, which also contributes to heat loss. The elderly have an impaired recognition of cold, a diminished basal metabolism, and poor constriction of blood vessels in the extremities (a heat-conserving mechanism). This can lead to a condition known as *urban hypothermia* (discussed later), in which an elderly person becomes hypothermic in her own home (Figure 24-5). Infants and young children are unable to use adaptive behaviors, such as moving to a warm environment or putting on warmer clothing.

- **Medical conditions.** At increased risk for hypothermia are people who have had recent surgery or who have shock, head injury, burns, generalized infection, spinal cord injuries, thyroid gland disorders, and diabetic emergencies such as hypoglycemia. The outcome of a trauma patient with hypothermia is dramatically worsened.

- **Alcohol, drugs, and poisons.** Some drugs, alcohol, and poisons can increase the risk of hypothermia. Substances that impair heat-generating or heat-conserving mechanisms include narcotics, alcohol, antiseizure medications, antihistamines, sedatives, antidepressants, and pain medications such as aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs.

- **Duration of exposure.** The longer the time a person spends unprotected in a cold environment, the greater the chance that he will become hypothermic.

- **Clothing.** Clothing that is inappropriate for the temperature will allow a person to lose heat at a greater rate than if he had layers of clothing for cold environments. Layers of clothing provide insulation from

![FIGURE 24-3](image-url)  Signs and symptoms of a sinking core temperature.
Hypothermia can occur in cold or merely cool environments. All of the persons in these photographs are subject to possible hypothermia: (a) a person dressed too lightly for outdoor activity on a very cold day, (Photo a: © Corbis) (b) a person sleeping outdoors on a cool surface in cool weather.

An elderly person living in an inadequately heated home may be subject to hypothermia.

The cold and protect against excessive heat loss. A hat reduces heat loss from the head, and appropriate gloves and boots protect against local cold injury. Clothing that doesn’t protect against rain and moisture and allows the body to become wet will contribute to the rate of cooling. If in a body of water, it is recommended that a person keep his clothing on to trap a layer of water between the skin and the clothing. This layer of water will be heated by the body and will provide something of a warm insulating water layer.

Activity level. Physical activity requires muscular movement that produces heat as a by-product (thermogenic). Thus, a person who continues to move may generate internal heat that maintains the body’s core temperature at a higher level than if he was not moving. In order to continue to move, however, the person must have an adequate amount of fuel in the form of carbohydrates, protein, or fat. In addition, the person must drink an adequate amount of water to remain hydrated. A person in a body of cold water who continues to move may cool faster from convection. As the person continues to tread water, he moves cold water molecules next to his skin, which promotes cooling at a faster rate. If instead he curls into a ball and floats, the water around him will become warmer from his body heat and his curled-up position will lessen the cooling from convection.

**Stages of Hypothermia**

Hypothermia can occur with little warning and can progress very rapidly from mild to moderate to severe to profound (Table 24-1). Initial reactions to cold exposure are increases in the basal metabolic rate, muscular shivering, and “goosebumps” (caused by piloerection). All of these are thermogenic in nature. However, in hypothermia, these compensatory mechanisms are not enough to maintain body temperature. As the core temperature drops, the body’s thermal-regulating mechanism and perception become confused. A person, even though dangerously cold, may undress, thinking he is too warm.

Immersion Hypothermia

Immersion hypothermia occurs as a result of the lowering of the body temperature from immersion in cool or cold water. You should consider the possibility of immersion hypothermia in all cases of accidental immersion. Familiarize yourself with normal spring, summer, fall, and winter river and lake temperatures in your community.

Body temperature can drop to the water temperature in as little as 10 minutes in some circumstances. In fact, body temperature drops 25 to 30 times faster in water than in air of the same temperature (Figure 24-6). Extra fat layers tend to insulate people from cooling. Pound for pound, adult women have greater resistance to heat loss in cold water than men. Similarly, adults can withstand the cold longer than children, and girls have more resistance than boys. Layers of clothing can help to insulate a patient in the water.

Contrary to the popular idea that people die in water only when the water temperature approaches freezing, death can occur within a few minutes when the water is 50°F. The priority with a patient immersed in water is only when the water temperature approaches freezing than boys. Layers of clothing can help to insulate a patient in the water.

Urban Hypothermia

Urban hypothermia, although not clearly defined in medical literature, occurs in those individuals who have a predisposition, disability, illness, or medication usage that renders them more susceptible to hypothermia. Predisposing factors include situations that result in increased heat loss (such as the very young or very old, because of their lower amount of body fat), interference with heat production from medical illnesses or medication use, alterations in mental status, or limited mobility that make the person unable to take protective measures to minimize heat loss.

Urban hypothermia can be further subdivided into two general etiologies: external and internal. The “external” category includes patients who are subject to hypothermia because they do not have the access to a warm environment during the cold months. These are patients who live on the streets or try to take refuge in shelters for the homeless. Because of a lack of access at times during cold temperatures, these patients may be found outdoors in a city without adequate shelter or clothing to keep them warm. This category of patients may suffer from hypothermia not from a medical or traumatic cause, but simply from lack of protection from the cold environment.

Urban hypothermia may also occur when the person is indoors. This “internal” category of urban hypothermia includes patients (typically the elderly) who are subject to colder temperatures in the winter months when they attempt to minimize heating bills to save money. Since the elderly commonly have a limited ability to sense cold, coupled with decreased tissue insulation and likely a reduced mobility, they may become hypothermic in their own home without realizing hypothermia’s insidious onset.

The elderly patient may also be hypothermic even though the outside temperature is warm. Consider the elderly patient who lives in an air-conditioned home in the summer months when it would not be uncommon to have the indoor temperature set at 70°F–72°F. Should this same elderly patient slip while getting out of the shower and fall onto the bathroom floor, resulting in a broken hip, he will be immobile until discovered by someone else. Since most bathrooms have tiled floors, which hold cold temperatures, an elderly patient who is forced to lie on this surface for a prolonged period may become hypothermic. A patient in an air-conditioned environment who has decreased tissue insulation and inability to move from a cold surface is a prime candidate for urban hypothermia, even on a warm day.

Myxedema Coma

As mentioned earlier, certain medical illnesses and diseases may make a person more susceptible to becoming hypothermic. One such disease is hypothyroidism. Hypothyroidism is a clinical syndrome characterized by an absence or severe deficiency of a hormone secreted by the thyroid. The absence of this hormone causes metabolic processes to slow significantly. Symptoms of hypothyroidism can manifest in all organ systems and include a dull facial expression. The voice is often hoarse and the speech may be slow and drawn out.
There is commonly facial puffiness and periorbital swelling with droopy eyelids. The hair appears sparse, coarse, and dry, and the skin appears coarse and dry. There is commonly weight gain. The patient’s mental status may become altered, and forgetfulness is common. Hypothyroidism may also precipitate sudden psychosis (a condition called myxedema madness). The disease is typically chronic, occurring over months to years.

**Myxedema coma** is a complication that occurs late in the progression of hypothyroidism and can be fatal. It occurs most commonly in elderly women who present with extreme hypothermia (core temperatures often 75°F–90°F (24°C–32.2°C), seizures, slow reflexes, and respiratory depression. Although myxedema coma occurs rarely (in only 0.1 percent of hypothyroidism patients), it is a true emergency, as death from this complication is likely. Precipitating factors for the condition include exposure to cold temperatures, a recent illness or infection, trauma, and the use of drugs that depress the central nervous system. EMT treatment for this condition is limited to supporting lost functions of airway, breathing, and circulation. It is best if the EMT contacts medical direction regarding the rewarming techniques to be utilized for the severely hypothermic patient with myxedema coma.

**Local Cold Injury**

**Local cold injury**, the condition commonly called “frostbite,” results from the freezing of body tissue. Local cold injury requires much colder temperatures than are needed to produce generalized hypothermia. Such a local cold injury often accompanies generalized hypothermia; in cases where it does, emergency medical care for hypothermia always takes precedence over care for the local injury.

**Pathophysiology of Local Cold Injury**

Local cold injury occurs when ice crystals form between the cells of the skin and then expand as they extract fluid from the cells. Circulation is obstructed, causing additional damage to the tissue. Such injuries tend to occur on the hands, feet, ears, nose, and cheeks, which are most commonly exposed to cold.

**Predisposing Factors**

The following factors can increase the likelihood of a person suffering a local cold injury:

- Any kind of trauma (always check for local cold injury on people injured in cold weather)
- Extremes of age (especially elderly and newborn)
- Tight or tightly laced footwear, which tends to diminish perfusion to the feet
- Use of alcohol during exposure to cold
- Wet clothing

- High altitudes
- Loss of blood
- Arteriosclerosis

**Stages of Local Cold Injury**

Local cold injuries fall into two basic categories: early or superficial injury and late or deep injury (Figure 24-7).:

- **Early or superficial cold injury** usually involves the tips of the ears, the nose, the cheekbones, the tips of the toes or fingers, and the chin. The patient is usually unaware of the injury, which commonly develops after direct contact with a cold object, cold air, or cold water. As exposure time lengthens or temperature drops, the patient will lose feeling and sensation in the affected area, and the skin may begin to turn a waxy gray or yellow color. The skin remains soft but cold to the touch, and normal skin color does not return after palpation. If the affected area is rewarmed, the patient will usually report a tingling sensation as the area thaws and circulation improves.

- **Late or deep cold injury** involves both the skin and tissue beneath it. The skin itself is white and waxy in appearance. Palpation of the affected area will reveal a firm to completely solid, frozen feeling. The injury may involve the whole hand or foot. Swelling and blisters filled with clear or straw-colored fluid may be present (Figure 24-8). As the area thaws, it may become blotty or mottled, with colors from white to purple to grayish blue (Figure 24-8b). Deep cold injury is an extreme emergency and can result in permanent tissue loss.

**Assessment-Based Approach: Cold-Related Emergency**

**Scene Size-up**

Your first step should be to ensure your own safety and that of your partner. Do not put yourself in danger by attempting to make rescues for which you are not properly trained or prepared.

For example, you might be called to a scene at which a skater has fallen through the ice on a pond and is partially or completely immersed when you arrive. Your first reaction would probably be to go immediately to his aid by walking out onto the ice. You must stop and consider the situation, noting that the ice is obviously unstable, resulting in one person already having broken through. Walking out onto the ice would likely make you a second hypothermia patient at best or a drowning victim at worst. Without adequate ropes and gear such as ladders or boats to reach the patient (and training in how to use them), you should await the arrival of rescuers from the fire department or other agencies.

Cold temperatures and high winds pose hazards for EMT crews. Be prepared for exposure to the cold by...
STAGES OF LOCAL COLD INJURY

EARLY OR SUPERFICIAL COLD INJURY
usually involves the tips of the ears, the nose, the cheek bones, the tips of the toes or fingers, and the chin. The patient is usually unaware of the injury. As exposure time lengthens or temperature drops, the patient will lose feeling and sensation in the affected area. The skin remains soft but cold to the touch, and normal skin color does not return after palpation. As the area rewarms, the patient may report a tingling sensation.

LATE OR DEEP COLD INJURY
involves both the skin and tissue beneath it. The skin itself is white and waxy with a firm to completely solid, frozen feeling. Swelling and blisters filled with clear or straw-colored fluid may be present. As the area thaws, it may become blotchy or mottled, with colors from white to purple to grayish-blue. Deep cold injury is an extreme emergency and can result in permanent tissue loss.

Once you have taken appropriate measures to ensure your own safety at the scene, and that of your crew, consider how the characteristics of the scene may have affected the patient. Be alert for signs or evidence of how the patient interacted with the environment before your arrival. Things to look for include the following:

- Is the patient protected from the cold environment?
- Is the ambient (surrounding air) temperature cool or cold?
consider the possibility of hypothermia. Even though the temperature never got below 65°F, should alert you to and his prolonged exposure, even though the temperature decreases, however, the respirations will become slow and shallow and eventually absent. As the body core temperature decreases to less than 93°F (34°C), the carbon dioxide production begins to decline as the cell metabolism slows down drastically. At approximately 86°F (30°C), the carbon dioxide production will decrease by about 50 percent for every 8-degree Celsius drop in temperature. Carbon dioxide is the major stimulus to breathe in the normal patient. Thus, a decrease in carbon dioxide production will decrease the drive to breathe, causing the respiratory rate and tidal volume to decrease and eventually become ineffective.

Be prepared to provide positive pressure ventilation with supplemental oxygen if the breathing is inadequate. If the patient is breathing adequately, as evidenced by an acceptable respiratory rate and good alveolar breath sounds, administer supplemental oxygen, warmed and humidified if possible, to maintain an SpO2 of ≥94% or if an SpO2 is unobtainable. Insertion of a nasal or oral airway was once thought to precipitate cardiac dysrhythmias such as ventricular fibrillation in the hypothermic patient. This belief is now falling into question, as some recent studies are suggesting that aggressive airway management does not increase the risk of precipitating ventricular fibrillation. In either situation, the use of an airway adjunct should be considered if necessary for establishing and maintaining the airway.

Check the carotid and radial pulses carefully. They may be difficult to find in the severely hypothermic patient. Early, the pulse rate may become elevated as the body’s cardiovascular system responds to the heat loss, but it will continue to decrease with a falling core body temperature. If the pulse is completely absent, begin chest compressions with artificial ventilation. The skin may appear red early in hypothermia, but as the condition worsens, the skin too will change to pale, then cyanotic, then gray. As the skin continues to cool, it will become firm and cold to the touch.

Primary Assessment

Gather a general impression of the patient. Is the patient dressed appropriately for the weather conditions? Is his posture stiff or does he appear to be rigid? The patient may be staggering or appear uncoordinated. His mental status will deteriorate with the level of hypothermia. He may appear drowsy or irrational or may be completely unresponsive in severe cases and appear dead in the most severe cases.

Closely assess the airway, especially in the unresponsive patient. It may be necessary to perform a manual maneuver to establish and maintain an open airway. Early in hypothermia, the breathing rate may be increased and of a normal depth. As the body temperature decreases, however, the respirations will become

Secondary Assessment

The secondary assessment should be conducted in the back of the warmed ambulance. Do not delay moving
the patient out of the cold environment to conduct the exam. If the patient is responsive, gather a history. Document complaints of pain or of other symptoms. Determine if the patient is using any medications, especially drugs that might depress the central nervous system or cause blood vessels to dilate. A past medical history is important because the patient with preexisting diseases or significant medical conditions may deteriorate much faster than the previously healthy individual. Determine the last intake of food and what the patient was doing prior to the incident. Determining how long the patient has been out in the cold is extremely important, because the longer he has been exposed, the more severe the hypothermia is likely to be.

If a mechanism of injury consistent with trauma is suspected or the patient complains of pain to several areas of the body, perform a physical exam. Look for evidence of trauma to the head, neck, or spine, and immobilize the spine. Look for any other evidence of injury to the chest, abdomen, or pelvis if trauma is suspected. Significant burns may lead to hypothermia because the skin’s temperature-regulating functions have been destroyed with the destruction of the skin. Feel with your hand the warmth of the abdomen to get an idea of how cold the patient actually is. When assessing the extremities, be alert for signs of local cold injuries. The patient may experience a decrease in sensation in the extremities and may exhibit lack of coordination or difficulty in movement during motor assessment.

The baseline vitals may reveal a blood pressure that decreases with a falling core body temperature. The heart rate will initially be increased but will fall with the temperature decrease. Respirations will be full initially with an increased rate, but will begin to decrease and become shallow as the hypothermia worsens. The skin early on will appear red, then turn pale, then cyanotic, then gray. It will eventually become cold and firm to the touch.

If the patient is unresponsive, perform a physical exam as already described, and attempt to gather information for the history from family or bystanders.

Signs and Symptoms of Generalized Hypothermia. It is possible to measure the core body temperature only with a specialized thermometer. This measurement is not always practical in the field, but some EMS systems are using tympanic thermometers rather than the traditional glass thermometers, which must be inserted either orally or rectally. The thermometer used must be of a medical grade that records a broad range of temperatures (rather than traditional home thermometers that only measure a narrow range of temperatures). The tympanic thermometer’s accuracy has come under question when it is used in environmental extremes in the prehospital setting. As an alternative, or in conjunction with a thermometer reading, the EMT can rely on presenting signs and symptoms in the assessment of generalized hypothermia.

Remember the factors predisposing people to hypothermia:

- Exposure to a cold environment
- Age (either very young or elderly)
- Preexisting medical conditions
- Use of drugs (including medications such as beta blockers or antipsychotics), alcohol, or poisons

Be especially cautious for hypothermia when treating a patient who was resuscitated outside. Sometimes rescuers lose track of the time as they work on a patient in a snowbank or on an icy road. Remember that a patient in a motor vehicle is actually inside a microclimate. If the vehicle is involved in a collision, that microclimate can be disrupted, with the heat of the vehicle lost and the patient exposed to environmental conditions similar to those outside the vehicle. For temperature assessment, place the back of your hand on the patient’s abdomen beneath the clothing. A patient with generalized hypothermia will have cool abdominal skin.

Signs and symptoms of generalized hypothermia typically occur in stages as the body core temperature falls (Table 24-2). The signs and symptoms of generalized hypothermia include the following (Figure 24-9):
Emergency Medical Care for Generalized Hypothermia

The basic principles of emergency care for generalized hypothermia are:

- Preventing further heat loss
- Rewarming the patient as quickly and safely as possible
- Staying alert for complications

The steps to follow in care are these:

1. **The top priority is to remove the patient from the cold environment and to prevent further heat loss.** Remove any wet clothing, dry the patient, and use blankets to insulate the patient from the cold. Insulate the patient from the ground up; get something underneath the patient as quickly as possible. Remember to insulate the head. Protect the patient from exposure to the wind. You can help prevent further heat loss by using warm, humidified oxygen when possible.

2. **Handle the patient gently.** Rough handling can cause a cardiac dysrhythmia, especially ventricular fibrillation. (Cardiac arrest from ventricular fibrillation is a frequent cause of death in people with severe hypothermia.) Never allow the patient to walk or exert himself in any way. Even minor physical activity can disrupt the rhythm of the heart. Whenever possible, keep the patient in a supine position to increase blood flow to the brain. Elevate the patient’s head if the patient has head or chest injuries, shortness of breath, or chest pains, or if the patient needs to be transported over steep terrain.

3. **Maintain adequate oxygenation.** Administer supplemental oxygen to maintain an $\text{SpO}_2 \geq 94\%$. If possible, use warm, humidified oxygen. There is increasing evidence that the application of warm humidified oxygen can be extremely beneficial to the hypothermic patient during resuscitation. Do not aggressively ventilate or hyperventilate the patient. A patient with hypothermia has a reduced metabolism and need for oxygen, and unnecessary hyperventilation can cause further cardiac complications. In fact, a spontaneously breathing patient is probably getting adequate ventilation.

4. **If the patient goes into cardiac arrest from ventricular fibrillation or pulseless ventricular tachycardia, immediately initiate CPR beginning with chest compressions and apply the AED.** According to the AHA 2010 guidelines, if ventricular fibrillation or ventricular
SIGNS AND SYMPTOMS OF HYPOTHERMIA

Decreasing mental status
- Amnesia, memory lapses, and incoherence
- Mood changes
- Impaired judgment
- Reduced ability to communicate
- Dizziness
- Vague, slow, slurred, or thick speech
- Drowsiness progressing even to unresponsiveness

Decreasing motor and sensory function
- Stiffness, rigidity
- Lack of coordination
- Exhaustion
- Shivering at first, little or no shivering later
- Loss of sensation

Changing vital signs
- Breathing rapid at first; shallow, slow later; absent near end
- Pulse rapid at first; slow and barely palpable later; irregular or absent near end
- Skin red in early stages, changing to pale, to cyanotic, to gray, waxen, and hard; cold to the touch
- Slowly responding pupils
- Low to absent blood pressure

Tachycardia persist after the initial defibrillation, it may be reasonable to continue to defibrillate as the patient is being rewarmed. Follow your local protocol. Continue CPR aggressively, since prolonged survival in cases of hypothermia has been reported. Respiration of only three or four breaths a minute and a pulse of five to ten beats per minute is enough to sustain life in a hypothermic patient.

5. Actively rewarm patients with moderate and severe hypothermia. Note: Some experts advise active rewarming only if you are more than 15 minutes from the receiving facility. According to the AHA 2010 guidelines, active rewarming should be applied to patients with a body core temperature less than 34°C or 93.2°F or those in moderate or severe hypothermia. Follow medical direction and your local protocol for hypothermia treatment.

Active rewarming is a technique of aggressively applying heat to warm the patient’s body and includes these measures: wrapping the patient in warm blankets; placing heat packs or hot water bottles in the groin, in the armpits, and on the chest (Figure 24-10); and turning up the heat in the patient compartment of the ambulance.

Heat should be added to the patient gradually and gently; slower is safer in such cases. Never immerse a patient in a tub of hot water or in a hot shower. The body temperature should not be increased more than 1°F per hour. As a general rule, keep the patient’s extremities protected from cold, but do not apply heat to them; the object is to rewarm the core body, and rewarming the extremities can be dangerous. Check the patient often to make sure you are not burning his skin with the hot packs or water bottles.
Passive rewarming should be applied to all hypothermic patients as the first priority in the rewarming process. According to the AHA 2010 guidelines, mild hypothermia patients are those with a body core temperature >34°C or 93.2°F. Seek medical direction and follow local protocol. Passive rewarming is taking measures to prevent further heat loss and giving the patient’s body the optimum chance to rewarm itself. Passive rewarming includes inhibiting further heat loss by wrapping the patient in blankets and then increasing the heat in the patient compartment of the ambulance (Figure 24-11). All hypothermic patients should receive passive rewarming.

Do not allow the patient to consume stimulants, including tobacco, coffee, or alcohol.

Never rub or massage the patient’s arms or legs. You could force cold venous blood into the heart, resulting in cardiac irritability or cardiac arrest.

Transport as quickly as possible. The safest rewarming takes place at a medical facility, so transport is the most important factor.

Emergency Medical Care for Immersion Hypothermia

In general, patients with immersion hypothermia should be treated the same as patients with generalized hypothermia with the following steps also taken:

1. Instruct the patient to make the least effort needed to stay afloat until you reach him. Turbulence and activity in the water decrease survival time by about 75 percent. If the patient continues to move or struggle, he will cool more quickly because of the increase in the movement of cold water molecules next to the skin and around the body.

2. Lift the patient from the water in a horizontal or supine position to prevent vascular collapse and provide spinal stabilization if spinal injury is suspected.

3. Remove the patient’s wet clothing carefully and gently. Excessive activity can cause the heart to go into ventricular fibrillation. If it is too difficult to remove the clothing, cut it off and layer dry, warm materials around the patient.

Continue treatment as you would for a patient with generalized hypothermia.

Signs and Symptoms of Local Cold Injury. Local cold injury can be difficult to assess. While still frozen, even severely affected tissue may appear almost normal with purplish or other abnormal colors appearing only with thawing. The tissue may be completely numb when frozen but will be painful—burning, stinging, and throbbing before it freezes and as it thaws. While you may not be able to assess its severity accurately, you can almost always see a clear demarcation at the site of a local cold injury.

The signs and symptoms of early or superficial local cold injury include the following:

- Blanching of the skin (when you palpate the skin, normal color does not return)
- Loss of feeling and sensation in the injured area
- Continued softness of the skin in the injured area and in the tissue just beneath it
- Tingling sensation during any rewarming

The signs and symptoms of late or deep local cold injury include the following:

- White, waxy skin
- A firm-to-frozen feeling when the skin is palpated
- Swelling
- Blisters
- If partially or wholly thawed, the skin appears flushed with areas of purple and blanching or the skin appears mottled and cyanotic

Emergency Medical Care for Local Cold Injury

The key to emergency care for local cold injury is never to thaw the tissue if there is any possibility of its refreezing. Always seek medical direction and follow local protocol. General guidelines for care include the following:

1. Remove the patient immediately from the cold environment, if possible.

2. Never initiate thawing procedures if there is any danger of refreezing. Keeping the tissue frozen is less dangerous than submitting it to refreezing.

3. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. If signs of hypoxia or respiratory distress are present, the SpO2 reading is less than 94%, or an SpO2 reading is unobtainable, apply a nasal cannula at 2 to 4 lpm. (The SpO2 reading may provide an inaccurate reading or no reading because of the severe peripheral constriction of
vessels and lack of adequate perfusion from the cold in the extremities.)

4. Prevent further injury to the injured part.
   - If the patient has an early or superficial injury:
     - Carefully remove any jewelry or wet or restrictive clothing to prevent causing further injury. If clothing is frozen to the skin, leave it in place.
     - Immobilize the affected extremity to prevent movement and elevate. No part of the injured extremity should be in direct contact with a hard surface.
     - Cover the affected skin with dressings or dry clothing to prevent friction or pressure.
     - Never rub or massage the affected skin.
     - Never re-expose the injured skin to the cold.
   - If the patient has late or deep injury:
     - Carefully remove any jewelry or wet or restrictive clothing to prevent causing further injury. If clothing is frozen to the skin, leave it in place.
     - Cover the affected skin with dressings or dry clothing to prevent friction. Avoid pressure.
     - Do not break any blisters or treat them with salve or ointment.
     - Do not rub or massage the affected skin.
     - Never apply direct heat to rewarm the affected part.
     - Do not allow the patient to walk on an injured extremity.

If you are in a wilderness situation or are facing an extremely long or delayed transport, you should initiate active, rapid rewarming of the injured tissue, provided you will be able to keep it thawed. In such circumstances, contact medical direction or follow local protocol. Do not thaw tissue and then allow it to refreeze, because this will completely destroy the tissue. It is also a mistake to thaw frozen tissue gradually; thaw the tissue as rapidly as feasible without causing accidental burning. Slow rewarming has been associated with increased tissue loss.

Rewarming frozen tissue is extremely painful for the patient, and medical direction may want him to take an analgesic, such as aspirin or a nonaspirin product, to help relieve pain during the process. Contacting ALS providers can administer intravenous analgesics to help manage pain.

To rewarm frozen tissue, follow these steps:

1. **Immerse the affected tissue in a warm-water bath** (Figure 24-12). The water temperature should be just above body temperature (ideally 104°F). Never use dry heat as it is too difficult to control the temperature.

2. **Monitor the water to make sure it stays at an even temperature.** If possible, use a thermometer. (Water that is too hot can inflict a burn injury.) Keep the water warm by adding warm water. Never heat cooled water with any type of flame or electric unit.

3. **Continuously stir the water to keep heat evenly distributed and constant about the frozen extremity.**

4. **Keep the tissue in warm water until it is soft and color and sensation return to it.** The affected skin should turn a deep red or bluish color, and the skin should be soft and pliable.

5. Following the thawing process, **dress the area with dry sterile dressings.** If the affected area is a hand or foot, place dry sterile dressings between the toes and fingers. Once the skin is thawed, anything that contacts it, including water, must be sterile.

6. **Elevate the affected extremity.**

7. **Protect against refreezing of the warmed part.**

8. **Transport as soon as possible.** Maintain a warm ambient temperature in the patient compartment of the ambulance. ALL patients with frozen tissue require hospitalization.

**Reassessment**

During the reassessment of cold emergency patients, it is important to carefully reassess the patient’s mental status. A decreasing mental status will indicate deterioration in the patient’s condition. Closely monitor the airway and breathing. The breathing rate and depth may continue to decrease to a point of inadequacy where positive pressure ventilation with supplemental oxygen may be required. The pulses may also continue to decrease. Be prepared to begin CPR or to stop the ambulance to defibrillate the patient as warranted. Inspect the skin for changes in color and temperature. The patient may begin to feel sensations and pain if being rewarmed. Repeat and record the baseline vital signs every 5 minutes. Keep the patient warm and try not to re-expose him to the cold.

**Summary: Assessment and Care—Cold Emergency**

To review assessment findings that may be associated with a cold emergency and emergency care for a cold emergency, see Figures 24-13 and 24-14.
**COLD EMERGENCY**

The following findings may be associated with a cold emergency.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Unstable ice
- Water hazards
- Source of cold exposure
- Ambient temperature
- Wind chill
- Wet clothing
- Alcohol or drugs
- Suspected head or spinal injury
- Exposed areas of skin

**Primary Assessment**

**General Impression**

Is the patient dressed appropriately for the weather?
- Stiff posture
- Staggering or incoordination
- Drowsy or irrational appearance
- Shivering may be apparent if body core temperature is above 90°F or absent if body core temperature is below 90°F.

**Mental Status**

Alert to unresponsive based on body core temperature

**Airway**

Potentially closed airway if mental status is altered

**Breathing**

Initially fast and normal depth, becoming shallow and slow as body temperature decreases

**Circulation**

Pulses may be difficult to find and assess.
- Heart rate is usually increased initially.
- Heart rate decreases as body temperature continues to decrease.
- Skin is red early, becoming pale, cyanotic, and mottled as body temperature drops; skin becomes cold to touch.

**Status:**

Priority patient if generalized cold injury (hypothermia) is suspected

**Secondary Assessment**

**Signs and symptoms of generalized cold injury:**

- Decreasing mental status

- Decreasing motor and sensory function
- Changes to vital signs

**Signs and symptoms of local cold injury—early or superficial:**

- Blanching of skin
- Loss of feeling or sensation in injured area
- Underlying tissue remains soft
- Tingling sensation when rewarmed

**Signs and symptoms of local cold injury—late or deep:**

- White, waxy skin
- Underlying tissue is firm and hard to touch
- Blisters
- Swelling
- Skin purple, blanched, mottled, or cyanotic if thawed

**History**

Did the patient ingest alcohol or drugs?
Does the patient have a circulatory disorder, cardiac disorder, or other medical condition?
How long has the patient been exposed to the cold?

**Physical Exam**

**Head, neck, and face:**

Pupils may be dilated, sluggish to respond to light
- Slurred speech
- Difficulty forming words and moving mouth
- Red, blanched, cyanotic, or white and waxy if exposed

**Abdomen:**

Cold to touch

**Extremities:**

- Stiff and rigid
- Lack of coordination
- Shivering (body core temperature above 90°F)
- Reduced sensation
- Blanched skin that remains soft to touch (superficial local cold injury)
- Skin white, waxy, cyanotic, swelling, blisters, cold, and firm (deep local cold injury)

**Baseline Vital Signs—Generalized Cold Injury**

BP: normal early, continues to decrease, may be absent
HR: increased early, becoming decreased and barely palpable as body core temperature continues to drop
RR: initially increased, decreases as body continues to cool
Skin: red early, becoming pale, cyanotic, gray, waxy, and firm to touch late
Pupils: dilated; sluggish to respond to light
\( \text{SpO}_2 \): in severe cases will not produce a reading because of the severe peripheral vasoconstriction
Emergency Care Protocol

GENERALIZED COLD EMERGENCY

1. Remove the patient from the cold environment and remove all wet clothing. Prevent further heat loss.
2. Establish and maintain an open airway.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen to maintain an SpO₂ of ≥94%. If possible, deliver warm humidified oxygen.
6. If no pulse is present, apply the AED. Defibrillate and perform CPR. Contact medical direction for further orders.

LOCAL COLD EMERGENCY

1. If you suspect a decreased body core temperature, follow the “Generalized Cold Emergency” protocol before proceeding with the “Local Cold Injury” protocol.
2. Remove the patient from the cold environment and remove all wet clothing; prevent further heat loss.
3. Remove jewelry and wet or restrictive clothing. (Do not remove clothing that is frozen to the skin.)
4. Cover affected skin with dry sterile dressings.
5. For early or superficial injury:
   • Immobilize affected extremity.
   • Do not rub or massage.
   • Do not re-expose to cold.
6. For late or deep injury:
   • Do not rub or massage.

7. If required or instructed to rewarm, follow these guidelines:
   • Immerse affected tissue in warm water bath at 104°F.
   • Monitor water and stir to keep at constant temperature.
   • Keep immersed until color returns and skin and underlying tissue become soft.
   • Dress affected area.
   • Elevate involved extremity. Avoid contact with hard surfaces.
   • Protect against refreezing.
8. Transport.

E X P O S U R E T O H E A T

Just as exposure to cold can produce a variety of medical problems, so too can exposure to heat. Problems created by heat exposure can range from mild discomfort to life-threatening emergencies.

Hyperthermia

Heat-related emergencies are grouped under the name hyperthermia. They are brought on by an increase in the body’s heat production or by an inability to eliminate the heat produced. Most heat injuries occur early in the summer season, before people have acclimated themselves to the season’s higher temperatures. Various stages of hyperthermia are commonly called “heat cramps,” “heat exhaustion,” and “heat stroke.”

Pathophysiology of Heat-Related Emergencies

- **Heat Cramps.** The least serious form of heat-related injury is muscle spasms, or cramps, that are thought by some researchers to result from the body losing too much salt during profuse sweating. The cramping is made worse when not enough salt is taken into the body, when calcium levels are low, or when too much water is consumed by the patient. Such cramping is occasionally caused by overexertion of muscles, inadequate stretching or warm-up, and lactic acid buildup in poorly conditioned muscles. This condition is referred to as “heat cramps.” Heat cramps characteristically occur to the large flexor muscle groups of the body first, such as the abdominal muscles, gluteus muscles, and hamstrings (large flexor muscles surrounding the femur).
Emergency Care Algorithm

COLD EMERGENCY

Mechanism of injury present?

Yes
Consider manual in-line stabilization
Assess mental status
Alert and able to obey commands
Consider oxygen administration
Assess circulation
Secondary Assessment
Place patient in position of comfort
If generalized moderate to severe hypothermia suspected, actively rewarm by applying hot packs to armpits, groin, and chest
Frostbite suspected?
Yes
Remove jewelry and restrictive clothing
Cover affected area with dry sterile dressings
Elevate injured extremity
Do not rub or massage affected area
Immerse in water bath only if transport delayed
Remove wet clothing
Place ambulance heater on high
Wrap patient in warm blankets
Transport
Reassessment
No

No

Assess mental status
Alter ed or unresponsive
Airway open?
Yes
Suction if necessary
Head-tilt, chin-lift or jaw-thrust maneuver
Oro- or nasopharyngeal airway
Assess breathing
Adequate
Inadequate
Administer oxygen
PPV with O₂
Assess circulation
Rapid secondary assessment
Lateral recumbent position (no spinal injury)
If generalized moderate to severe hypothermia suspected, perform active rewarming as in sequence

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

FIGURE 24-14  Emergency care algorithm: cold emergency.
Heat cramps are caused by electrolyte imbalance to the muscles, most commonly from overexertion in hot temperatures with excessive diaphoresis (sweating).

Heat cramps are the mildest form of the heat emergency and are rapidly identified by muscle spasms and pain to the large flexor muscles of the body.

**Heat Exhaustion.** Extreme physical exertion in a hot, humid environment can affect even an otherwise fit individual. It can produce a disturbance of the body's blood flow, resulting in a mild state of shock. This is brought on by the pooling of blood in the vessels just below the skin resulting from vaso-dilation as the body works to increase heat loss, but in extreme cases this can also cause excessive blood flow away from the major organs of the body. Prolonged and profuse sweating causes the body to lose large quantities of salt and water. When these are not adequately replaced, blood circulation diminishes, affecting the brain, heart, and lungs. This condition is referred to as “heat exhaustion.” *In such cases, a patient’s skin will be normal to cool in temperature, either pale or ashen gray in color, and sweaty.* In summary, heat exhaustion is thought to occur when the body has maximized the heat-dissipating mechanisms to a point where other body systems are starting to dysfunction.

Heat exhaustion occurs when the body’s cooling mechanisms have been expended, and the central nervous system and other systems are starting to show the consequences of this depletion.

**Heat Stroke.** If measures are not taken to remove the patient to a cool environment or to stop the physical activity and replace lost fluid, the hyperthermic patient’s condition can deteriorate into an extreme form of hyperthermia called “heat stroke.” This is a life-threatening medical emergency with a mortality ranging from 20 to 80 percent. It occurs when the body’s heat-regulating mechanisms break down and become unable to cool the body sufficiently. The body becomes overheated, body temperature rises, and sweating ceases in about half the patients. Because no cooling takes place, the body stores increasingly more heat, the heat-producing mechanisms speed up, and eventually the brain cells are damaged, causing permanent disability or death. Such patients are commonly unresponsive, and the skin will be hot and red; it may be either moist or dry, since about half the patients in this stage of hyperthermia sweat while about half cease to sweat.

The patient with heat stroke does not have to first suffer from heat cramps or heat exhaustion. Heat stroke can occur independently and can be more than an extreme type of heat exhaustion. Classic non-exertional heat stroke (NEHS) occurs typically to elderly patients with sedentary lifestyles, patients who are chronically ill or are on medications inhibiting the temperature-sensing ability of the body, or patients who live in regions of the country that rarely experience heat waves. Exertional heat stroke (EHS) commonly occurs to younger individuals who are engaged in strenuous physical exertion in a very hot environment for prolonged periods. In either instance, heat stroke is a dire medical emergency that carries with it high morbidity and mortality rates if treatment is delayed or inappropriate (up to 80 percent, as previously noted). With effective and timely treatment, morbidity and mortality drops to 10 percent.

Heat stroke occurs when the thermoregulatory mechanism of the body fails to sense and compensate for elevations of the core temperature, and an extremely high core temperature results.

Heat stroke should always be considered in a patient with a heat-related emergency coupled with unresponsiveness.

**Predisposing Factors**

Several factors can predispose an individual to heat-related injuries. They include the following:

- **Climate.** Hot temperatures reduce the body’s ability to lose heat by radiation; high humidity reduces the body’s ability to lose heat by evaporation.
- **Exercise and strenuous activity.** They can cause the loss of more than one liter of sweat per hour and increase heat production (Figure 24-15). Exertional heat stroke is the second leading cause of death in high school students, surpassed only by accidental spinal cord injuries.
- **Age.** Individuals at the extremes of age, such as the elderly and infants (especially newborns), have poor ability to regulate body temperature. Elderly patients often take medications that increase the risk of heat
injury and may lack the mobility to escape a hot environment. Infants cannot remove their clothing if they get too hot.

- **Preexisting illnesses.** Including the following:
  - Heart disease
  - Kidney disease
  - Cerebrovascular disease
  - Parkinson disease
  - Thyroid gland disorders
  - Skin diseases, including eczema, scleroderma, and healed burns
  - Dehydration
  - Obesity
  - Infections or other conditions that cause fever
  - Fatigue
  - Diabetes
  - Malnutrition
  - Alcoholism
  - Mental retardation
  - Peripheral vascular disease

- **Certain drugs and medications.** Including alcohol, cocaine, amphetamines, diuretics, barbiturates, hallucinogens, and medications that hamper sweating and increase heat production.

- **Lack of acclimation.** It may take days to weeks to acclimate to a consistently hot environment, especially with a high humidity. Prior to acclimation, the patient is prone to suffering a heat emergency.

### Assessment-Based Approach: Heat-Related Emergency

#### Scene Size-up

Scan the scene for evidence that the patient is suffering from a heat-related emergency. Probably the most important factors to consider are the ambient temperature and humidity. High temperatures, especially if greater than 90°F, and relative humidity greater than 75 percent, combine to create an environment that renders the body’s cooling mechanisms less effective (Figure 24-16).

Exercise and activity are common precursors to heat-related emergencies. Look for clues to the patient’s activities prior to the incident. Where is he found? If you find someone lying in a flower bed in the middle of a humid August afternoon with gardening tools at his side, you could assume that he had been working outside in the hot sun before collapsing.

A person’s clothing can also give clues to his activity. If you receive a call to assist a patient in the park in mid-July and find someone dressed in jogging shorts and running shoes, you might assume that he was exercising before the incident. You might find a patient collapsed in a cool, air-conditioned home on a summer day. If he is wearing jogging shorts and running shoes, you might at least suspect that he was outside exercising, felt ill,
and returned home to call EMS. Reports of an ill or collapsed patient at an outdoor sporting event held in hot, humid weather should also make you suspect possible heat emergency.

Infants and children left in closed vehicles or in structures that are hot and poorly ventilated are prone to heat emergencies, especially if the infant or child is over-dressed and too young to remove his own clothing. Elderly patients, especially those who are not mobile enough to escape their hot environments, are also likely to become victims of a heat emergency.

Look for medications, alcohol, or drugs since these may precipitate a heat-related emergency.

During the scene size-up, recognize your own limits and protect yourself from overexposure to the heat. Dress appropriately and be sure to drink enough water to stay hydrated. If you are on standby at a public event held during the summer or if you have to walk long distances carrying heavy gear on a hot, humid day, you will be exposed to the same environmental extremes as the patients you are expected to treat.

Primary Assessment

While gathering a general impression of the patient, determine if he is dressed inappropriately for the hot environment. The mental status of the patients you encounter in heat emergencies may range from alert and oriented to completely unresponsive. The patient may complain of dizziness or may have fainted prior to your arrival. The mental status may deteriorate as the condition worsens.

Assess the airway and breathing. Closely monitor the airway. If the breathing is adequate, provide supplemental oxygen if the SpO₂ is <94%; the SpO₂ is unobtainable; or signs of hypoxia, hypoxemia, poor perfusion, or heart failure are present. If the breathing is inadequate, begin positive pressure ventilation with supplemental oxygen.

The patient’s radial pulse may be weak and rapid or absent, depending on the level of dehydration. The skin may be moist and pale with a normal-to-cool temperature or hot and dry or moist. The patient with altered mental status who has hot skin should be considered a priority patient.

Secondary Assessment

If the patient is found in a hot environment, move him to a cool environment as quickly as possible. If the patient is responsive, gather a history, paying particular attention to the symptoms of which the patient complains. The OPQRST can be modified to gather further information about some of the symptoms. Pay particular attention to medications the patient may be taking, since some can contribute to the heat emergency. Be sure to determine the patient’s last oral intake, especially consumption of water or other liquids. Get a description of events that preceded the incident. Conduct a physical exam, targeting areas of complaint that were gathered during the history.

The baseline vital signs may reveal a blood pressure that is normal or low. The heart rate and respirations are typically elevated in heat emergencies. Pulses may be bounding or weak. Skin could be cool, normal, or hot to the touch and either moist or dry. Hot skin is most alarming, since it indicates the most severe type of heat emergency.

If the patient is unresponsive, conduct a physical exam, take baseline vital signs, and then gather the history from family or bystanders.

Signs and Symptoms of Generalized Hyperthermia. The general signs and symptoms of heat-related injuries include the following (Figure 24-17 ●):

- Elevated core temperature
- Muscle cramps
- Weakness or exhaustion
- Dizziness or faintness
- A rapid pulse that is usually strong at first, but becomes weak
- Initial deep, rapid breathing that becomes shallow and weak as damage progresses
- Headache
- Seizures
- Loss of appetite, nausea, or vomiting
- Altered mental status, possibly unresponsiveness
- Skin that is either moist and pale with a normal-to-cool temperature, or hot and either dry or moist (Hot skin that is either dry or moist represents a dire medical emergency.)

Emergency Medical Care for a Heat Emergency Patient with Moist, Pale, Normal-to-Cool Skin

For a patient whose skin is moist and pale, with normal-to-cool skin temperature, provide the following care:

1. Move the patient to a cool place, such as the back of an air-conditioned ambulance, away from the source of heat. If no cooler location is immediately available, at least move the patient into the shade.

2. Maintain adequate oxygenation. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and no signs or symptoms of hypoxia, hypoxemia, poor perfusion, respiratory distress, or heart failure are present, oxygen may not be necessary. If signs of hypoxia, hypoxemia, respiratory distress, poor perfusion or heart failure are present or the SpO₂ reading is less than 94%, apply a nasal cannula at 2 to 4 lpm to achieve and maintain the SpO₂ reading at or above 94%. Provide positive pressure ventilation if needed.

3. Remove as much of the patient’s clothing as you can; loosen what you cannot remove. The patient should be kept as comfortable as possible.
4. **Cool the patient by applying cold, wet compresses and/or by misting the patient with water and then fanning lightly** (Figure 24-18 ■). You want to help cool the patient, but make sure he does not get chilled in order to prevent shivering, which increases heat production.

5. **Place the patient in a supine position.** Consider raising the feet and legs 8 to 12 inches in an attempt to improve blood circulation to the brain and other core organs by reducing pooling in the lower extremities.

If the patient is nauseated or vomiting, place the patient in a lateral recumbent position.

6. **If the patient is fully responsive and is not nauseated, have him drink cool water.** Consult with medical direction and follow local protocol.

7. **If the patient is unresponsive or has an altered mental status or is vomiting, do NOT give fluids.**

8. Generally, a hyperthermic patient with moist, pale skin that is normal to cool in temperature needs transport when the patient:
   - Is unresponsive or has an altered mental status
   - Is vomiting or is nauseated and will not drink fluids
   - Has a history of medical problems
   - Has a core temperature above 101°F
   - Has a continuously rising temperature
   - Does not respond to therapy (symptoms do not improve)

---

**Emergency Medical Care for a Heat Emergency Patient with Hot Skin That Is Moist or Dry**

A patient with hot skin that is either moist or dry represents a dire medical emergency. Cooling the patient takes priority over everything other than airway, breathing, and circulatory management. Provide the following care:
1. **Remove the patient from the source of heat and place him in a cool environment**, such as an air-conditioned room or ambulance. If nothing else, move the patient out of the sun and into the shade.

2. **Remove as much of the patient’s clothing as is possible or reasonable.**

3. **Maintain adequate oxygenation.** If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and no signs or symptoms of hypoxia, hypoxemia, poor perfusion, respiratory distress, or heart failure are present, oxygen may not be necessary. If signs of hypoxia, hypoxemia, respiratory distress, poor perfusion or heart failure are present or the SpO₂ reading is less than 94%, apply a nasal cannula at 2 to 4 lpm to achieve and maintain the SpO₂ reading at or above 94%. Provide positive pressure ventilation if needed.

4. **Immediately begin to cool the patient.** Generally, one method alone will not effectively cool the patient, so use a combination of the following (Figure 24-19):

   - Pour tepid water over the patient’s body. Avoid the use of cold water since this may stimulate peripheral thermoreceptors and produce reflexive vasoconstriction and shivering.
   - Place cold packs in the patient’s groin, at each side of the neck, in the armpits, and behind each knee to cool the large surface blood vessels.
   - Fan the patient aggressively or direct an electric fan at the patient.
   - Keep the patient’s skin wet to promote cooling through evaporation.

5. Because the patient’s entire body is involved in the heat emergency, several complications may result from the condition or from the treatment of it. **Be prepared to manage seizures or prevent the aspiration of vomitus.**

6. Transport immediately, continuing to administer oxygen and cooling methods during transport. **Always transport a hyperthermic patient with hot skin that is moist or dry.** Such a patient always needs further emergency care. Consider early ALS intercept.

### Emergency Medical Care for Heat Cramps

As mentioned earlier, one of the symptoms of a heat emergency is muscle cramping. In some patients with the mildest hyperthermia, cramping may be the only symptom. Cramping typically occurs to the muscles of the legs and abdomen.

To treat a patient with heat cramps:

1. **Remove the patient from the source of heat to a cool environment.** If nothing else, move the patient out of the sun and into the shade.

2. **Consult medical direction before giving the patient sips of low-concentration salt water** at the rate of half a glassful every 15 minutes. If possible, use a commercial product, such as Gatorade, with a low glucose content. Salt water is made by diluting one teaspoon of salt in one quart of water. Do not give the patient salt tablets. If in question, either follow local protocol or contact medical direction.

3. **Apply moist towels to the patient’s forehead and over the cramping muscles.** Try to gently stretch the involved muscle groups. Some experts advise massaging the involved muscles if it does not cause additional pain. Consult with medical direction and follow local protocol.

4. **Explain to the patient what happened so be can avoid a recurrence of the problem.** Advise the patient to avoid exertion for 12 hours.

   Generally, you need to transport a patient with heat cramps only if the patient has other illnesses or injuries, develops other symptoms, or does not respond to your care and deteriorates.

### Reassessment

During the reassessment, reevaluate the mental status, airway, breathing, circulation, baseline vital signs, and treatment. The mental status may continue to deteriorate if the body temperature continues to rise. The mental status may improve once the patient is cooled and treatment is initiated. Closely reassess the airway and breathing. Be prepared to establish an airway and to provide positive pressure ventilation if breathing becomes inadequate, especially in patients with hot skin. Also, be prepared to manage seizures with such patients.

The pulse may continue to weaken, or the rate may increase further. Correlate changes in the pulse rate with the patient’s mental status. If the pulse is decreasing and the mental status improving, it is a sign that the treatment is proving effective. If the pulse is rapidly increasing or decreasing and the patient’s mental status is declining, it...
is a grave indication that the patient is deteriorating. Re-assess and record the vital signs every 5 minutes. Report your assessment to the receiving hospital.

Summary: Assessment and Care—Heat Emergency

To review assessment findings that may be associated with a heat emergency and appropriate management for heat-related emergencies, see Figures 24-20 and 24-21.

HEAT EMERGENCY

The following findings may be associated with a heat emergency.

Scene Size-up

Pay particular attention to your own safety. Look for:
- High ambient temperatures, usually greater than 90°F
- Humidity greater than 75 percent
- Evidence of exercise or other activity
- Patient’s clothing

Primary Assessment

General Impression
- Is the patient dressed appropriately for the weather?
- Excessive sweating or excessively dry skin
- Dizziness or fainting

Mental Status
- Alert to unresponsive based on body core temperature

Airway
- Potentially closed airway if mental status is altered

Breathing
- Initially fast and normal depth; becoming shallow and slow as body temperature increases

Circulation
- Heart rate is increased.
- Bradycardia may occur very late.
- Skin may be excessively dry or wet, but may be extremely hot (heat stroke).
- Skin may be moist, pale, and normal to cool (heat exhaustion).
- Status: Priority patient if hot skin, whether moist or dry, or altered mental status is present.

Secondary Assessment

History
- Signs and symptoms:
  - Dizziness and weakness
  - Headache
  - Nausea and/or vomiting
  - Seizures
  - Muscle cramps
  - Hot, dry, or moist skin
  - Pale, cool, and moist skin
  - Altered mental status
  - Did the patient ingest alcohol or drugs?
  - Does the patient have a circulatory disorder, cardiac disorder, or other medical condition?
  - How long has the patient been exposed to the heat?

Physical Exam
- Head, neck, and face:
  - Pupils may be dilated and sluggish to respond to light
  - Slurred speech
  - Headache
- Extremities:
  - Muscle cramps
  - Hot skin that is dry or moist (priority patient)
  - Cool, pale, and moist skin

Baseline Vital Signs—Heat Emergency
- BP: normal to decreased
- HR: increased; may decrease very late if body core temperature becomes excessively high
- RR: initially increased; may decrease if body core temperature continues to rise excessively
- Skin: may be hot, dry, or cool (priority patient) or cool, moist, and pale
- Pupils: midsize to dilated; sluggish to respond
- SpO2 ≥94%: core temperature may be normal, lowered, or elevated.

Bites and Stings

Many people who venture into the outdoors fear the possibility of a snakebite. But, in fact, such bites are relatively uncommon and the number of people who die from a snakebite each year is extremely small. Still, the possibility of death or crippling injury from a snakebite does exist and you should be prepared to deal with the situation if you encounter it.

Insect bites and stings are far more common, and luckily most are considered minor. It is only when the patient has an allergic reaction and runs the risk
Emergency Care Protocol

HEAT EMERGENCY

1. Remove the patient from the hot environment and remove clothing. Prevent further heat gain.
2. Establish and maintain an open airway; insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen to maintain an SpO₂ of ≥94%.
6. Turn up the air conditioner to maximum in the back of the ambulance.

7. If skin is cool, moist, and pale (heat exhaustion), do the following:
   • Cool patient by applying cold, wet compresses; fan lightly.
   • Place patient in supine position with legs elevated 8–12 inches.
   • If patient is vomiting, place in lateral recumbent position.
   • If patient is responsive and not nauseated, administer water by mouth at a half glass every 15 minutes.
8. If skin is hot and dry or moist (heat stroke), do the following:
   • Pour cool water over patient.
   • Place cold packs in armpits, behind each knee, and at side of the neck.
   • Fan patient aggressively.
   • If patient shivers, slow cooling process.
   • Be prepared to manage seizures.
10. Perform a reassessment every 5 minutes.

FIGURE 24-20b  Emergency care protocol: heat emergency.

Snakebite

About 45,000 people per year are bitten by snakes in the United States; of those, 7,000 receive bites from one of the two types of poisonous snakes: coral snakes and pit vipers (rattlesnakes, copperheads, and water moccasins). More than half the poisonous snake bites involve children, and most occur between April and October during daylight hours.

The bites of nonpoisonous snakes are not considered serious and are generally treated as minor wounds; only bites of poisonous snakes are considered medical emergencies. In only about a third of the cases of bites by poisonous snakes do the snakes inject venom into the victim. When venom is injected, symptoms generally occur immediately. If it is difficult to delineate the poisonous from nonpoisonous snakebite based on the patient’s description of the snake or the appearance of the bite wound, assume the bite was from a poisonous snake and provide care as appropriate.

A poisonous snakebite is characterized by one or two distinct puncture wounds (Figure 24-22 ). The exception is the coral snake, which leaves a semicircular pattern with its teeth as it “chews” the skin. Most poisonous snakes have the following characteristics:

• Large fangs; nonpoisonous snakes have small teeth. The exception is the coral snake, a poisonous snake that does not have fangs.
• Elliptical pupils or vertical slits, much like those of a cat; nonvenomous snakes have round pupils.
• A pit between the eye and the mouth.
• A variety of different-shaped blotches on backgrounds of pink, yellow, olive, tan, gray, or brown skin. The exception is the coral snake, which is ringed with red, yellow, and black.
• A triangular head that is larger than the neck.

The signs and symptoms of a pit viper bite generally occur immediately; those of a coral snake bite are usually delayed by at least 1 hour and as many as 8 hours. The severity of a pit viper bite, depending on how much poison was injected, is gauged by how rapidly symptoms develop (Figure 24-23 ). Other factors that determine the severity of a snakebite include the following:

• The location of the bite, since fatty tissue absorbs the venom more slowly than muscle tissue
• Whether pathogens (organisms or substances capable of causing disease) are present in the venom
• The patient’s size and weight
• The patient’s general health and condition
• How much physical activity the patient engaged in immediately following the bite, since physical activity will spread the venom
Emergency Care Algorithm

**HEAT EMERGENCY**

1. Mechanism of injury present?
   - Yes
     - Consider manual in-line stabilization
   - No
     - Assess mental status

2. Alert and able to obey commands
   - Consider oxygen administration
   - Assess circulation

3. Altered or unresponsive
   - Airway open?
     - Yes
       - Suction if necessary
       - Head-tilt, chin-lift or jaw-thrust maneuver
       - Oro- or nasopharyngeal airway
     - No
       - Assess breathing

4. Assess breathing
   - Adequate
     - Administer oxygen
     - Assess circulation
     - Rapid secondary assessment
     - Lateral recumbent position (no spinal injury)
   - Inadequate
     - PPV with O₂
     - Rapid secondary assessment
     - Lateral recumbent position (no spinal injury)

5. Skin findings
   - Hot, dry, or moist
     - Heat stroke
     - Actively cool patient with cold packs, cool water, air conditioner, and fanning
   - Moist, pale, and cool
     - Heat exhaustion
     - Passively cool by applying wet compresses, and fanning patient

6. Alert and not nauseated?
   - Yes
     - Give water to drink
     - Half glass every 15 minutes
     - Transport
   - No
     - Reassessment

**PPV = positive pressure ventilation**
**Cream = assessment**
**Green = key decision points**
**Blue = interventions**

**FIGURE 24-21** Emergency care algorithm: heat emergency.
Black Widow Spider

The black widow spider is characterized by a shiny black body, thin legs, and a crimson red marking on its abdomen, usually in the shape of an hourglass or two triangles. Of the five species in the United States, only three are black, and not all have the characteristic red marking.

The female black widow spider, larger than the male, is one of the largest spiders in the United States. Males generally do not bite; females bite only when hungry, agitated, or protecting the egg sac. The black widow spider is usually found in dry, secluded, dimly lit areas; it has an extremely strong, funnel-shaped web. They are generally nocturnal, and it is said that they avoid human dwellings. They have been found, however, in outhouses and garages or sheds.

Black widow spider bites are the leading cause of death from spider bites in the United States. Those at highest risk for developing severe reactions to the bites are children under the age of 16, people over the age of 60, people with chronic illness, and anyone with hypertension.

In addition to the general signs and symptoms of bites and stings, black widow spider bites cause the following:

- A pinprick sensation at the bite site, becoming a dull ache within about 30 minutes
- Severe muscle spasms, especially in the shoulders, back, chest, and abdomen
- Rigid, boardlike abdomen
- Dizziness, nausea and vomiting, and respiratory distress in severe cases

When treating patients with black widow spider bite, you should usually provide general wound care and transport.

Brown Recluse Spider

The brown recluse spider is generally brown but can range in color from yellow to dark chocolate brown. The characteristic marking is a brown, violin-shaped marking on the upper back. The bite of the brown recluse spider is a serious medical condition: The bite usually does not heal and may require surgical repair (Figure 24-24).

Unfortunately, most brown recluse spider bite victims are unaware that they have been bitten, since the bite is often painless at first. Several hours after the bite, it becomes bluish surrounded by a white periphery, then a red halo or “bull’s-eye” pattern. Within 7 to 10 days, the bite becomes a large ulcer.

Scorpion

Of the three species of scorpion in the United States that sting and inject poisonous venom, the sting of only one is generally fatal. The severity of the sting depends on the amount of venom injected. Ninety percent of all scorpion stings occur on the hands.
In addition to the general signs and symptoms of bites and stings, scorpion stings cause a sharp pain at the injection site, drooling, poor coordination, incontinence, and seizures.

**Fire Ant**

Most common in the southeastern United States, the fire ant gets its name not from its red to black color, but from the intense, fiery, burning pain its bite causes. Fire ants bite down into the skin, then sting downwardly as they pivot; the result is a characteristic circular pattern of bites. Fire ant bites produce extremely painful vesicles that are filled with fluid. At first the fluid is clear; later it becomes cloudy. Fire ant bites can also cause a large local reaction, characterized by swelling, pain, and redness that affect the entire extremity.

**Tick**

Tick bites (Figure 24-25) are serious because ticks can carry tick fever, Rocky Mountain spotted fever, and other bacterial diseases. Lyme disease, usually transmitted by the tiny deer tick but now thought sometimes to be transmitted by the larger dog tick, can cause long-term neurological and other complications if not identified and treated early.

Ticks are visible after they have attached themselves to the skin; they often choose warm, moist areas, such as the scalp, other hairy areas, the armpits, the groin, and skin creases. Many patients are unaware that they have been bitten by a tick.

The only appropriate prehospital treatment for tick bite is prompt removal of the tick, which can help prevent infection. To remove a tick, use tweezers and grasp the tick as close as possible to the point where it is attached to the skin. Pull firmly and steadily until the tick is dislodged. Do not twist or jerk the tick, since that may result in incomplete removal. Never pluck an embedded tick out of the skin, as you may force infected blood into the patient. Avoid squashing an engorged tick during removal, since infected blood may spread contamination. After removal, wash the bite area thoroughly with soap and water and apply an antiseptic.

**Assessment-Based Approach:**

**Bites and Stings**

**Scene Size-up**

Your priority during scene size-up should be to protect yourself and your partner. If your patient has been bitten or stung, you too might fall victim to bites and stings unless you exercise caution.

Rather than going directly to the patient’s side, pause and look and listen for swarming bees or hornets. If they are present, you may have to wait until they disperse before approaching.

When you get to the patient’s side, scan the ground around him carefully, looking for snakes, ant hills, or openings to underground yellow jacket nests. When you begin to examine the patient, be alert to the possibility that insects have become trapped in his clothing and may bite or sting when you move it.

Once your safety is ensured, look around the scene for evidence of what may have bitten or stung the patient. Is an insect nest visible in a nearby tree, or under the eaves of a house, or in the ground nearby? Are there signs that the patient was engaged in activity such as clearing underbrush or gardening that might have disturbed snakes or insects? Was the patient working in a garage, basement, attic, or shed where spiders and other insects might nest? Are there dead insects on the ground around the patient?

**Primary Assessment**

During the primary assessment, gather a general impression of the patient and his mental status. If elements of the scene size-up have led you to suspect the possibility
of bites or stings, be especially alert when assessing the airway and breathing. Remember that some patients have an allergic reaction to bites and stings that can lead to anaphylactic shock, an emergency that generally has a rapid and life-threatening effect on the airway and breathing.

**Secondary Assessment**

If you detect the signs and symptoms of anaphylactic shock listed in the next section, continue with assessment and emergency medical care as described in Chapter 21, “Anaphylactic Reactions,” and in the sections on anaphylactic shock later in this chapter. If the patient displays the more common signs and symptoms of reaction to bites and stings, continue with the assessment as described in the section on injected poisons in Chapter 22, “Toxicologic Emergencies.” Then, provide emergency care as described under “Emergency Medical Care for a Bite or Sting” in this chapter.

**Signs and Symptoms of Anaphylactic Shock.** As noted earlier, anaphylactic shock, a life-threatening medical emergency, may develop following bites or stings. If a patient develops signs and symptoms of this condition, perform the necessary emergency care and transport immediately. Signs and symptoms include the following:

- Hives
- Flushing
- Upper airway obstruction
- Faintness
- Dizziness
- Generalized itching
- Generalized swelling, including eyelids, lips, and tongue
- Difficulty swallowing
- Shortness of breath, wheezing, or stridor
- Labored breathing
- Abdominal or uterine cramps
- Confusion
- Loss of responsiveness
- Convulsions
- Hypotension (low blood pressure)

**Emergency Medical Care for Anaphylactic Shock**

Care for anaphylactic shock is as follows:

1. **Maintain a patent airway.** Suction secretions.
2. **Maintain adequate oxygenation.** If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and no signs or symptoms of hypoxia, hypoxemia, poor perfusion, respiratory distress, or heart failure are present, oxygen may not be necessary. If signs of hypoxia, hypoxemia, respiratory distress, poor perfusion or heart failure are present or the SpO₂ reading is less than 94%, administer oxygen to achieve and maintain the SpO₂ reading at or above 94%. Provide positive pressure ventilation with supplemental oxygen at 10–12 per minute if breathing is (or becomes) inadequate.
3. **Administer epinephrine by a prescribed auto-injector** with permission from medical direction for patients with airway obstruction, wheezing, hypotension, or prior anaphylaxis.
4. **Call for advanced life support.**
5. **Initiate early transport.**

Review the complete description of signs and symptoms and emergency medical care for this condition in Chapter 21, “Anaphylactic Reactions.”

**Signs and Symptoms of a Bite or Sting.** General signs and symptoms of bites and stings include the following:

- History of a bite from a spider or snake, or a sting from an insect, scorpion, or marine animal
- Pain that is often immediate and severe or burning; within several hours the area may become numb
- Redness or other discoloration around the bite
- Swelling around the bite, sometimes gradually spreading
- Weakness or faintness
- Dizziness
- Chills
- Fever
- Nausea or vomiting
- Bite marks
- Stinger

**Emergency Medical Care for a Bite or Sting**

General emergency medical care for bites and stings includes the following steps:

1. **If the stinger is still present, remove it by gently scraping against it** with the edge of a credit card or similar item. Scrape in the direction of the base of the stinger to avoid breaking it off below the skin. Be careful not to squeeze the stinger with tweezers, forceps, or your fingers as doing so can force additional venom from the venom sac into the wound. Make sure you remove the venom sac because it can continue to secrete venom even though the stinger is detached from the insect.
2. **Wash the area around the bite or sting gently with a mild agent or strong soap solution.** If necessary, irri-gate the area with a large amount of sterile saline. Make sure contaminated saline flows away from the body. Never scrub the area.
3. **Remove any jewelry or other constricting objects** as soon as possible, ideally before any swelling begins.
4. **Lower the injection site below the level of the heart.**
5. Apply a cold pack to an insect bite or sting to relieve pain and swelling. Do not apply cold to snakebites or to injuries inflicted by marine animals.
7. Observe the patient carefully for the signs and symptoms of an allergic reaction; in cases of reaction, treat as described in Chapter 21, “Anaphylactic Reactions.”
8. Keep the patient calm, limit his physical activity, and keep him warm. Transport as soon as possible. If the patient shows any signs of allergic reaction, begin transport immediately.

Reassessment

Most important during the reassessment is to monitor the patient’s airway, breathing, and circulation carefully. The signs and symptoms of anaphylactic shock may take minutes to several hours to develop. You should be alert to their appearance and be prepared to provide the emergency medical care for this life-threatening condition as just outlined.

Marine Life Bites and Stings

There are approximately 2,000 poisonous marine animals. While most types live in temperate or tropical waters, some can be found in virtually all waters. Most poisonous marine life is not aggressive; in fact, most cases of such poisoning occur when a person swims into or steps on an animal.

There are two important differences between the bites and stings of marine animals and those of land animals. First, the venom of marine life may cause more extensive tissue damage than that of land animals. Second, venoms of aquatic organisms are destroyed by heat; so heat, not ice, should be applied to marine bites and stings.

In cases of marine life bites and stings, try to identify the animal because some very effective antivenins are available.

Emergency Medical Care for Marine Life Poisoning

In general, bites and stings inflicted by marine life should be treated the same as soft tissue injuries. However, follow these specific guidelines as needed:

- Use forceps to remove any material that sticks to the sting site on the surface of the flesh, then irrigate the wound with water.
- Do not attempt to remove spines that are embedded in joints or that are deeply embedded in skin.
- If the patient was stung by a jellyfish, coral, hydra, or anemone, carefully remove dried tentacles and pour vinegar on the affected area to denature the toxin. If meat tenderizer is available, sprinkle the area with it; doing so will help stop the stinging.
- Apply heat or soak the affected area in hot water for at least 30 minutes or throughout transport.

LIGHTNING STRIKE INJURIES

Lightning strikes cause more deaths per year than any other meteorological phenomenon. Approximately 1,000 to 5,000 people are struck each year in the United States, with 300 to 500 deaths occurring as a result of the strikes. The highest incidence of a lightning strike is in July, followed by August and June. The highest number of reported lightning strikes occur on Sundays. The second highest incidence occurs on Saturday, followed by Wednesday. These months and days reflect an increase in outdoor activities, including work and recreation. Males are more than eight times more likely to be struck by lightning than females. Children who are playing outside or involved in recreational or sporting activities are frequent victims. A majority of the lightning strikes involve only one person. Approximately 70 percent of lightning deaths involve only one person, whereas 15 percent of lightning deaths involve two people, and 15 percent of the deaths involve three or more victims from the same incident.

Many people believe the highest incidence of lightning strikes is on golf courses. Actually, the majority of lightning strikes, approximately 30 percent, occur in work-related situations, while recreational and open field activities account for 27 percent. Approximately 14 percent of lightning strikes occur to people who are standing under trees. Only 5 percent of all lightning strikes occur when playing golf. Interestingly, talking on the telephone accounts for 2.4 percent of lightning strikes. EMS and other public safety call takers and dispatchers commonly use a headset as part of their communication equipment. The number of call takers and dispatchers struck while connected to the headset is 0.7 percent.

Pathophysiology of a Lightning Strike Injury

Lightning is neither alternating current (AC) nor direct current (DC); however, it acts much more like direct current than alternating current. This has many clinical implications. The current associated with a lightning strike is massive. A lightning bolt’s current ranges from 100 million to 2 billion volts with an amperage as high as 200,000. As a point of comparison, standard household current is typically 110–200 volts and 100–200 amps at a breaker box, and 120 volts and 15–20 amps at an outlet. The duration of the lightning strike is 1/100 to 1/1,000 of a second. The speed of a lightning bolt is 1–2 million meters per second. The contact temperature of a lightning bolt is 15,000°F–60,000°F. Even though the contact temperature is so high, the extremely short duration of
time prevents deep internal and external burns to the body. Contrary to a common misconception, lightning injuries are not typically major burn injuries.

Thunder associated with a lightning bolt is produced by a rapid expansion of the air immediately surrounding the bolt. The rapid explosion and implosion of the superheated and then cooled air, which creates the typical thunder sound, has a major effect on a lightning strike victim. The rapid explosion and implosion of air will propel the person, leading to blunt trauma. Also, the rapid change in air pressure can cause pressure changes in the body’s air-containing cavities, leading to damage and possible rupture. Thus, a lightning strike patient is not only a medical patient but also commonly a trauma patient. Head, neck, chest, abdominal, pelvic, spinal, and extremity trauma must be suspected in lightning strike patients. This is a reason to provide complete immobilization to all suspected lightning strike patients.

There are four major lightning strike mechanisms:

- **Direct strike.** Lightning bolt makes direct contact with the patient.
- **Contact strike.** Lightning strikes an object the patient is in contact with.
- **Splash or side flash strike.** Lightning strikes an object and jumps to a nearby person.
- **Ground current or step voltage strike.** Lightning current energizes the ground.

The direct strike carries the highest rate of injury and death. In a ground current, the farther the patient from the strike, the less the injury and other effects suffered by the patient.

The nervous tissue and the heart are most sensitive to lightning strikes. The lightning will overwhelm and short circuit the body’s electrical system. When lightning involves the heart, the heart is depolarized similarly to the depolarization that occurs in a defibrillation. Actually, defibrillation is nothing more than a direct-current shock. If an oscilloscope is present following the defibrillation in a patient, you can note the period of asystole (no rhythm or heart contraction that appears as a flatline on the monitor) following the discharge of energy. The same effect (asystole or ventricular fibrillation) following the discharge of energy. The same effect is created by a lightning strike. The heart is depolarized by the massive discharge of energy through the body. Because the energy is so massive, the asystole lasts for a much longer period of time. Since asystole is a condition where there is no cardiac contraction, the result is cardiac arrest. This is called primary cardiac arrest.

The brain is also very sensitive to the lightning strike. The medulla, which houses the respiratory center, is shut down by the lightning strike, and the patient stops breathing. The muscles in the chest, along with all the other muscles in the body, contract severely and for a long period of time. This is similar to defibrillation when the muscular contraction from the shock causes the patient to “jump.” Again, the main difference is that the chest muscles during defibrillation only contract for a brief period of time, whereas in a lightning strike, muscle contraction can be prolonged. Another consideration is that the severe muscular contraction may propel the patient, causing blunt trauma.

The heart muscle has properties of automaticity, which means that it can stimulate its own impulse without the help of the brain. What commonly happens in a lightning strike patient is that the heart will begin to beat spontaneously on its own without any intervention; however, the inspiratory centers in the medulla of the brain remain dormant for a much longer time. Despite the patient’s heart resuming its beat and regaining a spontaneous pulse, the patient is yet unable to begin to breathe on his own. As the heart beats without any supporting respiration, it begins to circulate severely deoxygenated blood. The heart then becomes hypoxic and acidic. As the hypoxia and acidosis build up, the heart becomes irritable. The irritability may trigger ventricular fibrillation, leading to a secondary cardiac arrest. This patient will be more difficult to resuscitate, since he will be more severely hypoxic and acidic.

You, as an EMT, may arrive on the scene and find that the patient—who was in cardiac arrest without pulses, as witnessed by bystanders—has regained a pulse by the time of your arrival with little or no intervention. However, the patient will still not be breathing spontaneously. In this circumstance, aggressive airway management, ventilation, and oxygenation are necessary.

### Assessment of the Lightning Strike Patient

The body systems affected by a lightning strike and the related signs and symptoms are:

**Nervous System**

- Altered mental status—may range from confusion to unresponsiveness
- Retrograde amnesia—cannot remember events before the incident
- Anterograde amnesia—cannot remember events after the incident
- Weakness—most often in the lower extremities
- Pain, tingling, and numbness
- Pale, cool, and clammy skin—may be mottled or cyanotic
- Temporary paralysis
- Dizziness
- Loss of pupillary function
- Seizures
- Vertigo

Keep in mind that abnormal nervous system findings may be due to head injury from the blunt trauma and not the lightning strike itself.

**Cardiac System**

- Asystole or ventricular fibrillation
- Irregular pulse

---

**Lightning Strike Patient**

Assessment of the Lightning Strike Patient

The body systems affected by a lightning strike and the related signs and symptoms are:

**Nervous System**

- Altered mental status—may range from confusion to unresponsiveness
- Retrograde amnesia—cannot remember events before the incident
- Anterograde amnesia—cannot remember events after the incident
- Weakness—most often in the lower extremities
- Pain, tingling, and numbness
- Pale, cool, and clammy skin—may be mottled or cyanotic
- Temporary paralysis
- Dizziness
- Loss of pupillary function
- Seizures
- Vertigo

Keep in mind that abnormal nervous system findings may be due to head injury from the blunt trauma and not the lightning strike itself.

**Cardiac System**

- Asystole or ventricular fibrillation
- Irregular pulse
Respiratory System
• Respiratory distress
• Apnea—absence of breathing

Skin
• Burns—most often are superficial; partial-thickness and full-thickness burns are typically associated with metal on the patient (e.g., chains, coins, hairpins) heating up and causing the burns
• Linear burns—appear as streaks down the body and are associated with sweat on the surface of the body heating up and causing the burns
• Feathering—not a true burn; appears as a nonblanching, reddish brown fern pattern (Figure 24-26 ■)
• Punctuate burns—appear similar to cigarette burns
• Thermal burns—may occur if the clothing catches on fire

Musculoskeletal
• Dislocations
• Fractures

Both dislocations and fractures occur as a result of either the strong muscular contraction or the patient being propelled by the thunder.

Ophthamlic (Eye)
• Unequal pupils
• Drooping eyelid (ptosis)

Otologic (Ear)
• Ruptured tympanic membrane (eardrum)
• Tinnitus (ringing in the ear)
• Deafness

Emergency Care for the Lightning Strike Patient

When managing a lightning strike patient, remember that a lightning strike is not typically a serious burn injury. Rather, you must manage the patient as a medical patient with nervous system and possibly cardiac rhythm dysfunction and as a trauma patient with possible blunt injury. Emergency care includes the following:

• Ensure that the scene is safe; do not become a lightning strike patient yourself.
• If the patient’s clothes are on fire, put out the fire.
• Establish in-line manual stabilization.
• Establish an airway if the patient has an altered mental status.
• If the patient is in cardiac arrest, immediately begin CPR and attach the AED. Deliver defibrillation based on the analysis and prompts of the AED. Provide aggressive ventilation with a high concentration of oxygen.
• If the patient has a pulse but is not breathing or not breathing adequately, begin aggressive positive pressure ventilation at 10–12 per minute. Supply high concentrations of oxygen while ventilating.
• If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia, hypoxemia, poor perfusion, respiratory distress, or heart failure are present, oxygen may not be necessary. If signs of hypoxia, hypoxemia, respiratory distress, poor perfusion, or heart failure are present or the SpO2 reading is less than 94%, apply a nasal cannula at 2 to 4 lpm to achieve and maintain the SpO2 reading at or above 94%.
• Completely immobilize the patient to a backboard. Stabilize any fractures or dislocations.
• Transport while continuously monitoring the patient’s condition.

HIGH-ALTITUDE SICKNESS

At high altitudes, the pressure of the ambient atmosphere is decreased. As a consequence, the total pressure of oxygen is also decreased, making oxygen less available. An environment with less oxygen may aggravate existing medical conditions, such as angina, congestive heart failure, and respiratory diseases, or it may cause new illnesses to occur. Even healthy individuals can experience illness at a high altitude, especially if the ascent is rapid.

A high altitude is considered to be an altitude above 5,000 feet. At this altitude, the hypoxic environment may be noticeable to the person, but serious illness rarely occurs. An altitude above 8,000 feet is where serious altitude illnesses may present, especially if a rapid ascent is involved. General signs and symptoms of altitude illness are:

• General ill feeling
• Loss of appetite
• Headache
• Disturbance in sleep
• Respiratory distress upon exertion

Respiratory System
• Respiratory distress
• Apnea—absence of breathing

Skin
• Burns—most often are superficial; partial-thickness and full-thickness burns are typically associated with metal on the patient (e.g., chains, coins, hairpins) heating up and causing the burns
• Linear burns—appear as streaks down the body and are associated with sweat on the surface of the body heating up and causing the burns
• Feathering—not a true burn; appears as a nonblanching, reddish brown fern pattern (Figure 24-26 ■)
• Punctuate burns—appear similar to cigarette burns
• Thermal burns—may occur if the clothing catches on fire

Musculoskeletal
• Dislocations
• Fractures

Both dislocations and fractures occur as a result of either the strong muscular contraction or the patient being propelled by the thunder.

Ophthamlic (Eye)
• Unequal pupils
• Drooping eyelid (ptosis)

Otologic (Ear)
• Ruptured tympanic membrane (eardrum)
• Tinnitus (ringing in the ear)
• Deafness

Emergency Care for the Lightning Strike Patient

When managing a lightning strike patient, remember that a lightning strike is not typically a serious burn injury. Rather, you must manage the patient as a medical patient with nervous system and possibly cardiac rhythm dysfunction and as a trauma patient with possible blunt injury. Emergency care includes the following:

• Ensure that the scene is safe; do not become a lightning strike patient yourself.
• If the patient’s clothes are on fire, put out the fire.
• Establish in-line manual stabilization.
• Establish an airway if the patient has an altered mental status.
• If the patient is in cardiac arrest, immediately begin CPR and attach the AED. Deliver defibrillation based on the analysis and prompts of the AED. Provide aggressive ventilation with a high concentration of oxygen.
• If the patient has a pulse but is not breathing or not breathing adequately, begin aggressive positive pressure ventilation at 10–12 per minute. Supply high concentrations of oxygen while ventilating.
• If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia, hypoxemia, poor perfusion, respiratory distress, or heart failure are present, oxygen may not be necessary. If signs of hypoxia, hypoxemia, respiratory distress, poor perfusion, or heart failure are present or the SpO2 reading is less than 94%, apply a nasal cannula at 2 to 4 lpm to achieve and maintain the SpO2 reading at or above 94%.
• Completely immobilize the patient to a backboard. Stabilize any fractures or dislocations.
• Transport while continuously monitoring the patient’s condition.

HIGH-ALTITUDE SICKNESS

At high altitudes, the pressure of the ambient atmosphere is decreased. As a consequence, the total pressure of oxygen is also decreased, making oxygen less available. An environment with less oxygen may aggravate existing medical conditions, such as angina, congestive heart failure, and respiratory diseases, or it may cause new illnesses to occur. Even healthy individuals can experience illness at a high altitude, especially if the ascent is rapid.

A high altitude is considered to be an altitude above 5,000 feet. At this altitude, the hypoxic environment may be noticeable to the person, but serious illness rarely occurs. An altitude above 8,000 feet is where serious altitude illnesses may present, especially if a rapid ascent is involved. General signs and symptoms of altitude illness are:

• General ill feeling
• Loss of appetite
• Headache
• Disturbance in sleep
• Respiratory distress upon exertion
High-altitude sickness can be prevented by ascending gradually, allowing the body time to acclimate, limiting exertion at high altitude, descending to a lower altitude to sleep, and eating a high-carbohydrate diet. Some people may take acetazolamide (Diamox) or nifedipine (Procardia, Adalat) to try to prevent altitude sickness.

**Acute Mountain Sickness**

Acute mountain sickness (AMS) typically occurs in people who rapidly ascend to 6,600 feet or greater. Signs and symptoms could develop from 6 to 24 hours after the ascent.

**Signs and Symptoms**

Signs and symptoms of AMS include:
- Weakness
- Nausea
- Headache
- Shortness of breath
- Light-headedness
- Loss of appetite
- Fatigue
- Difficulty sleeping

Severe signs and symptoms of AMS include:
- Severe weakness
- Decreased urine output
- Vomiting
- Increased shortness of breath
- Altered mental status

These signs and symptoms may worsen if the person ascends higher. Acute mountain illness will often resolve itself within 1 to 2 days if the patient does not ascend any higher.

**Emergency Medical Care**

The primary treatment is to stop the ascent and considering moving the patient down to a lower altitude. Administration of supplemental oxygen may relieve the signs and symptoms. If the case is severe, administer oxygen and move the patient down to a lower elevation. At high altitude, the SpO2 reading is lower than at sea level. An SpO2 of 90% is often considered a normal SpO2 reading or the number to achieve during oxygenation to relieve hypoxia. Follow your local protocol.

**High-Altitude Pulmonary Edema**

High-altitude pulmonary edema (HAPE) is a condition affecting the lungs and gas exchange. Changes in the pressure in the pulmonary vessels cause fluid to be forced out of the capillaries and to collect in and around the alveoli. Children and men are more prone to HAPE. The condition can occur above 8,000 feet; however, it more commonly occurs above 14,500 feet.

**Signs and Symptoms**

Signs and symptoms of HAPE include:
- Shortness of breath at rest
- Cough
- Fatigue
- Headache
- Loss of appetite
- Tachypnea
- Tachycardia
- Cyanosis
- Crackles or wheezing in at least one lobe of the lung
- Weakness

**Emergency Medical Care**

The best emergency care is to move the patient to a lower altitude and administer oxygen. If descent is not possible, administration of oxygen may eliminate the HAPE. This may take 36 to 72 hours to resolve with oxygen therapy alone.

**High-Altitude Cerebral Edema**

High-altitude cerebral edema (HACE) occurs from the collection of an excessive amount of fluid in the brain tissue. This increases the pressure within the skull and puts pressure on the brain. Most cases occur at altitudes above 12,000 feet; however, cases have been reported at 8,200 feet.

**Signs and Symptoms**

Signs and symptoms of HACE include:
- Severe headache
- Uncoordination (ataxia)
- Nausea and vomiting
- Altered mental status
- Seizures
- Coma

**Emergency Medical Care**

The emergency medical care focuses on immediately moving the patient to a lower altitude and administering oxygen. If descent is not possible, administration of oxygen may eliminate the HAPE. This may take 36 to 72 hours to resolve with oxygen therapy alone.
SUMMARY

The environment, loosely defined, is all the surrounding factors that can have an impact on a human. And despite the need for humans to rely on the environment for existence, they also must have certain mechanisms to protect themselves from any abnormalities (or extremes) of the environment. An occasion when environmental influences on a person are so extreme that the body cannot adequately cope is said to be an “environmental emergency.” Environmental emergencies as discussed in this chapter include extremes in temperature conditions, which can precipitate either hyperthermia or hypothermia; the adverse effects that result when humans are bitten or stung by insects, snakes, or marine life; lightning strike injuries; and high-altitude sickness.

Although environmental emergencies can affect anyone, they commonly have the most severe effect on patients at either end of the age range (very young or very old), those with significant medical conditions, and individuals taking certain medications.

As an EMT, you must remain acutely aware of environmental influences on every patient you encounter. The first reason is obvious: A person subjected to extreme temperature changes will eventually start to falter, especially if he is not adequately prepared or acclimated to the temperature. Second, changes will eventually start to falter, especially if he is not adequately prepared or acclimated to the temperature. And despite the need for humans to rely on the environment for existence, they also must have certain mechanisms to protect themselves from any abnormalities (or extremes) of the environment. An occasion when environmental influences on a person are so extreme that the body cannot adequately cope is said to be an “environmental emergency.” Environmental emergencies as discussed in this chapter include extremes in temperature conditions, which can precipitate either hyperthermia or hypothermia; the adverse effects that result when humans are bitten or stung by insects, snakes, or marine life; lightning strike injuries; and high-altitude sickness.

Although environmental emergencies can affect anyone, they commonly have the most severe effect on patients at either end of the age range (very young or very old), those with significant medical conditions, and individuals taking certain medications.

As an EMT, you must remain acutely aware of environmental influences on every patient you encounter. The first reason is obvious: A person subjected to extreme temperature changes will eventually start to falter, especially if he is not adequately prepared or acclimated to the temperature. Second, a person with either a medical or a traumatic emergency may deteriorate more quickly if the emergency happened in a location where the environmental temperature was abnormally high or low. Third, regarding bites and stings, the person may be unaware for several hours that he was bitten or stung, or he may try to minimize the injury, resulting in a delay of care. Yet another environmental scenario is when the EMT is summoned to care for a patient who was bitten or stung, and the offending agent (e.g., swarming bees) is still within close proximity to the patient. This latter scenario creates a potential environmental concern for the care providers as well as for the patient. When responding to patients who have been struck by lightning, the EMT may be exposed to the possibility of being struck if the storm is still active. High-altitude rescue presents with many complications. Most often, specially trained teams are used to perform high-altitude rescue.

The assessment approach to the patient with an environmental emergency is the same as for any other type of emergency the EMT responds to. The first phase of assessment, the scene size-up, will many times give the EMTs insight as to the type of environmental emergency they may be dealing with. The goal for the EMTs then becomes protecting themselves from the environmental extreme while they are providing care to the patient.

The approach to environmental emergencies, although complex at times, is usually straightforward. First, attempt to remove the environmental influence causing the emergency or remove the patient from the environmental influence. Second, support the body’s own compensatory mechanisms. Third, provide specific interventions for any lost function of the airway, breathing, and circulation. And last, determine the best transport destination and continue care en route with ALS backup as warranted.

Case Study Follow-up

Scene Size-up
Your initial call was for a disoriented elderly woman who fell into a snowbank wearing only a housecoat and slippers approximately 2 hours prior to the call. The woman has also complained of pain in her left ankle.

You pull up at 2125 Central Avenue at 1321 hours. The police radioed in the call, and their presence on the scene assures you that it is secure. It is an overcast afternoon, with gusty winds. The outside temperature is 26°F. Because of information in the dispatch and the weather conditions, you are alert to the probability of generalized hypothermia as well as possible local cold injury and other injuries that might have resulted from a fall. With police on the scene to watch the ambulance, you leave its motor running and the heat turned up in the patient compartment as you get out. One officer stays with the ambulance, while another leads you to the woman.

The scene size-up reveals no obvious hazards; the patient is in the alley behind the house and there are no traffic hazards. Because there is only one patient and the mechanism of injury was a fall, there is no need for additional units.

Primary Assessment
You approach the woman and say to her, “Hello. My name is Sonia Weill and this is my partner, Jake Gallow. Could you tell us your name and if you’re in any pain?” The woman replies, “I’m Harriet Rector. I’m cold. I want to go home. My husband fell once like this, but not for so long. He’s dead now. I just want to go inside. I have to feed Fluffy. Nothing hurts. I should have taken out the garbage tomorrow. Is that Thursday? But I hadn’t taken it out yesterday. My ankle hurts. On the right. No, the left. Where’s my dog?”

continued
Case Study Follow-up continued

In spite of the fact that Mrs. Rector fell into a big, soft snowbank, your partner initiates manual in-line stabilization of her head and neck as a precaution. Your general impression is of an elderly female who is responsive but disoriented. The patient knows her name but is unclear as to the day of the week and exactly where she is. You proceed to assess airway, breathing, oxygenation, and circulation and find no life threats other than the cold environment. You cover the patient with a blanket, making sure to roll her carefully in order to place the blanket under her. The SpO₂ is 91% so you apply a nasal cannula at 2 lpm.

Secondary Assessment

Although the possibility of spine injury is small, you and Jake transfer and immobilize Mrs. Rector to a long spine board and quickly move her into the back of the warm ambulance before undertaking the secondary assessment. You take care to be extremely gentle in moving her.

Once Mrs. Rector is comfortably settled inside the ambulance, you continue questioning her, using the OPQRST format. You determine that her chief complaint is that her left leg hurts from the fall. You attempt to obtain a history, but Mrs. Rector does not respond appropriately to your questions, chiefly asking about her dog. You reassure her that you will get someone to take care of Fluffy.

You perform a physical exam. As you are examining the abdomen, you slide your hand inside Mrs. Rector’s housecoat and place the back of your hand on her abdomen. You note that the skin there is cool to the touch, and normal skin color does not return after palpation. You have already removed the slippers and splinted the painful, swollen ankle. Now you splint the other foot as well to prevent movement and protect both feet with dry dressings.

Jake, meanwhile, has finished gathering the vital signs: they are blood pressure 102/60, heart rate 60, respiration rate 12, and skin pale, cold, and firm to the touch.

Reassessment

Once en route to the hospital, you cover Mrs. Rector in an additional warm, dry blanket. You had previously turned up the heat in the patient compartment, producing a suitable environment for passive rewarming.

Your priority is to maintain an airway, breathing, and adequate oxygenation and reassess vital signs and mental status. Mrs. Rector continues to speak distractedly about her dog and a number of seemingly unconnected events, indicating that her airway and breathing are adequate but her mental status is still altered. The SpO₂ reading is now 95% so you continue the oxygen at 2 lpm. Jake takes another set of vital signs: Blood pressure is still 102/60, but the heart rate has increased to 65 and the respiration rate is now 14. The skin is still cool, but it now has a mottled appearance. Mrs. Rector begins to complain that her feet tingle and hurt.

You arrive at Ellis Hospital at 1341 hours. You give your report on the case to the emergency nurse, being sure to include the latest set of vitals taken in the ambulance and to note Mrs. Rector’s new complaints about pains in her feet. Then you telephone Mrs. Rector’s neighbor who agrees to take care of the dog. Before you leave the hospital, you see the emergency physician and ask about Mrs. Rector’s prognosis. She says that they’ve begun actively rewarming Mrs. Rector, but that it’s too early to tell how she will respond.

A few weeks later, you and Jake pass by 2125 Central Avenue on your way back from a call and see Mrs. Rector out walking Fluffy. You return her wave and smile as you go by.

IN REVIEW

1. Name the five processes through which the body loses heat.
2. Explain the difference between hypothermia and hyperthermia.
3. List the signs and symptoms of generalized hypothermia.
4. Explain the steps in treatment of a patient suffering from a local cold injury.
5. Explain the treatment of the patient suffering from a heat emergency.
6. List conditions that would predispose a patient to experience a cold emergency.
7. List conditions that would predispose a patient to experience a heat emergency.
8. Explain the difference between active and passive rewarming.
9. Explain some of the effects of a lightning strike on the nervous, cardiac, respiratory, and musculoskeletal systems, as well as the skin, eyes, and ears.
10. Explain the emergency medical care for the lightning strike patient.
List the signs and symptoms associated with bites and stings.

Explain the general emergency medical care for a patient suffering from a bite or sting.

List the various conditions the patient may suffer when exposed to high altitude.

Describe the emergency care for high-altitude conditions.

CRITICAL THINKING

You are called early one summer morning for a patient who has fallen at a gated retirement community near your station. As you proceed to the ambulance, your partner comments on how hot the day is already. You agree, and as soon as you get into your ambulance en route to the scene, you turn on the air conditioning so that the patient compartment is cool. When arriving on scene, you are met at the doorway by a middle-aged female who states she is the patient's daughter. Her father, she explains, did not answer his telephone yesterday afternoon, last night, or this morning, so she became concerned and drove 2 hours to his home to check on him. When she found him, he was lying naked on the bathroom floor.

She escorts you into the home and, as you complete your scene size-up, you note that there are no signs of struggling, the ambient temperature is cool from air conditioning, probably 70°F – 72°F, and the entry and egress from the residence will be easy and straightforward. With your gloves on, you and your partner greet the patient, Mr. Ward.

Mr. Ward recounts a history of getting out of the shower yesterday afternoon and stepping onto the tile bathroom floor where he slipped and fell, injuring his hip. This means, by your estimation, that the patient has been lying naked on a cold tile floor in an air-conditioned home for almost 18 hours. You note that the patient is a rather inconsistent historian, and the daughter states to you, “He is just not acting like himself.” You assess the area of complaint and find palpable instability, pain, and an overlying contusion to the injured hip.

The patient continues to complain of pain and of being cold, and you note he is becoming less and less compliant to your questioning. The patient’s daughter is urging you to hurry up and leave, and the patient wants you to put him in bed and cover him so he can warm up. He now seems not to be concerned with his injured hip at all. At this point, your partner tells you he is going to retrieve the immobilization equipment from the ambulance, and he asks you if, while he is there, he should grab the tympanic thermometer.

1. Does this call initially present as one with an environmental concern?
2. What is the patient’s initial emergency that rendered him susceptible to an environmental emergency?
3. What would you expect to find regarding the patient’s core temperature with the tympanic thermometer?
4. How might your treatment of this patient change, given a disturbance in his core temperature?
5. Describe the factors that contributed to the potential change in his core temperature.
CHAPTER 25

Submersion Incidents: Drowning and Diving Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Trauma** (Content Area: Environmental Emergencies)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

25-1. Define key terms introduced in this chapter.
25-2. Discuss ways to reduce the risk of submersion incidents.
25-3. Describe factors that can lead to submersion incidents in infants, children, adolescents, and adults.
25-4. Explain factors that affect the likelihood of survival from submersion incidents.
25-5. Describe the pathophysiology of drowning.
25-6. Discuss the association between shallow water diving and spinal injuries.
25-7. Explain actions you should take to protect your own safety when responding to a water emergency.
25-8. Explain the necessity of taking spinal precautions to any swimmer or diver who may have suffered trauma.
25-9. Given a scenario in which a patient has suffered a submersion incident, explain how to provide resuscitative care.
25-10. Explain the assessment-based approach to drowning and other water-related injuries, including emergency medical care for the drowning victim.
25-11. Explain the formation and relief of gastric distention in patients involved in submersion incidents.
25-12. Describe laws of physics as they relate to scuba or deepwater diving, including:
   a. Boyle law
   b. Dalton law
   c. Henry law
   d. Charles law
25-13. Explain the pathophysiology of decompression sickness.
25-14. Recognize the signs, symptoms, and patient history associated with:
   a. Type I decompression sickness
   b. Type II decompression sickness
   c. Arterial gas embolism
25-15. Explain the pathophysiology of barotrauma injuries.
25-16. Describe the emergency medical care of patients suffering from air embolism, decompression sickness, and barotrauma.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

drowning p. 714  
dysbarism p. 725  
gastric distention p. 722  
mammalian diving reflex p. 718  
surfactant p. 716
Commonsense precautions include the following:

- All pools should be fenced.
- Children should be under constant supervision if they are in the area of a lake, pool, pond, or container of water of any significant size.
- Water activities and alcohol do not mix.
- Life preservers or personal flotation devices (life jackets) must always be worn when boating.
- Avoid diving into shallow or unexplored bodies of water.
- Those with seizure disorders must be especially careful when in or around bodies of water.

**Definitions**

The terms used to describe water-related submersions and deaths vary. The two most common terms that have been used in the past, but commonly misunderstood, are *drowning* and *near-drowning*. There has been much confusion regarding the terms used when describing submersion incidents; therefore, the Utstein style of reporting data associated with drowning should continue to be used, according to the AHA 2010 guidelines.

Because of the confusion and the need for consistent reporting of submersion incidents, drowning is the only recommended term to be used to describe a submersion event. A *drowning* is an incident in which someone is submerged or immersed in a liquid that results in a primary respiratory impairment. The liquid prevents

---

**Case Study**

**The Dispatch**
EMS Unit 631—proceed to a submersion incident at 99 Wolf Road in the Delmar Hotel. The manager stated a 25-year-old male is in trouble in the pool. Police are en route at this time. Time out is 2132 hours.

**Upon Arrival**
Your ambulance arrives at the same time as the police unit. You are met at the hotel entrance by a frantic man who identifies himself as the manager. He leads you back to the pool, saying on the way, “I told them they couldn’t have alcohol in the pool area. But they’re so smart. They sneak it in anyway. Then they come running into the office, drunk, yelling for help. One of them thinks he can do a jackknife into the shallow end. Idiots.”

As you reach the pool area, you note a small crowd of young men and women on the deck. Some of them are yelling, “Come on, Robby! Get out, man! Come on!” A couple of paper bags and carry-alls are tipped over near the deck chairs, and empty beer bottles have rolled out from them. The police move the bystanders back and quiet them down.

With the scene secure, you approach the edge of the pool and observe in it a young man floating supine with the support of a hotel employee. The young man appears very scared and tells you he cannot feel his arms or legs.

**How would you proceed to assess and care for this patient?**

*During this chapter, you will learn special considerations of assessment and care for patients in water-related emergencies. Later, we will return to the case and apply what you have learned.*
the patient from breathing air. The patient may live or may die from the event. Regardless of the outcome, it is termed a drowning.

**Incidence of Drowning**

There are approximately 4,500 drowning deaths per year in the United States, making drowning the third most common cause of accidental death. Approximately 40 percent of the deaths are in children less than 5 years of age, with the second most common age group being teenagers and the third the elderly. Approximately 85 percent of the drownings are in males. Often, alcohol is involved in the incident.

In children less than 1 year of age, the bathtub is the most common location of drowning. Most often, the child will drown when the parent or primary caregiver leaves the child alone for less than 5 minutes. Keep in mind that drowning that occurs in a bathtub or pail of water may result from child abuse. Look for any other evidence of injury to the child. In children 1 to 5 years of age, the highest incidence of drowning occurs in swimming pools.

Adolescents and young adults most often drown in ponds, lakes, rivers, and oceans. There may be associated trauma, especially cervical spine injuries from diving into shallow water or areas with rock or other obstructions. Alcohol and recreational drugs may also put the adolescent or young adult at greater risk for drowning.

In the adult patient, consider the following conditions that may have led to the submersion:

- Hypoglycemia
- Myocardial infarction (heart attack) from exertion
- Cardiac dysrhythmia
- Syncope
- Seizure
- Depression or a suicide attempt
- Anxiety or a panic disorder
- Arthritis, Parkinson’s disease, or other neuromuscular disorder that leads to poor body control
- Exhaustion
- Hypothermia
- Alcohol or drug use
- Trauma (especially head or spinal)

Water sports also pose a hazard of submersion and drowning. The use of alcohol and drugs may impair judgment and lead to boating and other water-related accidents. Water skiing, jet skiing, and surfing can cause head or spinal trauma leading to submersion and drowning. Scuba diving accidents from exertion, inexperience, panic, and poor judgment may also cause a drowning. Panic can contribute to a drowning death (Figure 25-1 ■).

---

**FIGURE 25-1** Panic can often contribute to the death of the person who loses self-control.
Prognostic Predictors

Quick rescue of the submerged patient from the water and early resuscitation are the most critical factors associated with better outcomes. No single individual characteristic has been found to predict survivability. The following characteristics are part of the Orlowski score that predicts likelihood that a patient would survive neurologically intact. The best chance for survival is in a patient who has two or fewer of the characteristics listed next. If three or more are present, the chance of survival is only 5 percent. The Orlowski predictors of poor survival are:

- Patient is 3 years of age or older.
- Patient was submerged for greater than 5 minutes.
- Resuscitation did not begin for more than 10 minutes after rescue.
- Patient is comatose on delivery to emergency department.
- Patient’s arterial blood is very acidic (pH less than 7.10).

Moderate body core hypothermia associated with submersion is thought to provide a protective mechanism that reduces brain and other organ damage in children. However, most people do not become hypothermic quickly enough after submersion to reduce the severe cerebral injury from hypoxia and ischemia.

Pathophysiology of Drowning

Drowning can be very traumatic for the individual involved. As the person is submerged in water, he attempts to breathe, and either he aspirates water or his larynx spasms and causes him to suffocate. The most significant consequence of a drowning is the lack of ventilation while submerged, which leads to severe and prolonged hypoxia and the accumulation of carbon dioxide in the blood, which may lead to severe acid buildup within the body. The combined hypoxia and acidosis may lead to severe brain injury and cardiac arrest. In any drowning, the factor that has the greatest impact on the patient’s prognosis is the duration of the submersion and the consequent severity of the hypoxia. The severe hypoxia associated with the initial drowning event (primary injury) could produce prolonged effects that continue to damage tissue and organs create an ongoing hypoxia (secondary injury).

Not all patients who are involved in a drowning aspirate water into their lungs. Approximately 10–15 percent of drowning patients are prevented from aspirating water into their lungs during submersion by the spasm and tight closing of the larynx (laryngospasm) that lasts until all inspiratory efforts have ceased. This is referred to as a “dry drowning.” Drowning patients who do aspirate water usually aspirate only a small amount that is quickly absorbed by the respiratory tract and into the circulation and does not pose a major problem with airway obstruction.

Thus, the standard practice of performing abdominal thrusts is not necessary during the resuscitation of a drowning patient. In fact, performing abdominal thrusts may lead to regurgitation and aspiration of gastric contents. If water is present in the airway, suction it out. The only time abdominal thrusts should be performed is when a foreign body airway obstruction is suspected in the drowning patient. If the patient vomits during the resuscitation, log roll the patient onto one side and sweep or suction the oropharynx clear of the vomitus.

The issue of saltwater versus freshwater drowning does not play a major role in resuscitation attempts by emergency medical services. Theoretically, there are differences between saltwater and freshwater aspiration; however, clinically there is no difference in the resuscitation of the patient. Both types of drowning have a tendency to wash out surfactant.

Surfactant is a substance that maintains surface tension in the alveoli to keep them from collapsing. If surfactant is washed out, the alveoli tend to collapse (a condition called atelectasis). The damage to alveolar-capillary structures creates ventilation problems by decreasing functional lung volume and allowing fluid to leak around and into the alveoli, which creates pulmonary edema. The alveolar-capillary damage also interferes with gas exchange, impairing oxygenation of the blood and off-loading of carbon dioxide from the blood. This complication is known as acute respiratory distress syndrome (ARDS).

The key to emergency care is to monitor the breathing status closely and provide positive pressure ventilation to any drowning patient with an inadequate respiratory rate, inadequate tidal volume, or both. Auscultate the lungs for evidence of crackles (rales), which would indicate fluid in and around the alveoli. The patient who is breathing spontaneously but has signs or symptoms of respiratory distress or hypoxia can benefit dramatically from continuous positive airway pressure (CPAP) application. If CPAP is not available, consider early positive pressure ventilation with a bug-valve-mask device.

Maximize the oxygen being delivered to the patient by applying a nonrebreather mask at 15 lpm in the patient who has an adequate respiratory rate and tidal volume. If positive pressure ventilation is being performed, be sure to connect oxygen to the ventilation device and deliver the highest possible concentration.

PATHOPHYSIOLOGY PEARLS

Surfactant is a lipoprotein that lines the inner surface of the alveoli. It maintains a surface-wall tension that keeps the alveoli from completely collapsing.

ASSESSMENT TIPS

The most important determining factors for patient survival in a drowning are the duration and severity of the hypoxia the patient suffers.

Hypothermia is another problem that may be encountered in a drowning patient. Hypothermia may occur as a result of extremely cold water (<41°F or <5°C). This occurs almost immediately and is considered...
primary hypothermia. Primary hypothermia may actually provide a role in protecting tissues against hypoxia. In other submersion patients, a secondary hypothermia may occur from heat loss through evaporation once the patient is removed from the water and resuscitation is attempted. Secondary hypothermia plays no role in protecting the patient against hypoxia and may cause further detrimental effects on patient outcome.

A patient with a core body temperature of 95°F or less (35°C or less) is considered to be hypothermic. If hypothermia with a body core temperature of less than 86°F is suspected during resuscitation, and the AED indicates a shockable rhythm, a shock should be attempted. If the patient remains in a shockable rhythm, continue CPR. Additional shocks may be delivered—even if the patient is suspected of being hypothermic. Follow your local protocols.

Hypovolemia (loss of fluid volume within the vascular system) can occur during and after the initial resuscitation period from an increase in capillary permeability (capillaries becoming leaky), producing hypotension (low blood pressure). This may become especially evident when the patient’s body begins to rewarm, causing the vessels to dilate. Cardiac dysrhythmias may be present as a result of hypothermia and cardiac hypoxia as well as from an increased amount of acid or a disturbance in the balance of electrolytes (sodium, chloride, potassium) in the blood.

**PATHOPHYSIOLOGY PEARLS**

If the body core temperature (BCT) is less than 86°F, defibrillation and ALS medications are not effective. The patient must be rewarmed to a BCT above 86°F before proceeding with more than one defibrillation.

The important signs, symptoms, or factors to consider in determining the seriousness of a drowning event are the following:
- Persistent cough
- Dyspnea (shortness of breath) or apnea (absence of breathing)
- Altered mental status or loss of consciousness at some point during the submersion
- Vomiting
- Drug or alcohol use
- Pertinent past medical history (e.g., seizures, diabetes mellitus, neuromuscular disorder)
- Hypothermia
- Duration of cardiac or respiratory arrest
- Age of the patient
- Preexisting disease or conditions

**Diving Emergencies**

Drowning incidents can be additionally complicated in cases where diving is involved. In most such cases, people sustain injuries as a result of diving into a pool or other relatively shallow body of water. (Other diving emergencies, those resulting from diving in deep water with scuba gear, will be discussed later in this chapter.) Patients who dive into water from a diving board, shore, poolside, boat, or dock often sustain injuries to the head and spine and fractures of the arms, legs, and ribs.

You should always assume that a diver has sustained neck and spine injuries, even if the diver is still responsive. If the patient is still in the water, provide the care as described for a submersion patient under “Emergency Medical Care” later in this chapter. If the patient has left the water, provide care, including resuscitation if necessary, as you would for any other trauma or submersion patient.

**Safety Measures in Water-Related Emergencies**

In a water-related emergency, you need to reach the patient, but you must do it with utmost concern for your own safety. Certain deepwater accidents require specialized equipment to correct medical complications, but many patients in water-related emergencies can be saved by basic life support measures, such as removing them from the water and suctioning the airway.

Do not let your desire to provide these simple lifesaving measures overwhelm your judgment. You may easily fall victim to the same hazard as the patient. Remember that water can conceal many hazards. Holes, sharp drop-offs, and underwater entanglements such as fallen trees or wire fences may not be visible from shore. In addition, currents in streams, rivers, or storm drains can easily overpower the best swimmer.

Unless a water emergency occurs in open, shallow water that has a stable, uniform bottom, never go out into the water to attempt a rescue unless you meet all of the following criteria:
- You are a good swimmer.
- You are specially trained in water rescue techniques.
- You are wearing a personal flotation device.
- You are accompanied by other rescuers.

Failure to follow these guidelines can result in your becoming a patient or a fatality also. If the patient is responsive and close to shore, use the reach, throw, row, go strategy. Make sure you have firm, solid footing and can’t slip into the water. Try to reach to the patient by holding out an object for him to grab. You can use an oar, branch, fishing pole, towel, shirt, or other strong object that won’t break. Once the patient has grabbed the object, pull him to shore.

If the patient is responsive but too far away to grasp an object you are holding, another way of reaching him is to throw something. The best thing to throw is a rope. Any EMS unit whose territory includes bodies of water should carry 100 feet of polypropylene rope in a throw...
In the case of possible spine injury, the goal is to support the back and stabilize the head and neck as other care is given. It is important to stabilize the patient properly in the water, then to remove him carefully from the water. The American Red Cross suggests that the patient not be removed from the water until a backboard or other rigid support can be applied to the patient for stabilization (see the method outlined under “Emergency Medical Care” later in this chapter).

**Possible Spine Injury**

If the swimmer may have been involved in a diving accident or may have been struck by a boat, water skier, surfboard, or other object, you should suspect possible spine injury. You should also suspect spine injury in any swimmer or diver who has been diving or using a water slide, is suspected of being intoxicated, or has evidence of traumatic injury.

![FIGURE 25-2](image)

*FIGURE 25-2*  Use an object that floats and is unlikely to break tied to the end of a rope to pull the patient to shore.

![FIGURE 25-3](image)

*FIGURE 25-3*  Don’t become a patient yourself. Use a boat to reach an unresponsive patient.

**Resuscitation**

There is a significant difference between warm-water and cold-water drowning. When a person dives into cold water (below 70°F or 21°C), the mammalian diving reflex may drastically slow down metabolism and make the patient more likely to be resuscitated, even after prolonged submersion. There is controversy regarding the actual benefits of the mammalian diving reflex.

Here is how the mammalian diving reflex works: When the face of a human, or any mammal, is submerged in cold water, the larynx spasms, breathing is inhibited, the heart rate slows, and the blood vessels throughout most of the body constrict. Blood flow to
the heart and brain, however, is maintained. In this way, oxygen is sent and used only where it is needed to immediately sustain life. The colder the water, the more oxygen is diverted to the heart and brain. The diving reflex is more pronounced and cooling is more rapid in the young (whose skin surface is greater relative to their body mass). In water at or below 68°F, the body’s metabolic requirements are only about half of normal. The brain and heart remain oxygenated for some time and, as a consequence, death can be significantly delayed in the cold-water submersion patient.

Often, patients who have been submerged in cold water—even after 30 minutes or longer in cardiac arrest—can be resuscitated. As a guideline, you should attempt resuscitation on any pulseless, nonbreathing patient who has been submerged in cold water. Remember, hypothermic patients are not pronounced dead until after both rewarming and resuscitation have been performed.

Some experts advise providing resuscitation to every drowning patient, regardless of water temperature, even those who have been in the water for a prolonged period. Seek medical direction and follow local protocol.

**Assessment-Based Approach:**

**Drowning and Water-Related Emergencies**

**Scene Size-up**

The scene size-up is especially critical in water-related emergencies. As an EMT, one of your first responsibilities is to ensure your safety and that of your partner; you cannot aid a patient if you yourself become a casualty.

First, study the scene and make sure that it is safe for you to enter. Anytime you are within 10 feet of the water’s edge you should consider wearing a PFD. If you choose to go into the water to rescue a patient, be sure you are capable of swimming and do not put yourself in danger. Make sure to take appropriate Standard Precautions, because drowning patients often vomit. Note any relevant mechanism of injury that could contribute to the severity of the situation such as a deep dive in a shallow pool.

Decide if you will need any additional assistance such as a dry team to work on shore and a wet team to immobilize the patient in the water. Be aware that rescues in white water or swift water require specialized techniques and training. If you are not qualified to undertake a rescue, be prepared to contact rescue teams that are.

Survey the scene to determine the number of patients. Usually there will be just one patient, but in some circumstances, such as a car in the water or people struck by a moving boat, there could be more. Call for any extra or expert assistance that may be required.

---

**Primary Assessment**

Form a general impression of the patient. Is this a responsive or unresponsive patient? Assess the level of responsiveness and document it, especially noting the reaction to painful stimuli in all four extremities because of the possibility of spinal injury.

Assess the airway, keeping in mind the potential for spinal injury. If the patient is found face down, and a spine injury is suspected, work with a partner or partners, if possible, to carefully turn the patient over while maintaining manual in-line stabilization. Suction water, vomitus, and secretions from the airway. Insert an oral or nasal airway if the airway cannot be managed with manual maneuvers.

Check the breathing to be sure that respirations are present and adequate. Remember that patients with spinal injury often do not breathe if they have a high cervical injury. Assess for any open wounds to the chest that would seriously impede breathing. If the breathing is adequate, and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used.

If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen.

Check the circulation to make sure the patient has a pulse and no life-threatening external bleeding that needs to be controlled. Assess for signs or symptoms of internal bleeding or hypoperfusion (shock). Remember that some patients rescued from the water may have internal injuries, for example from jumping off a bridge into the water.

**ASSESSMENT TIPS**

If the drowning patient is suspected of being hypothermic, assess the pulse for 10 seconds. If no pulse is found, assume it is not present and begin chest compressions and apply the AED.

Make a decision on the priority of the patient. Is he a high priority in need of rapid transport to a hospital or is the patient a low priority at this time? Patients with high spinal injuries affecting respirations or who are found in respiratory distress or who are unresponsive are high priority.

**Secondary Assessment**

Perform a rapid secondary assessment if the patient has an altered mental status or is unresponsive. Also, look for evidence of possible injury. If the patient is alert, obtain a history from the patient. If the patient has an altered mental status, attempt to collect a history from relatives, friends, or bystanders at the scene.
**Signs and Symptoms.** For the water-related emergency patient, look for signs and symptoms of any of the following injuries or medical problems:

- Airway obstruction
- Absent or inadequate breathing
- Pulselessness (cardiac arrest)
- Spinal injury or head injury
- Soft tissue injuries
- Musculoskeletal injuries
- External or internal bleeding
- Shock
- Hypothermia
- Alcohol or drug abuse
- Drowning or submersion

Drowning patients may be unresponsive, not breathing, or pulseless, or they may be responsive and possibly gasping or coughing up water.

The drowning patient can be placed into one of the following four categories:

**Asymptomatic**
- Patient displays no signs or symptoms of the drowning event

**Symptomatic**
- Altered mental status (may be as slight as confusion)
- Altered vital signs (e.g., tachycardia, bradycardia, tachypnea, bradypnea, hypothermia)
- Respiratory distress or respiratory arrest (respirations may be agonal)
- Dyspnea (no matter how slight, patient is considered symptomatic)
- SpO₂ reading that is <94% with or without oxygen support (An SpO₂ reading may be difficult to obtain or may be very low if the patient is hypothermic.)
- Persistent cough
- Wheezing or crackles (rales) upon auscultation of breath sounds
- Decreased body core temperature (hypothermia)
- Cool skin or cyanosis
- Vomiting, diarrhea, or both
- Anxiety

**Cardiac Arrest**
- No pulses
- Apnea

Approximately half of drowning patients are in asystole (absence of rhythm, which appears as a flat line on the monitor), requiring CPR. Approximately one-third are in ventricular tachycardia or fibrillation and in need of CPR and defibrillation.

**Obviously Dead**
- Rigor mortis
- Dependent lividity (purplish color caused by blood pooling in the lowest areas of the body)

---

**Emergency Medical Care—Drowning Patient**

Unless otherwise directed by local protocol or medical direction, do not assume that a patient is dead, even if he is unresponsive and without breathing or pulse and has been submerged for some time. Rather, consider him to be a drowning patient in need of resuscitation. Follow these steps in caring for drowning patients:

1. Remove the patient from the water as quickly and safely as you can. If you suspect that the patient has a spine injury, maintain in-line stabilization and then secure the patient to a backboard before removing him from the water (Figure 25-4). Follow these steps to remove a patient with a suspected spinal injury from the water:
   - If you find the patient face down, stabilize the patient’s head and neck with your arms, then roll the patient over, supporting the back and stabilizing the head and neck.
   - If the patient is not breathing, begin rescue breathing, using a pocket mask if possible.
   - Keeping the head and neck in line with the spinal column, slide a long backboard under the patient; secure the torso and legs to the backboard with straps.
   - Apply a cervical spinal immobilization collar and a head immobilization device.
   - Float the board to shore or poolside and lift the patient from the water. The chest and head are heavier than the lower extremities, and this results in a tendency for the head of the backboard, and the patient immobilized to it, to slip underwater. Make sure that sufficient support is given to the head end of the backboard.

2. If you do not suspect spine injury, place the patient on his left side so that water, vomitus, and secretions can drain from the upper airway.

3. Be prepared to suction, as these patients often have water in the airways and have a tendency to vomit because of the water that has been swallowed.

4. If the patient is in respiratory arrest or is not breathing adequately, establish an airway and begin positive pressure ventilations with supplemental oxygen as rapidly as you can. Once you have determined that there are no foreign objects in the airway, provide ventilations with increasing force until you see the patient’s chest rise with compression of the bag-valve device. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a non-rebreather mask at 15 lpm could be used.
Chapter 25 • Submersion Incidents: Drowning and Diving Emergencies

**FIGURE 25-4** Water rescue, possible spinal injury.

**A** Splint head and neck with arms

**B** Roll patient over

**C** Ensure airway and breathing

- Patient not breathing. Begin rescue breathing using a pocket mask, and rescue from water as soon as possible
- Patient breathing. Slide backboard under patient

**D** Apply a rigid extrication collar

**E** Float board to poolside

**F** Remove patient from water
5. If the patient is pulseless and apneic, begin CPR and apply the AED and proceed with the AED protocol.  
6. The patient may suffer from severe gastric distention, a condition in which the stomach fills with water, enlarging the abdomen to the point that it interferes with the ability to inflate the lungs. Gastric distention can also be caused by air that is forced into the stomach during artificial ventilation when resistance along the airway or too-forceful ventilations cause air to be forced into the esophagus and stomach. When gastric distention reaches the point where it interferes with the ability to ventilate the patient, place the patient on his side. With suction immediately available, place your hand over the epigastric area of the abdomen and apply firm pressure to relieve the distention. This will cause regurgitation, which you must immediately manage by positioning the patient on his side (turning the backboard and patient as a unit if the patient is immobilized to a backboard) and suctioning. Do not apply the Heimlich as a routine maneuver in the submersion or drowning patient. It may lead to vomiting and aspiration. Apply pressure only if the gastric distention interferes with your ability to ventilate the patient effectively.  
7. Manage any other medical or trauma conditions associated with the drowning event, such as soft tissue injuries, seizure, or diabetic emergencies.  
8. Transport the patient as quickly as possible, continuing resuscitative measures during transport.

**Always transport a drowning patient**, even if you think the patient has not suffered any serious effects. A drowning patient can develop complications that lead to death as long as 72 hours after the incident. Approximately 15 percent of all drowning-related deaths result from secondary complications. During transport, you should keep the patient warm and continue to provide high-concentration oxygen.

**Reassessment**

During reassessment, be alert for signs the patient is deteriorating into respiratory or cardiac arrest, especially if you previously resuscitated this patient. Perform reassessment (repeating the primary assessment, repeating the secondary assessment, repeating vital signs, and checking interventions) every 5 minutes if the patient is unstable, every 15 minutes if the patient is stable.

**Summary: Assessment and Care**

To review possible assessment findings and emergency care for a drowning emergency, see Figures 25-5 and 25-6.
How long has the patient been submerged?
Did the patient dive into the water?

**Physical Exam**

**Head, neck, and face:**
- Pupils may be dilated and sluggish to respond to light
- Large amounts of water or vomitus in mouth
- Evidence of trauma to head, neck, or face
- Cyanosis
- Nasal flaring

**Chest:**
- Persistent cough
- Crackles in lungs on auscultation
- Wheezing
- Decreased breath sounds
- Retractions and accessory muscle use

**Abdomen:**
- Distended from ingested water
- May be cold to touch if hypothermia is present

**Extremities:**
- Loss of sensory or motor function in spine-injured patient
- Weak or absent peripheral pulses
- Cyanosis or pallor

**Baseline Vital Signs**
- BP: normal to decreased; may be absent or extremely difficult to obtain
- HR: normal, increased, decreased, or absent
- RR: normal, increased, decreased, or absent
- Skin: may be pale, cyanotic, cool to cold, depending on water temperature and length of submersion
- Pupils: dilated and sluggish to respond to light
- SpO₂: may be <94%, indicating hypoxia

---

**Emergency Care Protocol**

**DROWNING**

1. Establish and maintain in-line spinal stabilization if spinal injury is suspected.
2. Begin positive pressure ventilation with a pocket mask in the water, if possible.
3. Float a backboard under the patient and move to shore. Remove the patient on the backboard while maintaining in-line spinal stabilization.
4. Establish and maintain an open airway, insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
5. Suction secretions as necessary.
6. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
7. If breathing is adequate, administer oxygen by non-rebreather mask at 15 lpm. If possible, deliver warm, humidified oxygen if hypothermia is suspected.
8. If no pulse, begin CPR and follow AED protocol.
9. If hypothermia is suspected, follow the generalized cold injury protocol.
10. Place the patient in a lateral recumbent position only if spinal injury is not suspected.
11. Always transport a submersion patient.
12. Perform reassessment every 5 minutes.

---

**SCUBA OR DEEPWATER DIVING EMERGENCIES**

People who take part in scuba or deepwater diving may become victims of drowning incidents such as those described earlier. Scuba diving has evolved into a popular recreational sport for a large number of novice and experienced divers. Also, there is an increasing growth of commercial diving. The growing popularity of recreational and commercial diving has led to an increase in the number of diving incidents and emergencies.

You may not practice as an EMT in or around oceans, but accidents involving diving may occur anywhere. Many people dive in quarries, lakes, rivers, and caves. Air travel has made it easy to dive for an hour, board a plane, and be in a central location away from the ocean within hours. So if you think that—because you do not live or work near the ocean—there is no possibility you will ever have to deal with a diving patient, you are wrong. All EMTs must be prepared to recognize and manage a diving emergency.

The environmental extremes to which deepwater divers are exposed create some special problems. A major complication of deepwater diving emergencies is coma, which may result from asphyxiation, head injury, heart attack, air-tank contamination, intoxication, or aspiration. It can also result from decompression sickness, arterial gas embolism, or barotrauma.
Emergency Care Algorithm

DROWNING EMERGENCY

Mechanism of injury present?

Yes
Consider manual in-line stabilization

No
Assess mental status

Yes
Alert and able to obey commands

Consider oxygen administration

No
Assessed mental status

Altered or unresponsive

Airway open?

Yes
Oro- or nasopharyngeal airway

Suction if necessary

Assess breathing

Adequate
Administer oxygen

Inadequate
PPV with O₂

Ventilation severely impeded by gastric distention?

Yes
Decompress stomach

Assess circulation

No
Rapid secondary assessment

Lateral recumbent position (no spinal injury)

Generalized hypothermia suspected?

Yes
Body core temperature <93.2°F or 34°C
Actively rewarm
Transport
Reassessment

Body core temperature >93.2°F or 34°C
Passively rewarm

No

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

FIGURE 25-6 Emergency care algorithm: drowning emergency.
Dysbarism is a medical condition that results from the effects on the body of changes in ambient pressure. The pressure changes may occur when a person descends in water or ascends in altitude. Recreational and commercial divers, when descending into depths of water, experience a drastic increase of pressure on the body. The pressure affects only the compressible structures and substances within the body. The body is made up primarily of water, which is noncompressible, but the gas contained within the organs, dissolved in the blood, and found in hollow spaces is compressible and is affected by changes in pressure.

There are four laws of physics that play a major role in the adverse conditions and emergencies experienced by divers. They are:

- **Boyle Law.** At a constant temperature, the volume of a gas is inversely related to the pressure. That is, as the pressure increases, the volume of the gas decreases, and as the pressure decreases, the volume of the gas increases. If the diver breathes in compressed air at a depth where there is a higher pressure on the body and then suddenly ascends, the volume of air in the lungs will rapidly expand because of the decrease in pressure as the diver is ascending. This may lead to barotrauma, or rupture of the alveoli and other lung structures.

- **Dalton Law.** The total pressure of a mixture of gases equals the sum of the partial pressures of the individual gases that make up the mixture. For example, the air we breathe is about 78 percent nitrogen. Since the air pressure at sea level is 760 mmHg, the pressure of nitrogen at sea level (78 percent of the total) is about 593 mmHg. As a diver descends, the total pressure of the air that he is breathing increases proportionately. As the diver goes deeper underwater and the pressure of the inhaled nitrogen increases, the nitrogen begins to dissolve into the blood. (Other gases in the mixture of inhaled air do not have this action.) Nitrogen in the blood will affect the electrical properties of the brain and produce a “nitrogen narcosis” with effects similar to an anesthetic. As a result, every 50 feet of depth is equivalent to one alcoholic drink in its impairment of the diver’s judgment.

- **Henry Law.** At a constant temperature, the amount of gas that dissolves in a liquid is in contact with is proportionate to the pressure of the gas around it. As already noted, when a diver descends and pressure increases, the nitrogen inhaled will tend to dissolve into the body’s liquids, mainly the blood plasma. It will then also begin to dissolve into and accumulate in the body fat and tissues. If the diver then ascends too quickly, the dissolved nitrogen is returned to a gaseous state while it is still dissolved, causing bubbles to form in the blood and tissues.

- **Charles Law.** All gases will expand equally upon being heated. Thus, as a diver descends into colder water temperatures, the inhaled and dissolved gases will contract. As the diver ascends, the temperature increases and the gases will expand.

These laws all contribute to the conditions the diver may experience while descending into or ascending from deep water.

**Decompression Sickness**

**Pathophysiology**

Decompression sickness (DCS) occurs as the result of the bubbles formed from the expansion of nitrogen in the blood and tissues as described in the Henry law. The bubbles can cause cell damage and lead to organ dysfunction. The bubbles have two primary effects on the body: (1) They act as emboli and cause obstruction in the circulation; and (2) they compress or stretch the blood vessels and nerves. Also, the bubbles may cause coagulation of blood to occur. In response, the vessels and surrounding tissues may release substances as they would in an allergic reaction. These substances may produce signs and symptoms similar to those of an allergic reaction.

**Predisposing Factors of Decompression Sickness.** Factors that increase the risk of a patient developing decompression sickness are:

- Flying or going to a high altitude too soon after a dive (12–24 hours)
- Failure to take the necessary safety stops while ascending from a dive
- Inadequate surface intervals (allows nitrogen to accumulate during a sequence of dives)
- Inadequate decompression or passing the no-decompression limit
- Diving at depths for too long a period of time
- Repeated dives at depth on the same day

Physical characteristics or conditions that predispose an individual to decompression sickness are:

- Poor physical condition
- Obesity (nitrogen dissolves easily in fat)
- Age
- Dehydration
- Heart or lung diseases or conditions
- Preexisting musculoskeletal injury
- Fatigue

Other environmental factors that put the diver at risk are:

- Cold water (vasoconstriction decreases the ability of nitrogen to off-load)
- Rough sea conditions (increase workload and effort)
Categories of Decompression Sickness

Decompression sickness (DCS) is divided into three categories:

- Type I decompression sickness (mild)
- Type II decompression sickness (serious)
- Arterial gas embolism (AGE)

The pain characteristically associated with decompression sickness has given this disorder its nickname, “the bends.” It usually results from a diver ascending too rapidly from a deep, prolonged dive. As noted earlier, gases, typically nitrogen, form bubbles within the blood and tissues, causing obstruction of vessels and compression and stretching of tissue. The onset of DCS may occur up to 72 hours following the dive.

Type I Decompression Sickness. Type I DCS is a milder form of decompression sickness. Signs and symptoms include:

- Pain
- Pruritus (itching) and burning sensation of the skin (referred to as “skin bends”)
- Skin rash (mottling or marbling of skin)
- Skin has orange-peel appearance (rare)
- Painless pitting edema (uncommon)

Pain (the bends) is the hallmark symptom of DCS. It is seen in approximately 70–85 percent of patients with type I DCS. It is typically a dull, aching, throbbing pain usually in the joints or tendons. It can also be located in other tissue. The shoulder is the joint in which the pain is most commonly experienced. The pain typically begins as mild, or not severe, and then gradually intensifies. Many divers initially think that the pain they experience early on from DCS is due to a pulled muscle or muscle overexertion. A decreased function of the extremities may be seen as a result of muscle splitting. This most often affects the upper extremities.

Type II Decompression Sickness. Type II DCS is more serious than type I DCS. The patient experiences more significant signs and symptoms; however, they may be very diverse. The onset of the signs and symptoms is usually immediate, but it could be delayed for up to 36 hours after the incident. The signs and symptoms, which result primarily from effects on the nervous system, the respiratory system, and the circulatory system (hypovolemic shock), are as follows:

Nervous System

- Low back pain that progresses to paresis (weakness), paralysis, numbness or tingling, loss of sphincter control, and girdle pain to the lower abdomen from spinal cord effects—the most common site for type II DCS
- Headache, visual disturbances, dizziness, tunnel vision

Respiratory System

- Substernal burning sensation on inhalation
- Nonproductive cough
- Respiratory distress

The respiratory signs and symptoms are known as the “chokes.” The symptoms can begin up to 12 hours following the dive and last for 12–48 hours.

Circulatory System

- Signs of hypovolemic shock, primarily tachycardia and hypotension, resulting from fluid shifting from intravascular (inside the vessels) to extravascular (outside of the vessel)
- Formation of a thrombus from activation of the blood coagulation system

When performing an assessment on the patient, the following may be found in DCS:

- Fatigue
- Signs and symptoms of shock
- Pupillary changes
- Pallor to the tongue
- Bloody sputum
- Nasal flaring, retraction of the chest, and accessory muscle use
- Tachypnea
- Crackles (rales) upon auscultation
- SpO₂ reading of <94% prior to oxygen administration
- Vomiting
- Urinary bladder distention
- Seizure
- Uncoordinated movement (ataxia), weakness, motor and sensory deficits
- Joint pain, decreased range of motion
- Edema
- Cyanosis, pallor, itching, mottling, marbling

Important questions to ask in the history of a suspected DCS patient are:

- Where did the patient dive (river, lake, ocean, cave)?
- What was the lowest depth and for what period of time?
- What were the other depths and for what periods of time?
- What was the rate of ascent from the various depths?
- What has the patient done since the dive? Did the patient fly on an airplane?
- What did the patient do the 72 hours prior to the dive? number of dives? length of dives? time off between dives? surface intervals? water temperature?
- Did the patient do any type of work during the dive?
- What gases did the patient use during the dive?
- Were there any problems experienced by the diver (e.g., entanglement, marine animal bites or stings, equipment problems)?
• What physical condition was the patient in before, during, and after the dive (e.g., fatigue, drug or alcohol use, fever, dizziness, nausea)?
• Was any first aid provided for the patient (e.g., oxygen, position, medications)?

**Arterial Gas Embolism**

Arterial gas embolism (AGE) is a blocking of blood vessels by an air bubble or clusters of air bubbles. The blockage interferes with perfusion of body tissues with oxygen and nutrients normally supplied by the blood. During a dive, pressure on the diver’s body increases and the volume of a gas decreases as he descends. Conversely, that pressure is lessened as the diver ascends. If the diver ascends rapidly while holding his breath, the air in the lungs expands rapidly, rupturing the alveoli and damaging adjacent blood vessels. As a result, air bubbles enter the bloodstream.

The signs and symptoms of air embolism have a rapid onset, often appearing within 15 minutes of a diver’s surfacing. They include the following:

- Itchy, blotchy, or mottled skin
- Difficulty in breathing
- Dizziness
- Chest pain
- Severe, deep aching pain in the muscles, joints, and tendons
- Blurred or distorted vision
- Partial deafness
- Nausea and vomiting
- Numbness or paralysis
- Weakness or numbness on one side of the body
- Staggering gait or lack of coordination
- Frothy blood in the nose and mouth
- Swelling and crepitus in the neck
- Loss or distortion of memory
- Coma
- Cardiac or respiratory arrest
- Behavioral changes (sometimes the only sign)

**Barotrauma**

Sometimes called “the squeeze,” barotrauma occurs during ascent or descent when air pressure in the body’s air cavities (such as the sinuses or middle ear) becomes too great. As a result, tissues in the air cavities are injured; for example, the eardrum or sinus may rupture.

Divers with upper respiratory infection or allergy are at increased risk of barotrauma. Signs and symptoms of the condition include the following:

- Mild to severe pain in the affected area
- Clear or bloody discharge from the nose or ears
- Extreme dizziness
- Nausea
- Disorientation

Patients suffering from barotrauma must be cared for at a medical facility immediately to prevent permanent deafness, residual dizziness, or the inability to dive in the future.

**Emergency Medical Care**

Follow these steps in caring for a patient who you suspect has an air embolism, decompression sickness, or barotrauma:

1. If any suspected spinal injury exists, establish in-line spinal stabilization. Keep the patient in a supine position if spinal injury is suspected or if the patient is alert. If the patient does not have a suspected spinal injury and has an altered mental status, place the patient in a lateral recumbent position. Do not place the patient in a Trendelenburg or head-down position.
2. Open the airway and assess for adequate breathing. If the breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm, even if the SpO2 reading is greater than 95%. Oxygen is critical in diving emergencies, because it reduces the size of the nitrogen bubbles and improves circulation. Be sure to document the exact time of oxygen delivery. If the tidal volume or respiratory rate is inadequate, begin positive pressure ventilation. Be sure to connect oxygen to the ventilation device to maximize oxygen delivery during positive pressure ventilation.
3. Initiate CPR and apply the AED if indicated.
4. Transport the patient immediately. If it is a diving emergency, try to obtain the patient’s diving log and transport it with him to the hospital. Contact medical direction to consider transport to a facility with a recompression chamber. Continue to provide oxygen during transport.
SUMMARY

Drowning is a preventable event that leads to a significant number of accidental deaths, especially in children less than 5 years of age. Often, drowning involves high-risk behavior and alcohol ingestion in teenagers and adults. Water-related sports injuries also contribute to drowning incidences.

The term drowning has replaced all of the other terms that have been used in the past to describe a patient who was submerged in water. Drowning is now defined as a person who was submerged or immersed in a liquid substance that impaired his ability to breathe. This definition holds true regardless of whether the patient lives or dies from the incident.

Some drownings may involve the possibility of spinal injury. If spinal injury is suspected, attempt to provide spinal stabilization in the water and during removal of the patient. Emergency care for drowning patients focuses on the airway, ventilation, oxygenation, and circulation. If no pulse is present, begin CPR and apply the AED. Scuba diving is a popular sport that can result in decompression sickness, arterial gas embolism, and barotrauma. Even though there may be no scuba diving locations in your response area, it is easy for a patient to have been scuba diving, get on a plane to return home, and suffer his diving emergency in your response area. Be prepared to provide emergency care for the scuba diving patient even though you may not have diving locations in your response area.

Case Study Follow-up

Scene Size-up

Your initial call was for a submersion emergency involving a 25-year-old male reported in trouble in the Delmar Hotel pool. Your unit and the police arrive at the same time. You are led to the pool by the hotel manager, who complains that the young man and his friends have been drinking. A crowd of intoxicated bystanders has gathered around the pool and are shouting comments. The police move to clear the crowd. With the only obvious hazard under control, the scene is secure and you approach the pool.

In it is a young man, floating in a supine position supported by a hotel employee. According to the manager, the man had been drinking and suddenly dove into the shallow end of the pool. He floated to the top but said he couldn’t move his feet. A hotel employee jumped in and has been supporting him in a supine position in the water, keeping his head, neck, and spine in alignment.

Primary Assessment

Your general impression is of an adult male in no obvious distress except for his chief complaint, the inability to move his feet, which leads you to suspect a possible spinal injury. There is a lifeguard’s float board propped up by the poolhouse. You get it while your partner grabs a cervical spinal immobilization collar. You both slip into the pool, trying not to create unnecessary waves. Your partner takes over manual in-line stabilization from the hotel employee while you assess the airway, breathing, and pulse. The patient keeps up a stream of chatter as you assess, but his speech is somewhat disconnected and slurred. He knows his name, Robby Ash, but not exactly where he is or what day it is.

With Robby’s airway and breathing adequate, and no signs of major bleeding or immediate signs of shock, you maneuver the float board into position. You immobilize his torso, then apply the collar and immobilize his head to the board. Then you gently push the board to the side of the pool. There, with the assistance of the employee and two police officers, you remove the board and Robby, as a unit, from the water and set them down on the deck. You and your partner climb out of the pool.

Secondary Assessment

A physical assessment reveals no other injuries aside from a contusion on the top of the head and some point tenderness in the neck. Because of Robby’s complaint that he cannot feel his feet, you pay particular attention to the assessment of pulses and motor and sensory function in the extremities. In the upper extremities, radial pulses are present and strong. Robby cannot grip your fingers on command and cannot identify which of his fingers you are touching or pinching. In the lower extremities, pedal pulses are present. Robby cannot move his feet or toes on your command and cannot identify the location of a touch or pinch to any part of either foot.

You take a set of vital signs; they show blood pressure 112/72, a heart rate of 78, and a respiration rate of 15. The \( \text{SpO}_2 \) reading is 98% on room air. Because the patient has no signs of respiratory distress, hypoxia or hypoxemia, poor perfusion, and his \( \text{SpO}_2 \) is >94%, you decide not to apply supplemental oxygen. The patient’s overall skin color appears normal, but because of his extended time in the pool you cannot accurately assess the temperature of the skin or whether it would be wet or dry if
he had not just been removed from the water. His pupils are equal in size and reactive to light.

While your partner, with the assistance of the police officers, proceeds to prepare the patient for transport, you ask the history questions and find out that Robby’s only symptom is the lack of feeling in his feet. He has an allergy to penicillin, is taking no medications, and has no pertinent past medical history. His last solid meal was 2 hours ago. He has been drinking beer all night long, which, he agrees, probably led him to attempt the dive into shallow water.

When your partner has finished preparing the patient, you load him into the ambulance and begin transport.

Reassessment

The focus of your care en route to the hospital is to monitor Robby’s ABCs and keep him warm. You take another set of vital signs: Blood pressure is still 112/72, heart rate is now 76, and respirations 15. His skin is normal color, but still feels cool and damp. The SpO₂ remains at 98%. You check to be sure that Robby is well secured to the long spine board.

Because you know Robby has been drinking heavily and probably swallowed a fair amount of pool water, you are prepared for the possibility of vomiting and have suctioning equipment ready. And, in fact, he soon says, "I feel real sick, man." You remove the nonrebreather mask and with your partner’s help, turn the board so that Robby is on his left side. You apply suction to clear his mouth and airway as he vomits. When he stops, you return him to the normal position just as you arrive at the hospital.

Upon arrival, you give an oral report to the emergency nurse, being sure to mention the vomiting incident and the latest set of vital signs taken in the ambulance. You fill out the prehospital care report while your partner cleans up and restocks the ambulance. Before you leave the hospital, you see the emergency physician, who tells you that Robby has been taken upstairs for an MRI. He is not optimistic about the possibility that Robby will walk again.

As you pull away from the hospital, you contact dispatch and announce that you are temporarily out of service. You are going back to base so that you can change into dry uniforms.

Case Study Follow-up continued

1. List at least five common causes of drowning.
2. Explain the conditions that must apply before an EMT enters the water to attempt a rescue.
3. Describe the four basic methods used in attempting to rescue a patient from the water.
4. Explain why patients who have been submerged in cold water can often be resuscitated after 30 minutes or more.
5. List the injuries and medical problems whose signs and symptoms the EMT should be alert for when assessing the water-related emergency patient.
6. List the steps for removing a drowning patient with a possible spine injury from the water.
7. List the steps of emergency medical care for a drowning patient that should take place after the patient is removed from the water and, if necessary, immobilized to a spine board.

IN REVIEW

CRITICAL THINKING

It is February and the outside temperature is 34°F. You arrive on the scene of a residence and are directed to the back of the house. You find a 4-year-old male patient lying on the sidewalk next to a swimming pool. The family states that he was outside playing in the snow when he suddenly disappeared. After about 15 minutes of searching, they found the pool cover displaced and found the patient at the bottom of the shallow end of the pool. As you approach the patient, he is extremely pale, cyanotic, and not moving. He is apneic and has no carotid pulse.

1. How would you proceed with the emergency care of the patient?
2. Would you apply the AED and proceed with defibrillation?
3. What are some other special considerations when managing this patient?
Behavioral Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Medicine**  (Content Area: Psychiatric)

**COMPETENCY •** Applies fundamental knowledge to provide emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

26-1. Define key terms introduced in this chapter.
26-2. Explain the importance of recognizing and responding to patients suffering from behavioral emergencies.
26-4. Discuss the underlying physical and psychological causes of behavioral emergencies.
26-5. Describe the focus of assessment and history taking for patients who have behavioral emergencies.
26-6. Recognize behavioral characteristics of the following conditions:
   a. Anxiety
   b. Phobias
   c. Depression
   d. Bipolar disorder
   e. Paranoia
   f. Psychosis
   g. Schizophrenia
   h. Agitated delirium
26-7. Describe risk factors associated with suicide and violence toward others.
26-8. Discuss basic principles related to the assessment and management of patients with behavioral emergencies.
26-10. Prioritize patient care needs in terms of managing physical and behavioral problems.
26-11. Recognize indications for physical restraint of a patient and follow principles of safe physical restraint of patients.
26-12. Evaluate the need for law enforcement and medical direction involvement in a behavioral emergency situation.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- agitated delirium p. 736
- anxiety p. 733
- behavior p. 731
- behavioral emergency p. 731
- bipolar disorder p. 734
- depression p. 734
- dystonia p. 732
- humane restraints p. 743
- paranoia p. 734
- phobia p. 733
- psychosis p. 734
- reasonable force p. 745
- schizophrenia p. 735
- suicide p. 735
- tardive dyskinesia (TD) p. 732
INTRODUCTION

Emergency care for physical problems is tangible. You can see the wounds you bandage and touch the patient to provide treatments such as splinting bones or restoring breathing. Often, you can see immediately positive results from your efforts.

Care for behavioral emergencies is different. You cannot readily see the comfort that your words or your mere presence provides to someone who is panicked or agitated. It is hard to gauge the immediate results of your care for someone who is depressed. But the care you give patients in behavioral emergencies can just as easily save lives as the care you provide for physical problems.

BEHAVIORAL PROBLEMS

Behavior is the way a person acts or performs. A person’s “behavior” encompasses any or all of that person’s activities and responses, especially those responses that can be observed. A behavioral emergency is a situation in which a person exhibits “abnormal” behavior—behavior that is unacceptable or intolerable to the patient, the family, or the community. The abnormal behavior that precipitates the emergency may be due to a psychological condition (such as a mental illness), to extremes of emotion, or even to a physical condition (such as a lack of oxygen or low blood sugar). When a behavioral emergency is the result of a mental illness, the patient’s mental health status must be observed. Mental illness is defined as a disorder of thought, mood, perception, orientation, or memory that impairs judgment, behavior, recognition of reality, or the ability to complete activities of daily living.

Patients in the midst of behavioral emergencies may display panic, agitation, and bizarre thinking and actions. Such patients can pose a danger to themselves through suicidal or self-injurious acts, or to others through violent acts or actions whose consequences they may be incapable of understanding.

Behavioral Change

A number of factors may cause a change in a patient’s behavior, among them situational stresses, medical illnesses, psychiatric problems, alcohol, or drugs. Some
common reasons why behavior may change include the following:

- Low blood sugar in a diabetic, which can cause delirium, confusion, and even hallucinations
- Hypoxia (lack of oxygen)
- Inadequate blood flow to the brain
- Head trauma
- Mind-altering substances, such as alcohol, depressants, stimulants, psychedelics, and narcotics
- Psychogenic substances, which can cause psychotic thinking, depression, or panic
- Excessive cold or heat
- Infections of the brain or its coverings
- Seizure disorder
- Toxic ingestion or overdose
- Drug or alcohol withdrawal

As obvious as it sounds, you need to be sure you are dealing with a behavioral, and not a physical, emergency. For example, you may detect what smells like alcohol on a patient’s breath. Do not assume the patient is intoxicated; diabetic emergencies can cause alcohol-like odors on the breath, as can Antabuse, a drug used to decrease alcohol dependency.

During the assessment, pay particular attention to the following:

- **General appearance and demeanor.** Look to see if the patient is well groomed, unkempt, or disheveled. Pay attention to his build, if he is thin or overweight. How is his behavior? Is he hostile, mistrustful, withdrawn, preoccupied, or demanding?
- **Speech.** Listen to the speech pattern for abnormalities, such as slurring, bizarre or incoherent responses, or a combining of meaningless or unrelated words known as a word salad. Determine if the responses are appropriate, inappropriate, or incomprehensible. An abnormality commonly observed in behavioral emergencies is pressured speech, which is an increase in rapid, loud, and accelerated spontaneous speech. Pressured speech is most often observed in patients who are in an active phase of mania, schizophrenia, or an organic brain disorder.
- **Skin.** The color, temperature, and condition of the skin may provide some indication of the patient’s condition.
- **Posture or gait.** Does the patient have a normal posture or is he making unusual movements? When the patient walks, is his gait normal or abnormal?
- **Orientation.** Is the patient oriented to person, place, and time?
- **Memory.** Is the patient able to recall recent and past events? Does he show the ability to think abstractly or is his thinking more concrete? Concrete thinkers take things at face value, literally, and can’t conceive of alternative interpretations. Abstract thinkers, by contrast, are able to see more in depth and come up with meanings other than just a literal interpretation.

As an example, if someone said “You should walk a mile in my shoes,” a concrete thinker may respond with “Your shoes are ugly” or “I can’t walk that far.” An abstract thinker would be able to interpret that phrase as meaning that you could better understand the person if you were in his position.

- **Awareness.** Is the patient aware of his surroundings?
- **Body language.** Is the patient exhibiting any threatening signs, such as a closed fist or angry facial expression? Pay particular attention to the patient’s eye contact. Is it avoidant or intense? Is he restless, withdrawn, or showing signs of dystonia or tardive dyskinesia? Dystonia is a movement disorder that causes involuntary contractions of muscles resulting in twisting and repetitive movements that are sometimes painful. Tardive dyskinesia (TD) is another movement disorder that causes involuntary movements of the tongue, lips, face, trunk, and extremities. Patients who have been treated long-term with dopaminergic antagonist medications such as Thorazine or Prolixin are prone to tardive dyskinesia. Patients with schizophrenia and other neuropsychiatric disorders have a higher incidence of development of TD after being medicated with conventional neuroleptics or anticholinergics, or after being exposed to toxins, substances of abuse, and other agents.
- **Perception and thought content.** Are the patient’s thoughts in order? Is there any evidence of hallucinations, delusions, or phobias? Does he rapidly shift from one topic to the next or repeat words despite apparent efforts to make new responses?
- **Mood and affect.** Is the patient presenting as euthymic (in a normal mood)? Is he depressed, angry, euphoric, or irritable? Mood can be identified by paying attention to the patient’s affect. With a constricted affect, the patient shows a reduction in intensity of feeling tone. Flat affect, which is the absence in the amount of emotional tone or outward emotional reaction, is common in individuals who are depressed. Labile affect shows as rapid shifts in emotional expression and is most common in organic brain syndromes or intoxication.
- **Judgment.** Is the patient making rational decisions? Does he appear to lack insight into his behaviors or current situation?

Clues that the problem may be physical rather than psychological include the following:

- **The onset of symptoms was relatively sudden;** most behavioral problems develop more gradually.
- **The patient experiences hallucinations.** Note if the hallucinations are visual or auditory. Visual hallucinations are defined as the perception of an object or event with the absence of a stimulus. Auditory hallucinations are defined as the perception of received sounds without auditory stimulus. In addition to auditory and visual hallucinations there are also olfactory (smell) and gustatory (taste) hallucinations. Questions you
would ask regarding hallucinations are: “Do you see things that other people don’t see?” (visual); “Have you heard noises or sounds that other people don’t hear?”; “Do the voices come from inside or outside of your head?” (auditory); “Do you ever notice strange sensations in your body or on your skin?” (tactile); “Do you ever smell things that others don’t notice?” (olfactory); “Do you ever have strange tastes in your mouth?” (gustatory).

• The patient has memory loss or impairment; in most behavioral problems, the memory remains intact and the patient is usually alert, being oriented to person, place, and time. (An exception to this rule is if the patient is in a state of psychosis or has a mental illness such as schizophrenia in which he is disconnected from reality, which may disrupt his orientation to person, place, and time. This patient would be considered as having a behavioral emergency rather than a physical emergency.)

• The patient’s pupils are dilated, constricted, or unequal, or they respond differently to light.

• The patient has excessive salivation.

• The patient is incontinent (has lost bladder or bowel control).

• The patient has unusual odors on his breath.

Your history and physical exam will help determine whether the patient’s condition is behavioral in nature or has been caused by trauma or a medical illness. There is often an assumption that behavioral emergencies are the result of some crisis, precipitating event, or detrimental encounter. However, a patient who is experiencing his first psychotic break may begin hallucinating or having delusions in which he is disconnected from reality, which may disrupt his orientation to person, place, and time. This patient would be considered as having a behavioral emergency rather than a physical emergency.

Psychiatric Problems
A number of psychiatric conditions can lead to behavioral emergencies. Among them are anxiety, phobias, depression, bipolar disorder, paranoia, psychosis, and schizophrenia.

Anxiety
Anxiety is a state of painful uneasiness about impending problems. It is characterized by agitation and restlessness and is one of the most common emotions. Anxiety disorders impact the patient’s ability to carry out normal daily activities and are thought to be the most common form of mental illness. Most clinicians feel that many of the cases are never correctly diagnosed because they so closely mimic other disorders.

One form of anxiety disorder is the panic attack. A panic attack is a discrete period of intense fear or discomfort. Panic attacks often have a sudden onset that rapidly builds to a peak usually lasting 10 minutes or less. Some common criteria of panic attacks include heart palpitations, sweating, trembling, a sensation of choking, shortness of breath, dizziness, light-headedness, nausea, derealization or depersonalization, fear of losing control, fear of dying, chills, or hot flashes.

Patients who are panicked may show intense fear, tension, or restlessness. Their behavior may also cause anxiety among the people around them, so they may be surrounded by a crowd of anxious and excited people when you arrive. These patients often hyperventilate (breathe too deeply), which causes physical symptoms such as dizziness, tingling around the mouth and fingers, spasms of the hands and feet (carpal-pedal spasms), tremors, irregular heartbeat, palpitations (rapid or intense heartbeat), diarrhea, and sometimes feelings of choking, smothering, or shortness of breath. If severe, anxiety has been known to cause sudden cardiac death.

These symptoms, when serious, sometimes lead to a patient believing that he is experiencing a physical or medical problem that results in exacerbation of his anxiety symptoms. This is commonly seen when patients report they are having an asthma attack or believe they are having a heart attack but show no physical symptoms of these medical emergencies, leading to a suspicion of a panic attack.

**ASSESSMENT TIPS**
Panic-attack patients usually present with tachycardia, tachypnea, diaphoresis, and pale and cool skin.

**Phobias**
Phobias, which are closely related to anxiety problems, are irrational fears that are often triggered by a specific object or event. One of the most disabling is agoraphobia, which renders the person terrified of leaving the safety of his own home. Agoraphobia is anxiety about being in places or situations from which escape would be difficult or help may not be available. Just the thought of leaving the home can cause impending fear and often causes individuals to avoid specific social situations.

Patients suffering phobias may show evidence of intense fear. Tense and restless, they often wring their hands and pace. They frequently suffer from tremors, tachycardia (rapid heartbeat), irregular heartbeat, dyspnea (difficult breathing), sweating, and diarrhea. These symptoms of a severe anxiety response can occur at just the thought or sight of something that is a trigger.
Depression

Depression is one of the most common psychiatric conditions. It is characterized by deep feelings of sadness, worthlessness, and discouragement, feelings that often do not seem connected to the actual circumstances of the patient’s life. Depression is a factor in approximately 50 percent of all suicides and may cause other psychological disorders as well.

Depressed patients often present as sad, with a flat affect, which is the absence of affective expressions. They feel helpless, hopeless, withdrawn, and pessimistic and often experience periods of crying. Depression also often causes severe anhedonia, which is a loss of interest in activities of pleasure that the patient may have previously enjoyed. Patients with depression often suffer appetite loss, insomnia or hypersomnia, excessive guilt, as well as indecisiveness, fatigue, despondence, and psychomotor agitation. The risk of suicide is heightened when there is evidence of depression with recurrent thoughts of death and suicidal ideations.

**ASSESSMENT TIPS**

Depression in an elderly patient is considered to be a serious condition in which the patient must be provided care. Of all populations, the elderly are at the highest risk of suicide.

Bipolar Disorder

Bipolar disorder is often described as changes in mood from “very high highs” to “very low lows.” The high phase is considered to be either mania or hypomania and the low phase is that of depression.

Mania, also referred to as a manic state, is a period of abnormally elevated, expansive, or irritable mood that lasts for at least a week. Someone who is manic may display grandiose thinking or set unrealistic goals that are almost impossible to achieve. Mania is often compared to a feeling of being high on drugs, where everything is pressured and dangerous behaviors often take place, such as sexual promiscuity and drug use. When mania occurs, a patient is at increased peril of engaging in dangerous or risk-taking behaviors. If bipolar disorder is present, the manic phase is followed by a period of severe depression.

Hypomania is a milder form of mania. It is an elevated and expansive mood that is clearly distinguishable from a normal mood and lasts at least four days. The manic phases alternate with normal moods and also with periods of depression when the patient may experience loss of interest in activities that were previously enjoyed, feelings of worthlessness, and possible contemplation of suicide.

More often than not, bipolar patients enjoy the stage of mania with its “natural high,” and this often leads to them not wanting to take their medications in fear that a stabilized mood will cause them to lose the enjoyable feelings of mania.

In either the manic or the depressive stage, the patient with bipolar disorder may suffer delusions or hallucinations. Sometimes one phase may last for months; at other times, the patient may swing from one mood to another rather quickly (sometimes within hours).

Bipolar disorder is also sometimes called manic-depressive disorder.

Paranoia

Paranoia is a highly exaggerated or unwarranted mistrust or suspiciousness of others. Paranoid patients often interpret others’ motives as malevolent, believing that these people may exploit or harm them, even if there is no evidence to support these beliefs.

Most paranoid patients have elaborate delusions, often of persecution. A persecutory delusion is the intense belief that one is being plotted against, harmed, spied on, or followed. Persons with persecutory delusions tend to brood over real or imagined injustices, carry grudges, and recall wrongs done to them years earlier. As a result of their mistrust and suspiciousness of others they often present as detached, aloof, antagonistic, hypersensitive, defensive, and argumentative. They often cannot accept fault or blame, often avoid intimacy, and can be excitable and unpredictable. These patients’ behavior may present as bizarre. Use caution when assessing and managing paranoid patients as they may exhibit aggressive behavior.

Psychosis

Psychosis is a mental state in which the patient is out of touch with reality. The patient is truly living within his own world and often mistakes his reality for that which is actually occurring. Psychosis can manifest through delusions, hallucinations, disorganized speech or behaviors, and looseness of associations.

Several types of delusions and hallucinations fall under the heading of psychosis. Delusions of reference are the false belief that, for example, information seen on TV or read in the newspaper is actually secretly about that person. Hallucinations may be auditory, which is “hearing things”; visual, which is “seeing things”; tactile, which is “feeling things”; or olfactory, which is “smelling things.” The most dangerous type of auditory hallucination is a command hallucination. The patient may report wanting to harm himself or someone else because “the voices” are telling him to. When hallucinations are command in nature, timely stabilization is critical.

Acute psychosis may result from mind-altering drugs, which is the most common cause, or from intense stress, delusional disorders, or schizophrenia, which is another common cause. The psychosis may last for only a short period of time or may occur as a chronic condition. If a patient presents in a psychotic state, it is important to not discount what they are telling you but rather to question it as if you are interested. To the patient, the psychosis may be his reality, and your reacting negatively to his
reality may cause him to become angry or agitated, putting you in danger.

**Schizophrenia**

**Schizophrenia** is a chronic mental illness in which a patient does not return to his or her premorbid level of functioning. Patients with this illness suffer debilitating distortions of speech and thought, bizarre delusions, hallucinations, social withdrawal, catatonic behavior, and lack of emotional expressiveness. There are different types of schizophrenia with various diagnostic criteria including onset and symptomology. Being aware of the array of presentations is helpful in determining the best course of action to take.

There is a misconception that multiple personality disorder is developed from schizophrenia; however, these are two very different mental illnesses with different etiologies and forms of treatment. Multiple personality disorder, which is now referred to as dissociative identity disorder, is the presence of at least two or more identities or personality states that control a person’s behavior. It is also accompanied by memory impairment.

**Violence**

Patients with behavioral emergencies brought on by the conditions described earlier or by other circumstances sometimes express their inability to handle the pressures they are feeling through violent acts. Those acts can be directed against themselves or against others. These thoughts may not be acted on, but it is always important to assess risk for homicidal and suicidal ideations.

**Suicide**

A **suicide** is any willful act designed to end one’s own life. Males are four times more likely to die from suicide, but women make three times as many attempts. Fifty-five percent of all suicides are committed with firearms. Among unsuccessful attempts, the most common methods are drug ingestion and wrist slashing. Males often choose a more violent mechanism when attempting suicide, such as a gunshot, while females often choose less painful or disfiguring methods, such as drug overdose.

Suicide is the eighth leading cause of death in the United States among males and the third leading cause of death of young people between the ages of 15 and 24 years. Every 13.7 minutes someone in the United States dies by suicide. Many people believe that suicide is vastly underreported because of the stigma that still surrounds it.

At least half of all people who succeed at suicide have attempted it previously, and 75 percent give clear warning that they intend to kill themselves. The four most common methods of suicide are (1) self-inflicted gunshot wound, (2) hanging, (3) poisoning by ingestion, and (4) carbon monoxide poisoning.

Many suicide victims make last-minute attempts to communicate their intentions. It is thought that most do not really want to die but use the suicide attempt as a way to get attention, to receive help, or to punish someone. Suicide attempts, however, are too often dismissed as “just trying to get attention.” As an EMT, you must understand that the person who attempts suicide, whatever his motive, has a real problem and needs some kind of help or treatment. The patient who attempts suicide unsuccessfully is at high risk of making a successful attempt later if not helped. Every suicidal act or gesture should be taken seriously, and the patient should be transported for evaluation.

Some types of self-injurious behavior, such as cutting, are often not suicide attempts but rather a form of emotional release and coping that becomes addicting. However, erring on the side of caution is still of utmost importance, and this patient should undergo a psychiatric evaluation. Understanding the severity and signs of self-injurious behavior versus suicide attempts can help to better identify the critical needs of the patient.

The following are risk factors and potential signs of impending suicide:

- History of a mental illness such as depression or bipolar disorder
- Previous suicidal gestures or attempts (80 percent who are successful have made previous attempts)
- Family history of child abuse or maltreatment
- Genetic predisposition
- Feelings of hopelessness
- Unwillingness to seek mental health care because of the stigma attached to suicidal thoughts
- Feeling of being isolated from others
- Local epidemic of suicide
- A history of impulsive or aggressive behavior
- Inability to access mental health care
- A recent diagnosis of serious illness, especially an illness that signals a loss of independence
- The recent loss of a loved one, the loss of a job or money, or a social loss
- Ages between 15 and 24 years and between 40 and 59 years old
- Alcohol or drug abuse
- Divorced or widowed (five times more likely to commit suicide)
- Person who gives away personal belongings and cherished possessions
- Psychosis with depression
- Homosexuality (higher incidence of depression, HIV infection, alcoholism)
- Major physical stress such as surgery and long periods of sleep deprivation
- Suicide of same-sex partner
- Expression of a clear plan for committing suicide
- Availability of the mechanism to carry out the suicide
**Agitated Delirium**

Agitated delirium, also known as excited delirium, is a mental state and physiological response characterized by:

- Unusual strength and endurance
- Tolerance of pain
- Agitation
- Hostility
- Frenzied and bizarre behavior
- Hot and diaphoretic skin
- Unusual speech

Agitated delirium may be associated with drug use, especially cocaine, methamphetamine, and other central nervous system (CNS) stimulants and psychiatric illnesses.

It may be difficult to differentiate between a patient who is violent and a patient with agitated delirium. In agitated delirium, the patient may suffer a sudden cardiac arrest. Often, the patient fights against the restraints, suddenly appears to relax, and then becomes apneic and pulseless. One potential contributing factor in deaths associated with agitated delirium is allowing the patient to fight against being restrained. Without restraint, the patient is typically violent and a potential danger to you, your partner, bystanders, and himself. Consider early contact with advanced life support for the use of a drug as a chemical restraint to reduce the chance of sudden death.

**Violence to Others**

Behavioral emergency patients may become assaultive or violent. The angry, violent patient may be ready to fight with anyone who approaches and will probably be difficult to control. Violence can be caused by patient mismanagement (real or perceived), psychosis, alcohol or drug intoxication, fear, paranoia, panic, or head injury.

Early signs that a person may have lost control and may become violent include:

- Nervous pacing
- Shouting
- Threatening
- Cursing
- Throwing objects
- Clenched teeth and/or fists

**Basic Principles**

Keep the following basic principles in mind whenever you encounter a behavioral emergency:

- **Every person has limitations.** In a behavioral emergency, every person there, including you, is susceptible to emotional injury. Every person has a threshold, and some are able to cope more than others. Every individual has the ability to be resilient, but this ability is dependent on a number of factors such as support, resources, and inner strength.

- **Each person has a right to his feelings.** Persons who are experiencing an emotional or mental breakdown are often embarrassed about it, but at that particular time, those feelings are valid and real.

- **Each person has more ability to cope with crisis than he might think.** How individuals handle a crisis depends on their previous problem-solving experience, the way they view the problem, and the amount and kind of support or resources available to them.

- **Everyone feels some emotional disturbance when involved in a disaster or when injured.** You do not know what a particular physical injury might mean to a given individual. A relatively minor hand injury may seem of little consequence, but it could ruin the career or the personal fulfillment of a person who works with his hands as a profession or a hobby.

- **Emotional injury is just as real as physical injury.** Unfortunately, because emotional injury is less visible, it is often treated as being less “real.” Mental health stigmas continue to keep patients from seeking the help that they need from fear of being regarded as different or inferior.

- **People who have been through a crisis do not just “get better.”** They will probably suffer from their pain and loss for a long time, sometimes for years. Do not expect instantaneous or automatic results; the patient probably will not realize the extent of the event until long after you leave. You are likely to be first on the scene, and your role is to provide a positive beginning to a long, difficult healing process. The goal is not to provide a solution but rather to focus on providing comfort and support to help the patient achieve a degree of emotional stabilization.

- **Cultural differences have special meaning when you are called to intervene in behavioral emergencies.** Come to terms with your own feelings as you approach a situation, and take the time to understand where your patient is coming from.
Techniques for Treating Behavioral Emergency Patients

The situations presented by behaviorally disturbed patients can be difficult. However, there are a number of techniques that can make dealing with those situations easier for you and more helpful to the patient. You can use the following therapeutic interviewing techniques to establish a rapport:

- **Approach the patient slowly and with a purpose.**
- **Engage in active listening.**
- **Be supportive and empathetic.**
- **Limit the interruptions in the interview and allow the patient to fully express himself.**
- **Respect the patient’s space (you never know what his triggers may be).**
- **Limit physical touch until a rapport is established.**
- **Avoid any action the patient may interpret as threatening.**
- **Avoid any questions or statements the patient may construe as threatening.**

Other techniques to use include:

- **Speak in a calm, reassuring voice directly to the patient.** Explain who you are and why you are there.
- **Maintain a comfortable distance between yourself and the patient.** Many patients are threatened by physical contact. Unwanted touching could set off a violent response. After you have established some rapport with the patient, you might then ask if it is okay to touch or to get a little closer, which can be comforting to some patients (Figure 26-1). Touch that may normally be comforting to a patient may trigger an aggressive response in a behavioral emergency patient. This may be especially true of a patient who has a history of physical or sexual abuse or trauma.

**ASSESSMENT TIPS**

Touch that may normally be comforting to a patient may trigger an aggressive response in a behavioral emergency patient. This may be especially true of a patient who has a history of physical or sexual abuse or trauma.

**FIGURE 26-1** After establishing some rapport, ask the patient if it is OK for you to get a little closer, which some patients may find comforting.

- **Seek the patient’s cooperation.** Encourage him to explain the problem. Never assume that it is impossible to communicate with a patient until you have tried, even if friends or family members insist it cannot be done. Typically, a patient in crisis is willing to take action to return to his state before the crisis. When you give him the opportunity to tell his story in detail, you provide him a sense of control over his care. Use nonverbal gestures, such as head nodding, to encourage the patient and show you are paying attention. Verbal responses such as “okay” or “please go on” can also be helpful to obtain necessary information. Do not tell the patient that you know what he is going through. Instead, let him know you are listening and want to do all you can to understand what he is experiencing in order to provide the best care possible.

- **Maintain good eye contact with the patient.** It communicates your control and confidence. The patient’s eyes can reveal emotions, telling you whether he is terrified, confused, struggling, or in pain. Furthermore, the eyes can telegraph intentions. If a patient is about to reach for a weapon or make a leap or a dash, his eyes may alert you. Eye contact also conveys your engagement with the patient. Patients are aware of your behaviors and will know if you would rather be somewhere else or are acting insincerely.

- **Do not make any quick movements.** Act quietly and slowly; let the patient see that you’re not going to make any sudden moves (which could precipitate panic or violence on his part).

- **Respond honestly to the patient’s questions, but don’t foster unrealistic expectations.** Instead of saying, “You have nothing to worry about,” say something like, “Even with all the problems you’ve had, you seem to have lots of people around you who really care about you”—making sure that such statements are true, based on encouraging factors you are actually able to observe. By approaching the patient through the perspective of his strengths, you can help guide him into identifying strengths within himself that he may have been unable to see, which can be very helpful in guiding him to begin overcoming his issue.

- **Never threaten, challenge, belittle, or argue with the patient.** Many behaviorally disturbed patients will be adept at picking out your weaknesses; they may feel threatened themselves and may try to improve their situation by belittling you. Remain kind and calm and treat the patient with respect. Remember that the patient is ill, and comments are not directed at you personally.

- **Always tell the truth; never lie to the patient.**

- **Do not “play along” with visual or auditory disturbances.** If the patient seems frightened by these disturbances, reassure him that these are temporary and that, with a combination of medication and other therapies, these symptoms can be stabilized or even completely removed. However, the patient in an active state of psychosis may not find his hallucinations...
and delusions frightening; rather they may be his reality. Keep in mind, then, that some patients find comfort in their psychoses and may fear a life without the familiar hallucinations or delusions.

- **When you can, involve trusted family members or friends.** Some patients are calmed and reassured by the presence of these people, but others may be upset or embarrassed. Let the patient decide.

- **Be prepared to spend time at the scene.** Don’t rush to the hospital unless a medical emergency dictates the need for lifesaving care. Avoid panicking the patient.

- **Never leave the patient alone.** All behavioral emergency patients are escape risks, and violence to self or others is a distinct possibility. Once you have responded to the emergency, the patient’s safety is one of your primary concerns. Even if the patient pleads to be left alone for just a few minutes, firmly explain that you realize he is capable of handling things, but that you could get into trouble for leaving a patient alone. If the patient needs to go to the bathroom, first check the bathroom for potential weapons (e.g., razors, scissors). Leave the door ajar, but be discreet as you watch. Follow local protocol.

- **Avoid the use of restraint.** Enlist the support of law enforcement or those trained in the use of restraint if you decide restraint is absolutely necessary.

- **Do not force the patient to make decisions.** The patient has probably lost the ability to cope and make rational decisions. If necessary, “suggest” things that need to be done (e.g., “How about you lying back so we can take you to the hospital. OK?”) or even ask them what they believe they need to feel better.

- **Encourage the patient to participate in a motor activity, which helps reduce anxiety.** For example, have the patient gather an extra set of clothing or his medication to take with him. Deep breathing exercises are also helpful in briefly managing anxiety.

- **If the patient has attracted a crowd, do what you can to disperse it.** You need to deal with the patient on a one-to-one basis. If the scene is especially hectic, remove the patient from it or remove distressing stimuli from the scene before trying to calm the patient.

- **Always ensure that you have a preplanned and clear route for an exit.** When entering the scene, determine the fastest and safest route of egress from the scene. If there is a family member or bystander blocking that route, politely ask that he move to another location in the room without identifying exactly why you want him to move.

### Scene Size-up

Steps to ensure your safety should begin even before you arrive on the scene. Pay close attention to the dispatch. Does it indicate any violence or potential for violence? Check with dispatch to see whether police are on the way. Begin scene size-up immediately on arrival. Never enter a potentially violent situation without support. Scenes in which EMS providers are most often injured are those that involve drugs or alcohol, behavioral emergency patients, and domestic violence. Injury is most likely to occur in association with sudden behavioral change. Since the behavioral emergency patient is prone to sudden changes in behavior, be extra vigilant when at the scene and during your entire contact with this patient.

*If you cannot guarantee your own safety, call the police and wait for them to arrive before you leave your vehicle.*

Also be alert, if you are dispatched to the scene of a suicide or potential suicide, that you do not fall victim to a mechanism that the patient planned to use to end his own life. Running an automobile in a closed garage, blowing out a pilot light and turning on all the burners on a gas stove, and using electrical devices in water are common suicide methods that can pose risks for EMTs. Another newer method of suicide that poses an extreme risk to the EMT is the use of a chemical suicide bag (see Chapter 22, “Toxicologic Emergencies”).

### Assessment Tips

Scene size-up is extremely important in suicidal patients. If the patient is truly serious about ending his life, he may not hesitate to injure you in order to carry out the plan.

Locate the patient visually before you enter the scene (Figure 26-2). You can be too easily surprised or even jumped by a patient as you enter the scene if you don’t know exactly where he is. You will also be unable to observe his response to your entry if you can’t see him. If you can’t visually locate the patient, wait for police to enter and secure the scene. Always stay

---

**FIGURE 26-2** Visually locate the patient before approaching. Look for any weapons.

---

**Assessment-Based Approach: Behavioral Emergencies**

Behavioral emergencies can be unpredictable, volatile situations. You must make every effort to ensure your safety before you enter such a scene. Remember, if you become a victim, you will not be able to help the patient.
between the patient and an open door so you can exit quickly should the scene deteriorate.

Never let down your guard or turn your back on the patient. Scan quickly for instruments or objects the patient might use to injure himself or others. If you see any dangerous articles, discreetly move them out of the way if possible. If the patient displays a weapon, never ignore or disregard it. Instead, in a calm and nonconfrontational way, tell the patient that you want to help but cannot do so until the weapon is released. Ask the patient to give you the weapon. If he does not, back out of the scene and call or wait for police response. Remember that any weapon can be used against the EMT. Stay outside the danger zone—for a knife, 22 feet; for a gun, much farther.

Early in the assessment, before you physically approach the patient, determine whether you and your partner can handle the situation alone. Even a small person who is sufficiently agitated can be very difficult to handle. If you doubt that you can handle the patient alone, call the police and wait for them to arrive.

If the scene seems secure, scan it for signs of things that may have contributed to the crisis or that the patient might have used in a suicide attempt. Be especially alert for liquor bottles, containers for pills or other medications, or any drug paraphernalia.

What appears to be a behavioral emergency can actually be caused by trauma such as a blow to the head, or by a medical condition such as hypoglycemia. Study the scene for clues that will help you determine the nature of the emergency. Look for a mechanism of injury or a sign of the nature of illness. If a patient has made a suicide attempt, determining either the mechanism of injury (such as a razor blade or handgun) or the nature of illness (such as pills or carbon monoxide poisoning) will be critical.

Do not automatically assume that there is just one patient. Sometimes two or more persons will make a suicide pact. Occasionally a person tries a murder-suicide (attempting to kill someone else and then himself). A method such as carbon monoxide poisoning may have made others ill, too. A person with a violent behavior disturbance may have injured someone else. Always determine the number of patients and call for additional resources as needed.

**Primary Assessment**

Gather a general impression of the patient. Assess the patient’s mental status by asking specific questions that will help you measure the patient’s level of responsiveness and orientation. Watch the patient’s appearance, level of activity, and speech patterns. Specifically try to determine whether the patient is oriented to time, person, and place.

Pay particular attention to the patient’s airway and breathing. Patients who have attempted suicide may have trouble maintaining their airway and respiration. Be prepared to provide oxygen by a nonrebreather mask at 15 lpm or positive pressure ventilation with supplemental oxygen if necessary.

If a patient has attempted suicide, caring for his trauma or medical problem rather than his behavioral problem will be your priority. In the case of a hanging attempt, for example, it would be important to establish manual inline stabilization during the primary assessment, followed by complete immobilization. Proceed with assessment and care based on the mechanism of the suicide attempt. For example, if the patient has taken a large number of pills, or if he attempted to asphyxiate himself in his car, assess and treat him as a poisoning emergency. If he has slit his wrists, treat for bleeding and shock and soft tissue injuries. Make a priority decision regarding further assessment and transport.

**Secondary Assessment**

Once life threats have been managed, proceed with the secondary assessment. In the patient who is alert and has no significant mechanism of injury, try to obtain a history first. Pay particular attention to medications the patient has taken; they can help you clarify if the situation is a behavioral or medical emergency. Note carefully the events leading to the emergency to help clarify if a suicide attempt is involved.

Inform the patient of what you are doing. Once you have determined what the problem is, explain it to the patient. Without frightening the patient, be honest in explaining what will be done to help. (Uncertainty is likely to make the patient more anxious and fearful.) Ask questions in a calm, reassuring voice. Stay polite, use good manners, show respect, and make no unsupported assumptions.

Allow the patient to tell you what happened. If you can, interview the patient in a quiet room where he has privacy. A patient may be ashamed and hesitant to talk in front of family or friends. Avoid asking closed-ended questions that can be answered with a simple “yes” or “no.” The patient’s method of explanation can help you during the assessment.

Show you are listening by rephrasing or repeating part of what the patient says. Look at the patient’s eyes, show interest in what the patient is saying, and avoid being judgmental. Give the patient supportive information that is truthful. Acknowledge the patient’s feelings. Use phrases such as “I can see that you are very depressed” or “I understand that you must feel frightened.” You will have determined the patient’s level of responsiveness and orientation during the primary assessment. During the secondary assessment, note any answers to your questions that reveal his general contact with reality, such as an auditory or visual hallucination (the patient is “hearing things” or “seeing things” that are not there). Throughout the assessment attempt to evaluate the following:

- Intellectual function
- Orientation
- Memory
• Concentration
• Judgment
• Thought content (disordered, delusions, hallucinations, worries, fears)
• Language (speech pattern, appropriate words, inappropriate words, incomprehensible)
• Mood (anxiety, depression, elation, agitation, alertness, distractibility)

Determine the patient’s chief complaint, then perform a physical exam centered on those areas in which the patient has a complaint. Finally, take a set of baseline vital signs.

If the patient is unresponsive or has an otherwise severely altered mental status or a significant mechanism of injury, you should perform a rapid secondary assessment, head to toe, to seek physical clues or signs as to whether the problem is behavioral, medical, or traumatic. Obtain a set of baseline vital signs. Then try to obtain a history, if not from the patient himself, then from family or bystanders.

Specific tips for assessing suicidal and violent patients and preparing them for transport follow.

**Suicidal Patients.** When performing an assessment on a patient who has attempted or threatened suicide, keep these additional guidelines in mind:

• **Injuries or medical conditions related to the suicide attempt are your primary concern.**
• **Listen carefully.**
• **Accept all the patient’s complaints and feelings.** Do not underestimate what the patient may be feeling and do not dismiss what you consider to be minor.
• **Do not trust “rapid recoveries.”** Transport the patient even if he seems to be “better.”
• **Be specific in your actions.** Do something tangible for the patient such as arranging for a member of the clergy to meet the patient at the hospital.
• **Never show disgust or horror when you care for the patient.** Watch your body language; the patient is analyzing you, too!
• **Do not try to deny that the suicide attempt occurred.** Your denial may be perceived as condemnation of the patient’s feelings.
• **Never try to shock a patient out of a suicidal act.** Never try to argue the person out of it, and never challenge the patient to go ahead.

**Violent Patients.** When performing an assessment on a patient who has been violent or seems to offer the potential for violence, keep the following guidelines in mind:

• **Take a history.** Ask bystanders what’s been going on. Has the patient been violent or threatened violence? If family members or friends are on the scene, find out if the patient has a history of violence, aggression, or combativeness.

• **Look at the patient’s posture.** Anticipate violence if the patient is standing or sitting in a way that threatens anyone (including himself), if the patient’s fists are clenched, or if the patient is holding anything that could be used as a weapon.
• **Listen to the patient.** Anticipate violence if the patient is yelling, cursing, arguing, or verbally threatening to hurt himself or others.
• **Monitor the patient’s physical activity.** Signs of potential violence include moving toward the caregiver, carrying a heavy or threatening object, using quick or irregular movements, and having muscle tension.
• **Be firm and clear.** Give the patient instructions regarding his behavior. Clearly state the consequences of an aggressive behavior before such behavior occurs.
• **Be prepared to use restraints, but only if necessary.** See “Restraining a Patient” later in this chapter.

**Signs and Symptoms.** One or more of the following signs and symptoms may indicate a behavioral emergency:

• Fear—of a person or persons, an activity, or a place
• Anxiety—not related to any specific person, place, or situation
• Confusion—may be preoccupied with fears or imaginary attacks
• Behavioral changes—such as radical alterations in lifestyle, values, or relationships
• Anger—inappropriate anger directed at an inappropriate source; usually brief but intense and, often, destructive
• Mania—unrealistically optimistic and grandiose; pressured speech; prone to take unwarranted risks and display poor judgment
• Depression—crying; inability to function; feelings of worthlessness or hopelessness; threats of suicide
• Withdrawal—loss of interest in people or things previously considered important
• Loss of contact with reality—hallucinations and delusions, auditory or visual
• Sleeplessness
• Loss or increase of appetite
• Loss of sex drive
• Constipation
• Crying
• Tension
• Irritability

**Emergency Medical Care**

Behavioral emergencies come in many forms. A patient may be violent, raving, and threatening others, or depressed and totally withdrawn. One patient may attempt to commit suicide by shooting himself whereas another may take pills. You must be adaptable when providing...
emergency care for behavioral emergencies. Keep the following guidelines in mind when providing such care:

1. **Your safety is of utmost importance.** Be alert at all times to the possibility that the patient may become violent and do harm to you, others at the scene, or himself. Do not let yourself fall victim to the same mechanism of injury as the patient (e.g., carbon monoxide, electrocution). Never allow a patient to come between you and an exit. Always allow yourself an exit in case the patient becomes violent.

2. **Assess the patient for trauma or a medical condition.** Remember that what seems to be a behavioral emergency may arise from trauma or a medical condition. When patients have attempted suicide, their medical treatment has priority.

3. **Calm the patient, and stay with the patient.** Follow the guidelines discussed earlier for communicating with a patient in a behavioral emergency. Never leave a suicidal patient alone. Never turn your back or drop your guard with a violent or potentially violent patient.

4. **If it’s necessary to protect yourself or others, or the patient from harming himself, use restraints.** Never use restraints as a substitute for observation, and never use metal handcuffs if your local protocol does not authorize them and if you are not properly trained in their use. Use restraints only if emergency care would be dangerous or impossible without them. Enlist the aid of trained public safety personnel.

5. **Transport the patient to a facility where he can get the physical and psychological treatment that is needed.** If a patient attempted to commit suicide by drug or medication overdose, be sure to monitor airway, breathing, and circulation carefully and be prepared to assist ventilation. Bring any drugs or medications you find at the scene to the receiving facility with the patient.

**Reassessment**

Perform a reassessment as warranted by the patient’s condition. Monitor the patient’s airway, breathing, oxygenation, circulation, and mental status. Repeat vital signs assessment and check any interventions, such as the security of restraints. Continue to calm and reassure the patient.

**Summary: Assessment and Care**

To review possible assessment findings and emergency care for a behavioral emergency, see Figures 26-3 and 26-4.

**Restraining a Patient**

The patient who is aggressive and not responding to interventions is a difficult problem for the EMT. If no one is able to communicate with the patient and you believe that he may present a danger to himself, to you, or to others, you must notify the police. Never leave such a patient alone; unless he is an immediate threat to you, watch him constantly and stay alert for sudden threatening behavior.

If you need to transport a violent patient against his will, you may need to use restraints. Even if a violent patient comes with you voluntarily, be prepared to restrain the patient if the situation changes suddenly.

Restraint should be avoided unless the patient is a danger to himself or others. Restraints may require police authorization; seek medical direction and follow local protocol. If you are not authorized by state law to use restraints, wait for someone with the proper authority.

Do not restrain a patient in a prone (face-down) position. Also, never hogtie or hobble-restrain a patient (patient prone, arms tied behind the back, ankles and wrists restrained together). A higher incidence of death has been noted when patients are restrained in a prone position or when hogtied or hobble-restrained. Two significant problems associated with prone restraint of a combative or violent patient are:

- When a patient is placed in a prone position, the weight of the body places upward pressure on the abdomen and forces the abdominal organs to be displaced toward the diaphragm. The added compression prevents a normal downward movement of the diaphragm, leading to the inability of the patient to take in adequate breaths. This results in a decreased tidal volume and inadequate breathing. The inadequate breathing results in hypoxia and acidosis, which may cause further agitation and cardiac arrest.

- With a patient in a prone position, it is impossible to adequately assess the airway and the ventilatory status. You cannot assess for chest rise and adequate tidal volume with the patient in a prone position.

As the prone-restrained patient becomes hypoxic, he will typically begin to struggle more aggressively for a period of time. Remember that hypoxia leads to agitation and aggression, while hypercarbia (buildup of carbon dioxide) leads to confusion and somnolence. As the patient becomes more hypoxic and hypercarbic, he will become more confused and aggressive. This is usually viewed as the patient becoming more violent or combative when, in fact, it is related to the patient’s inability to breathe effectively. Subsequently, the patient will become less agitated as he becomes more severely hypoxic and hypercarbic. This is often mistaken by the EMTs as the patient “calming down.” Since the patient is in a prone position, it is difficult to see the obvious signs of hypoxia and inadequate breathing. Consequently, a period of time may pass before anyone recognizes that the patient is no longer breathing effectively, is not breathing at all, or is in cardiac arrest.
**Assessment Summary**

### BEHAVIORAL EMERGENCY

The following findings may be associated with a behavioral emergency.

### Scene Size-up

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Weapons
- Hazards in attempted suicide such as a hair dryer in a tub filled with water
- Alcohol or drugs
- Evidence of a medical condition
- Routes of escape

### Primary Assessment

#### General Impression
- Obvious life threat such as open wounds to chest, potentially self-inflicted
- Posture and body language, violent or nonviolent

#### Mental Status
- Alert
- Confusion or disorientation
- Hyperactivity
- Unresponsiveness

#### Airway
- Potentially closed airway in attempted suicide from altered mental status or vomiting

#### Breathing
- Normal
- May be adequate, inadequate, or absent in attempted suicide

#### Circulation
- Normal
- Pulse may be increased, decreased, or absent in attempted suicide
- Skin normal; may be pale, cyanotic, red, cool, or clammy in attempted suicide

#### Status:
- Priority Patient—if attempted suicide with life-threatening injuries or conditions

### Secondary Assessment

#### Physical Exam and History

**Signs and symptoms:**
- Fear
- Anxiety
- Confusion
- Anger
- Depression
- Withdrawal
- Hallucinations (auditory or visual)
- Irritability
- Excessive crying

**History:**
- Did the patient ingest alcohol or drugs?
- Does the patient want to commit suicide?
- Is the patient on medications for a behavioral condition?
- Has he taken the medication as prescribed?
- Does the patient have a history of violence, aggression, or combativeness?
- Has the patient had a recent tragic event?

#### Physical Exam

**Head, neck, face:**
- Pupils may be dilated, constricted, or midsize.
- Facial expression may indicate anger, depression, or anxiety.

**Chest:**
- Inspect for evidence of self-inflicted wounds.

**Abdomen:**
- Inspect for evidence of self-inflicted wounds.

**Extremities:**
- Inspect for needle marks or self-inflicted wounds.

**Blood glucose level:**
- Normal (70–140 mg/dL, depending on last oral intake)

#### Baseline Vital Signs

- **BP:** normal or increased, may also be absent or decreased in suicide attempt
- **HR:** normal or increased, may also be absent or decreased in suicide attempt
- **RR:** normal or increased, may also be absent or decreased in suicide attempt
- **Skin:** normal; may be pale, cool, and clammy in patients experiencing fear and anxiousness
- **Pupils:** normal or may be dilated or constricted in suicide attempt
- **SpO₂:** 94% or greater in room air

---

**FIGURE 26-3a** Assessment summary: behavioral emergency.
Emergency Care Protocol

**BEHAVIORAL EMERGENCY**

1. Ensure your own safety and be prepared to retreat if the patient is violent.
3. Establish and maintain in-line spinal stabilization if spinal injury is suspected.
4. Establish and maintain an open airway; insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
5. Suction secretions as necessary.
6. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.

**ASSESSMENT TIPS**

A patient who begins to “calm down” may be hypoxic from the efforts to fight against the restraints. Carefully and thoroughly assess the patient’s airway, ventilation, oxygenation, and circulation.

For these reasons, it is necessary to restrain patients in a supine position. If increased upper extremity movement in supine restraint is a problem, take the supine patient’s arms over his head and restrain each wrist to the head of the stretcher. This will limit his ability to move. If vomiting or secretions are a concern, restrain the patient in a lateral position.

Restraints used with a patient should be humane restraints. This means that they are padded so they will not injure a patient who struggles against them. Use soft leather restraints, cloth restraints, cravats, or wide roller gauze, but never use metal handcuffs. A violent physical struggle is usually brief, since most people cannot sustain the intensity of such a struggle. However, if you still feel the need for restraints, follow these guidelines (EMT Skills 26-1):

1. Gather enough people to overpower the patient rapidly before you attempt restraint. Effective teamwork is more important than the strength of any individual team member.
2. Plan your activities before you attempt restraint. Everyone involved should know what is going to happen.
3. Use only as much force as needed for restraint; never inflict pain or use unwarranted force in restraining a patient.
4. Estimate the range of motion of the patient’s arms and legs, and stay beyond that range until you are ready to begin imposing restraint.
5. Once you have made the decision to restrain, act quickly. A key to effective restraint is taking the patient by surprise; delay or indecision could allow the patient to gain control.
6. One rescuer should talk to the patient throughout the restraining process. However, you should never bargain with the patient or agree to remove the restraints if the patient promises to behave well.
7. Approach the patient with at least four rescuers at the same time; one person should be assigned to each of the patient’s limbs. If the patient is taken down in a prone position to gain control, immediately get the patient into a supine position to allow for adequate ventilation and assessment.
8. Secure the patient’s limbs with equipment approved by medical direction; as mentioned, restraints should be of soft leather or cloth. If available, use commercial wrist- and ankle-restraining straps.
9. Secure the patient to the stretcher in a supine position with multiple straps—effective placement is around the patient’s chest, waist, and thighs. Make sure none of the straps is unduly tight or impairs the patient’s breathing. The patient can be restrained to a long spine board or a scoop stretcher, which will allow you to avoid having to undo the restraints on arrival at the emergency department. If the patient is restrained directly to the stretcher, you will have to release the restraints to transfer the patient to the hospital bed.
10. If the patient is spitting on rescuers, cover his face with a disposable surgical mask. If a mask is used, reassess airway and breathing frequently to ensure that the mask is not interfering with them or that the patient has not vomited.

7. If breathing is adequate, administer oxygen based on the SpO₂ reading unless an underlying physical condition is suspected that requires higher concentrations of oxygen. If none is suspected and the SpO₂ is >94%, oxygen is not necessary unless other signs of hypoxia exist.
8. If no pulse is present, begin CPR and follow the AED protocol.
9. If the patient becomes responding, keep him calm.
10. If the patient becomes violent or threatens to injure himself, you, your partner, or others, restrain the patient.
11. Perform a reassessment every 5 minutes if the patient is unstable or every 15 minutes if stable.
Emergency Care Algorithm

Mechanism of injury present?

Yes

Consider manual in-line stabilization

Assess mental status

Yes

Alert and able to obey commands

Consider oxygen administration

Assess circulation

No

No

FIGURE 26-4 Emergency care algorithm: behavioral emergency.
11. Once you have applied restraints, do not remove them—not even during transport. It may be necessary to remove restraints to reposition the patient. This can be done by removing one restraint at a time and controlling the extremity until it is rerestrained to the stretcher. Reassess the patient’s circulation frequently to make sure the restraints are not binding.

Make sure you document on the prehospital care report why you felt it necessary to restrain the patient, and thoroughly document the technique you used for the restraint. Again, always avoid unnecessary force.

**LEGAL CONSIDERATIONS**

Every time you respond to a call as an emergency care provider, you have a chance of becoming involved with the legal system. That chance becomes greater when you are responding to patients with behavioral problems.

**Consent**

*Consent* is permission to treat. Under most state laws, any adult of sound mind has the right to determine whether he will be treated or, more specifically, touched by another person in the course of treatment. In most states, that consent must also be informed. *Informed consent* means that the person who is to receive the treatment must understand what it involves. This means that, with every conscious, mentally competent adult, you must explain the treatment, its nature, and its potential effects before starting it. Under laws in most states, forcing a person to have treatment against his will—that is, without consent—is grounds for a charge of assault and battery.

In most states, anyone age 18 or over is considered an adult, and anyone under the age of 18 who is in the armed services or is married, pregnant, or a parent is also considered an adult (emancipated minor). If the patient is under the age of 18 and is not an emancipated minor, consent to treat should come from a parent, guardian, or blood relative. Consent should also come from a parent, guardian, or blood relative of a person who is considered to be mentally incompetent.

If you cannot find a responsible adult to consent to the treatment of a minor or of a mentally incompetent patient, or if an adult patient is unresponsive, you can still go ahead and treat. You will act in such cases on the principle of *implied consent*. This is the belief that the person who could grant consent would if he were present or able to do so.

These principles can be difficult to apply in the case of a patient suffering a behavioral emergency. Is he considered mentally competent? Is he able to give, or withhold, informed consent? Consult medical direction and carefully follow local protocols.

**Refusal of Care**

Emotionally disturbed patients—especially those who are intoxicated or who have taken a drug overdose—commonly refuse treatment. If the disturbed person is alert and oriented, unless considered mentally incompetent, he still must legally provide consent before you can treat him. Under these situations, the patient, not concerned family members, must consent to the care. Depending on state and local law, a patient who is disoriented, in shock, mentally ill, or under the influence of drugs or alcohol may not be considered competent to refuse care.

Your best protection against legal problems when dealing with emotionally disturbed patients is to document carefully and thoroughly all aspects of the encounter. If a competent patient refuses care, complete a refusal-of-care form (or a similar form used in your jurisdiction), then have it signed and witnessed by a police officer.

If a patient threatens to hurt himself or others and you can demonstrate reason to believe that the patient’s threats are real, you can transport that patient without his consent. However, you must be able to show that your belief that the patient poses a threat is reasonable. This can be documented by providing direct quotations from the patient. In such cases, make every effort to have law enforcement personnel participate in the transport. They can provide important corroboration for your actions.

**Using Reasonable Force**

If it proves necessary to restrain a patient or to transport a patient without consent, make sure you use *reasonable force* when doing so. This is defined as the minimum amount of force required to keep the patient from injuring himself or others.

In most areas, police authorization is necessary to use reasonable force in restraining or transporting a patient without consent. Seek medical direction and follow local protocol. In most jurisdictions, an EMT can use reasonable force to defend against an attack by an emotionally disturbed patient without fearing legal consequences. The basic guideline in such circumstances is to avoid any act or use of physical force that may injure the patient during restraint.

The amount of force deemed reasonable depends on the situation. As a general guide, you’ll need to consider the following:

- **The size and strength of the patient.** What may seem a reasonable amount of force when used against a 275-pound weight lifter probably wouldn’t be considered reasonable when used against a 150-pound person with limited mobility.
- **The type of behavior exhibited by the patient.** You would not be expected to use the same kind of
force against a frightened, paranoid person as you would against a belligerent, aggressive person who is loudly and repeatedly threatening to kill you.

- **The mental state of the patient.** It would be considered reasonable to use more force on a patient who is agitated and threatening than on one who is quiet and subdued.

- **The method of restraint.** Soft restraints, commonly called humane restraints, and straps are generally considered reasonable; metal handcuffs are not. Do not use metal handcuffs unless you are specifically trained in their use. If the police apply handcuffs to the patient, ensure that a police officer accompanies the patient in the ambulance or drives directly behind the ambulance in case the handcuffs would need to be removed quickly. If you are not trained in the use of handcuffs, do not take a key to remove them from the patient. A trained individual must be immediately available to remove the handcuffs, if necessary.

  **Caution:** Always be aware that a patient who has become calm following a period of combativeness and aggression may suddenly revert to the earlier behavior. In such cases, you should use reasonable force to restrain the patient even though he has become calm.

### Police and Medical Direction

In any case where you might need to use reasonable force or transport without consent, the best way to protect yourself legally is to involve your chain of command. Before you restrain any patient for any reason, seek medical direction. If medical direction advises restraint, you can use that later as justification for your actions, should they be questioned.

Remember that law enforcement personnel should be involved when you need to restrain a patient or transport without consent or if there is any threat of violence. Law enforcement personnel serve a twofold purpose in cases like these: They can help protect you from injury, and they can serve as credible witnesses if a legal case should arise.

### False Accusations

The best way to protect yourself against false accusations by a patient is to carefully and completely document everything that happens during the encounter—including detailed aspects of the patient’s abnormal behavior. In most jurisdictions, anything documented during the call is considered legally admissible evidence. Anything that is not documented is considered hearsay (not legally admissible).

Another source of protection is to have witnesses, preferably throughout the entire course of treatment, including transport. It is common for emotionally disturbed patients to accuse medical responders of sexual misconduct. To protect against these kinds of charges, consider employing these measures:

- Involve other medical responders who can testify that there was no misconduct.
- Use medical responders that are the same gender as the patient.
- Involve third-party witnesses.
- Carefully document your physical assessment.

Whenever possible, have witnesses sign a written report of the incident.
EMT SKILLS 26-1

Restraining the Combative Patient

26-1A If a possibility of danger exists, the patient should be interviewed with another EMT present. Identify yourselves and let the patient know what you expect.

26-1B Never try to restrain a patient until you have sufficient help and an appropriate plan. If necessary, create a safe zone and wait for police. Follow local protocol.

26-1C Place the patient supine on the ambulance stretcher and apply ankle and wrist restraints. Never restrain the patient in a prone position.

26-1D One method is to pull arms across the patient’s chest and tie on opposite sides of the stretcher frame.
SUMMARY

A behavioral emergency is a situation in which a person exhibits a behavior that is not socially acceptable or tolerable. Behavioral emergencies may result from a psychiatric disorder or from a medical or traumatic condition. Psychiatric conditions that may cause a behavior change include anxiety, phobias, depression, bipolar disorder, paranoia, psychosis, and schizophrenia. Suicidal behavior is a self-inflicted action or injury intended to end the patient’s life.

Because behavioral emergencies may involve sudden changes in the patient’s behavior, they put the EMT at risk for violence and potential injury. Always remain vigilant on the scene and beware of behavior changes in the patient.

Your primary responsibility in managing a behavioral emergency patient is to provide emergency care for any underlying medical conditions or injuries that may be causing the disorder or that the patient may have inflicted on himself. Know and understand both the patient’s limitations and your own limitations.

If the patient is exhibiting aggression and violence, it may be necessary to restrain him. It is best to have law enforcement present prior to the restraint procedure. Follow your local protocol on restraint. Never restrain a patient in a prone position. Never hog-tie or hobble-restrain a patient. Once the patient is restrained, ensure that you have clear access to provide an adequate assessment of his airway, ventilation, oxygenation, and circulatory status, in addition to the ability to perform a secondary assessment. Understand the legal issues involving restraint and patient consent.

---

Case Study Follow-up

Scene Size-up

You have been dispatched to Room 22 at King’s Motel with a report of a woman bleeding. Because blood figures in the report, you take appropriate Standard Precautions. You observe no immediate hazards at the scene and exit the ambulance. The motel manager meets you and leads you to the room, but indicates he has no idea of the problem. The door opens at your knock, and a woman, in some distress, says she’s bleeding and asks for help. You enter the room cautiously and find the only occupant, a young woman, sitting on the bathroom floor bleeding from a wound on her left wrist. In her right hand she is holding a large hunting knife.

You say, “Miss, we’re emergency medical technicians and we’re here to help you. But first, could you please reach up and put the knife on top of the sink and slide back from it a little.” The woman is sobbing heavily and doesn’t move or give any sign that she’s heard you. You say again, “Please, miss, we want to help you, but before we can have to put the knife down. Just reach up and put it on the sink. Then move back, just a bit.” This time, she hears you. She slowly raises her arm and places the knife on the edge of the sink. Then she half turns away and buries her face in her hands. You then move into the bathroom, pick up the knife, and hand it to your partner, who secures it.

Primary Assessment

You introduce yourself and your partner to the patient and ask her name. She replies, “Maria Foster.” You tell her once again that you have come to help her. Your general impression is of a female in her early 20s who appears to be emotionally upset and is crying. She has an open wound to her left wrist. You ask, “Maria? May I call you Maria? Maria, may I please take a look at your wrist?” Maria nods yes, giving consent, and holds her wrist out toward you.

Bleeding from the wound has now stopped. The patient is alert and oriented. Her airway is open and her breathing is adequate. Her right radial pulse is present and her skin is slightly pale, cool, and moist. You explain, “Maria, you have lost some blood. I’d like to give you some oxygen. I think it would make you feel better and help you out a bit. Is that OK?” She nods her head again. The injury to her wrist is not severe and blood loss has not been extensive. Maria’s condition does not warrant a priority transport, so you proceed with the secondary assessment.

Secondary Assessment

You indicate to the motel manager that the situation is under control and ask him to wait outside the room. Then you ask Maria what happened.

She says, “No one cares. I got so tired of it. I just wanted it all over. All of it. I thought I’d come here where nobody knows me and slit my wrists and that would be it. Over. I had a couple of drinks and I was going to do it, I really was. I thought I could go through with it. I did one wrist and then I saw the blood and I chickened out. I called 911. Now I’m sorry I did. No, I’m not. Oh, I don’t know. I’m so confused. I don’t know . . . ” She trails off into sobs.

You have listened carefully to Maria’s story. You try to show your concern and acknowledge her feelings by continued
Case Study Follow-up continued

saying, “I’m sorry that you’re feeling so bad, Maria. I can understand how confused you feel. If it’s OK, I’d like to ask you a few more questions and then see if I can help you with that wrist.”

Maria nods her consent, so you go ahead with obtaining a history. You find that Maria has no other physical complaints. She has no known allergies, is on no medications, and has no significant past medical history. She last ate at about 4:00 yesterday afternoon and had about two glasses of rum over the 2 or 3 hours she was sitting in the room before cutting her wrist.

You ask if she inflicted any other wound to her body. She denies doing so. You inspect and palpate the area around the wrist wound. You note that a radial pulse is present. The skin below the wound is slightly pale and cool and dry to the touch. Maria is able to wiggle her fingers of her left hand and she can identify which of her fingers you are touching. You apply a dressing to the wound and bandage it. Your partner, meanwhile, obtains a set of baseline vital signs; they show a blood pressure of 148/84 mmHg, a heart rate of 94 per minute, and a respiration rate of 14 per minute.

You explain to Maria that you and your partner are going to put her on the stretcher and take her to Clarendon Hospital. You ask if there is anyone you can call to meet her at the hospital. Maria says nothing for a minute, then replies softly, “My mother.” She gives you her mother’s number and your partner calls it. Maria’s mother agrees to come to the hospital. You move Maria into the ambulance and begin transport.

Reassessment

En route, you quickly repeat the primary assessment, reassess the wound to the wrist to ensure that it is not bleeding, and get another set of vital signs. You continue to talk to Maria and listen carefully to what she says to you. Upon arrival at the hospital, you transfer care of the patient to the emergency department staff. After completing the prehospital care report and preparing the ambulance to return to service, you go back to see how Maria is doing. Her mother is with her, and they both thank you for your help and showing that you care. Just then you receive a call for another run, so you wish Maria luck as you head back to the ambulance.

IN REVIEW

1. List some of the clues that a behavioral problem may be due to physical rather than psychological causes.
2. Explain some of the causes that can lead to violence in the behavioral emergency patient.
3. Explain basic steps to follow during the assessment of a potentially suicidal patient.
4. Explain basic steps to follow during assessment of a violent patient.
5. List some of the basic signs and symptoms of a behavioral emergency.
6. Explain the basic steps of emergency medical care in a behavioral emergency.
7. Explain the proper way to restrain a violent patient.
8. List factors that would be considered in determining if the force used with a patient was reasonable.
9. Explain the circumstances in which you can transport a patient without his consent.
10. Explain basic steps to protect yourself against false accusations by a patient.

CRITICAL THINKING

You arrive on the scene and find a 26-year-old male patient with multiple self-inflicted stab wounds to his abdomen. The patient refuses your care and will not let you come within 10 feet of him without becoming very aggressive and violent. He is alert and pacing while holding his abdomen. You are unable to conduct any type of assessment on the patient.

1. What scene safety issues are involved?
2. How would you proceed in providing care for this patient?
3. What is your primary responsibility in managing the patient?
4. Would you consider restraining this patient?
5. What criteria would you use to make the decision to restrain the patient?
6. How would you proceed in restraining the patient?
7. What are some hazards involving patient restraint?
8. What legal issues are of concern in this patient?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Trauma** (Content Area: Trauma Overview)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

### OBJECTIVES

- **27-1.** Define key terms introduced in this chapter.
- **27-2.** Explain why an understanding of kinetics is helpful to understanding injury and trauma.
- **27-3.** Describe the relationship of mass and velocity to kinetic energy, including the relative contribution of each to the amount of kinetic energy.
- **27-4.** Explain the effects of acceleration and deceleration on kinetic energy and the potential for injury.
- **27-5.** Describe the impacts that take place in a typical motor vehicle collision.
- **27-6.** List situations in motor vehicle collisions in which you should have a high index of suspicion for critical injuries.
- **27-7.** Explain the typical patterns of injury associated with each of the following types of motor vehicle impacts:
  - a. Frontal
  - b. Rear
  - c. Lateral
  - d. Rotational and rollover
  - e. Vehicle–adult pedestrian
  - f. Vehicle–child pedestrian
- **27-8.** Discuss the effects of the use of restraint systems in motor vehicle collisions.
- **27-9.** Explain the typical patterns of injury associated with motorcycle collisions.
- **27-10.** Describe factors that affect the pattern and severity of injury produced in falls.
- **27-11.** Compare and contrast injury patterns produced by low-, medium-, and high-velocity penetrating mechanisms of injury.
- **27-12.** Describe the mechanisms by which blast injuries produce injury.
- **27-13.** Describe the principles of care for multisystem trauma patients.
- **27-14.** Explain the term “golden period” and identify indications for an on-scene time of 10 minutes (Platinum 10 minutes) or less when caring for trauma patients.
- **27-15.** Differentiate the characteristics of Levels I, II, III, and IV trauma centers.
- **27-16.** Identify patients who meet trauma triage criteria for transportation to a trauma center.
- **27-17.** Discuss the “golden principles” and special considerations in trauma care.

### KEY TERMS

- Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- cavititation p. 763
- dissipation of energy p. 763
- drag p. 763
- fragmentation p. 763
- kinetic energy p. 751
- kinetics p. 751
- kinetics of trauma p. 751
- mechanism of injury (MOI) p. 751
- profile p. 763
- trajectory p. 763
### Case Study

**The Dispatch**
EMS Unit 632—proceed to 49 Elm Street—police are on the scene of a minor motor vehicle collision with a driver complaining of pain in his knees. Time out is 1307 hours.

**Upon Arrival**
The police officer greets you and explains that he was taking a report of a minor rear-end collision when the driver of the car that was struck from behind began to complain of knee pain. As you approach the vehicle you notice that the driver is responsive and there are no cracks in the windshield of his car. Apparently the patient was waiting to make a left turn and another vehicle struck him from behind.

**How would you assess and care for this patient?**
During this chapter, you will learn special considerations in sizing up the mechanism of injury. Later, we will return to the case and apply what you have learned.

---

### INTRODUCTION

Since the early 1970s, trauma (injury) has been recognized as the leading cause of death for those between the ages of 1 and 44 and is the fourth leading cause of death for all age groups, after cardiovascular disease, stroke, and cancer. Trauma makes up a significant percentage of the calls to which prehospital personnel respond. With any trauma patient, determining the possible extent of injury is critical to making good priority decisions regarding on-scene assessment and care versus rapid transport with assessment and care continuing en route. To make these judgments, the EMT must not only recognize obvious injuries but also maintain a high index of suspicion for hidden injuries. An understanding of mechanisms of injury is the chief component of this crucial assessment skill.

### THE KINETICS OF TRAUMA

**Mechanism of injury (MOI)** refers to how a person was injured. The mechanism may be a motor vehicle collision, a fall, a gunshot, or other. The science of analyzing mechanisms of injury, sometimes called the kinetics of trauma, helps you to predict the kind and extent of injuries as a basis for your priority decisions regarding continuing assessment, care, and transport (Figure 27-1). Although MOI is used to predict injury, it is the assessment findings that are primarily used to develop a suspicion of injury and manage the patient. MOI is the third consideration in making a transport decision and is preceded by physiological indicators such as GCS, systolic blood pressure, and respiratory rate, and anatomical type or location of injury.

Trauma is nearly always the result of two or more bodies colliding with each other. (Except for blast injuries caused by pressure waves, it is difficult to think of an injury that does not involve a collision of bodies—a passenger’s head with a windshield, a knife with someone’s chest, and so on.) **Kinetics** is the branch of mechanics dealing with the movements of bodies, so understanding kinetics is helpful in understanding mechanisms of injury and trauma.

How severely a person is injured depends on the force with which he collides with something—or something collides with him. This force depends partly on the energy contained in the moving body or bodies. The energy contained in a moving body is called kinetic energy. The amount of kinetic energy a moving body contains depends on two factors: the body’s mass (weight) and the body’s velocity (speed). Kinetic energy in a moving body is calculated this way: the mass (weight in pounds), times the velocity (speed in feet per second) squared, divided by two. The formula can be written like this:

\[
\text{kinetic energy} = \frac{\text{mass} \times \text{velocity}^2}{2}
\]

This formula illustrates that as the mass of a moving object is doubled, its kinetic energy is also doubled.
You would be injured twice as badly if you were hit by a 2-pound rock as if you were hit by a 1-pound rock thrown at the same speed.

However, velocity is a much more significant factor than mass. Suppose you were hit by a rock thrown at a velocity of 1 foot per second, then hit by the same rock thrown again at 2 feet per second. The rock thrown at 2 feet per second would be not twice as harmful as at 1 foot per second, but four times as harmful—because the factor of velocity is squared.

Understanding the factor of velocity is important in evaluating mechanism of injury in vehicle collisions. During your scene size-up, as you try to get an idea of how seriously vehicle passengers may have been injured, it is important to estimate the speed the vehicle or vehicles were going at the time of collision, knowing that a high-velocity collision will almost certainly have caused greater injury.

Understanding velocity also helps in understanding gunshot wounds and knife wounds. The great damage bullets do results not from their mass (a bullet doesn’t weigh very much) but from their velocity. A bullet wound is potentially more traumatic than a knife wound (depending on which organs and structures are struck). Even if the bullet is smaller and lighter than the knife blade, a bullet exploding from the barrel of a gun impacts the body at a relatively higher velocity than a knife blade propelled by a human hand.

**Acceleration and Deceleration**

The *law of inertia*, which is one of the *laws of motion* described by Sir Isaac Newton, states: A body at rest will remain at rest, and a body in motion will remain in motion, unless acted upon by an outside force. A person hit by a car and a person thrown several yards by an explosion are examples of bodies at rest that were put into motion by an outside force. Conversely, the person who has fallen onto a concrete pavement and the car that hits a guard rail are examples of bodies in motion that were stopped by an outside force.

The rate at which a body in motion increases its speed is known as *acceleration*. The rate at which a body in motion decreases its speed is known as *deceleration*. While mass and velocity are major factors in determining the force of impact, acceleration and deceleration also play key roles.

A faster change of speed (acceleration or deceleration) results in more force exerted. For example, two cars of the same weight moving at the same rate of speed have the same kinetic energy. If one car is braked to a gradual stop and the other is stopped suddenly by striking a telephone pole, however, the one with the faster rate of deceleration—the one that struck the pole—exerts more force.

As another example, two people of the same size and weight riding in different cars at the same rate of speed have the same amount of kinetic energy. Suppose that one starts moving faster gradually by normal pressure on the gas pedal, and the other starts moving faster suddenly by being struck from behind by an out-of-control tractor trailer. The one with the faster rate of acceleration—the one struck from behind—will have his body jerked out from under his head and neck with sufficient force to cause a severe whiplash injury, while the one that accelerates gradually is not injured at all.

**Energy Changes Form and Direction**

Energy travels in a straight line unless it meets and is deflected by some kind of interference. If kinetic energy, transmitted to a human body, continues to travel in a straight line without interruption, injury may not occur. However, energy traveling through the human body is frequently interrupted. The interruption may be due to a curve in the bone, an organ that is caught against two hard surfaces, or tissue that is pulled against a fixed point. Energy is then forced to change form because it can no longer travel in a straight line. The result is either blunt or penetrating injury, which is discussed later in the chapter.

**Impacts**

In the typical vehicular collision, there are actually three impacts, each of which is an opportunity for energy to be absorbed by the vehicle and the patient. First, the vehicle is suddenly stopped and gets bent out of shape (Figure 27-2a ■). This is called the *vehicle collision*. Next, the patient comes to a quick stop on some part or parts of the inside of the vehicle, such as the steering wheel, causing injury to the chest (Figure 27-2b ■). This is called the *body collision*. Finally, there is the *organ collision* in which the patient’s internal organs, which are all suspended in their places by tissue, come to a quick stop, sometimes striking an inside surface of the body (e.g., the inner chest wall or the inner skull) (Figure 27-2c ■).

Occasionally, there may be more impacts, such as a motorcycle rider who hits a car and is thrown. The cyclist hits the handlebars of the motorcycle, then the hood of the car, and finally the ground. With the impact of the cyclist against the handlebars, car, and ground, the internal organs also strike the inner body. So there are six potential impacts—three body collisions and three organ collisions—each of which produces energy and potential injury.

By comparing the number of impacts, it is easy to understand why a person in or on a moving vehicle who gets thrown has a much greater chance for injury than one who is restrained or remains within the vehicle.

Your understanding of the kinetics of trauma also makes it clear why the faster a vehicle is traveling, the greater the kinetic energy—and the higher the rate of acceleration or deceleration, the greater the force. The greater these factors and the greater the number of impacts, the greater the potential for injury.
MECHANISMS OF INJURY

With an understanding of mechanisms of injury, you will be able to arrive on the scene of a vehicle collision and suspect, simply from looking at the damaged vehicle, what types of traumatic injuries the patient may have experienced. Or, you will be able to arrive at the scene of a fall and, judging by the patient’s position, quickly suspect the types of injuries associated with the fall. (As you read about the injuries that may be caused by various mechanisms of injury in the remainder of this chapter, keep in mind that later chapters will deal with these kinds of injuries in more detail.) Although the MOI may increase your suspicion of injury, it does not provide indications to specific emergency care.

MOI provides nothing more than a suspicion of injury and not an accurate indicator of injury. You must assess the patient thoroughly and gather from the examination findings indicators of actual injury or suspicion of injury. As an example, if a patient falls from a two-story building and has a normal blood pressure, pulse pressure, heart rate, and respiratory rate and no other signs of shock, you would not treat for shock or hypovolemia based on the two-story fall. The MOI makes you suspect significant trauma; however, the assessment findings do not indicate significant trauma. Therefore, no aggressive trauma management is needed in this case.

Common mechanisms of injury include vehicular collisions, falls, penetrating gunshots or stabbings, and explosions. The fall is actually the most common mechanism of injury, accounting for more than half of all trauma incidents. However, the fall is not the most lethal mechanism of injury. Over one-third of all deaths from trauma result from vehicle collisions.

Vehicle Collisions

As discussed earlier, velocity is a key factor in mechanism of injury. The greater the speed at collision, the greater the chance of life-threatening injury. If a vehicle
Types of impacts in motor vehicle trauma and their incidence of frequency in urban areas (by percentage).

Who has remained inside the vehicle. The ejected patient is exposed to a greater transfer of energy, which increases his risk of multiple or severe injuries. The patient’s chance of death increases by 25 times when ejected. There is also a much higher incidence of cervical spine fracture in ejected patients.

Motor vehicle collisions can be classified as frontal, rear-end, lateral, and rotational and rollovers (Figure 27-3). Each type has a predictable pattern of injury.

Frontal Impact

In the frontal impact (Figure 27-4), the driver will continue to move forward at the same speed the vehicle is traveling (Figure 27-5). Then he will proceed to go either up and over the steering wheel, causing injuries to the head, neck, chest, and abdomen and possible ejection through the windshield (Figure 27-6a), or he will go down and under the steering wheel, causing injuries to the knees, femurs, hips, pelvis, and spine (Figure 27-6b).

If the unrestrained occupants of a vehicle involved in a collision travel in an up-and-over direction, they may be ejected from the vehicle. Partial ejection is also possible, for example the head protruding through the

Death of another occupant of the vehicle. A force severe enough to kill one passenger will almost certainly cause severe injuries, if not death, to all other passengers in the same compartment. Even if another passenger does not appear to be badly injured, maintain a high level of suspicion that this passenger has potentially fatal injuries, which may be internal or otherwise hard to detect.

An unresponsive patient or a patient with an altered mental status. One of the earliest signs of brain injury is altered mental status or unresponsiveness. Consider the patient’s mental status prior to your arrival when determining a baseline mental status, especially in the patient with a suspected head injury. A brief period of unresponsiveness or disorientation that is followed by a return of alertness may be a sign of brain injury. If this has been reported to you about a patient whom you then examine and find to be alert, you should still consider him as a patient with an altered mental status. Alternatively, if bystanders report that the patient was alert and talking coherently after the crash, and your baseline mental status assessment indicates that he is not alert after your arrival at the scene but responds to verbal stimuli, this would be an extremely important assessment finding, especially when considering a possible head injury.

Intrusion of greater than 12 inches for the occupant site or greater than 18 inches anywhere to the vehicle. Intrusion of the vehicle is a deformity occurring to the interior compartment. The occupant site is anywhere in the vehicle where the patient was riding.

Ejection from the motor vehicle. A patient who has been partially or completely ejected from a motor vehicle is at a much greater risk of injury than one who has remained inside the vehicle. The ejected patient is exposed to a greater transfer of energy, which increases his risk of multiple or severe injuries. The patient’s chance of death increases by 25 times when ejected. There is also a much higher incidence of cervical spine fracture in ejected patients.
In a frontal collision, the occupant continues to move forward at the same speed the vehicle was moving.

The up-and-over pathway causes impact to the head, neck, chest, and abdomen.

The down-and-under pathway causes impact to the knees, femurs, hips, acetabulum, and spine.

Patients in a frontal collision who are unrestrained may come into contact with the steering wheel or dashboard as the air bag deploys. The explosive force of the air bag may produce chest injury.

**ASSESSMENT TIPS**

Be sure to lift a deflated, deployed air bag to assess for deformity of the steering wheel.

**Face, Head, and Neck.** The face, head, and neck are next to impact the dashboard, windshield, or window. As you approach the vehicle, always check for the typical “spider web” windshield cracking (Figure 27-10) or other impact marks to the windshield, which are usually caused by a head striking the glass. Depending on the impact point and amount of glass, the face may have extensive soft tissue damage. Head injuries usually

windshield. Severe soft tissue injuries, including avulsions and crushing injuries, often result. The chance of sustaining a spinal injury or a fatal injury is increased dramatically when the occupant is ejected.

Look for injuries to the abdomen, chest, face, head, and neck (Figure 27-7) when there is a frontal impact with the patient following an up-and-over pathway or with either full or partial ejection.

**Abdomen.** A damaged dashboard or steering wheel (Figure 27-8) should cause you to suspect abdominal injury. As the abdomen strikes the dashboard or steering wheel, the liver, spleen, and hollow organs of the abdomen are compressed between the front and back abdominal walls and spine. The hollow organs are more easily displaced, leaving the solid liver and spleen to bear the brunt of the compression.

**Chest.** As the chest hits the dashboard or steering wheel, bones and soft tissues are both affected (review Figure 27-8). The ribs and sternum may break, and the cartilage connecting the ribs to the sternum may separate. A torn intercostal artery can bleed 50 mL per minute into the chest cavity with no blood seen externally.

The heart and lungs are the major organs affected. The heart suffers the effect of two forces: compression and shear. Compression force occurs when the heart is caught between the sternum and the spine, which can bruise the heart muscle. The heart is suspended by the aorta, which is attached posteriorly at the arch by a ligament. Shear force tends to pull the aorta at the ligament, which may tear or transect the aorta.

The lungs can also be affected. Air, trapped in the lungs by sudden closure of the epiglottis, is compressed between the ribs and spine. This kind of compression injury is called a “paper bag injury” because it is like blowing up a paper bag, then popping it between your hands. Air compressed inside the limited areas of a lung can bruise or rupture the lung (Figure 27-9).
skull is very rough, with many sharp projections. When the brain moves across these projections, it can become lacerated or bruised. Second, the brain may rebound against the opposite side of the skull from the original point of impact. The brain can be bruised on the side of the impact or on the opposite side as the brain hits the wall of the skull.

Because force travels in a straight line, energy not dissipated by the face or head will continue down the neck, with the potential for causing cervical spine injury. If the occupant is thrown forward at such an angle that the neck is caught by the steering wheel or the dashboard, the trachea is in direct danger of being injured.

Deployment of the air bag may also cause injury to the face, head, and neck.

result when an occupant is ejected from the vehicle, and skull fracture may occur. Depending on the force involved, penetrating bone shards or a depressed skull fracture may result, lacerating the brain tissue.

Even in the absence of bone injury, the force of the impact may damage the brain. First, the floor of the skull is very rough, with many sharp projections. When the brain moves across these projections, it can become lacerated or bruised. Second, the brain may rebound against the opposite side of the skull from the original point of impact. The brain can be bruised on the side of the impact or on the opposite side as the brain hits the wall of the skull.

Because force travels in a straight line, energy not dissipated by the face or head will continue down the neck, with the potential for causing cervical spine injury. If the occupant is thrown forward at such an angle that the neck is caught by the steering wheel or the dashboard, the trachea is in direct danger of being injured.

Deployment of the air bag may also cause injury to the face, head, and neck.

**ASSESSMENT TIPS**

“Spider web” or other impact marks to the windshield would heighten your suspicion of a potential head injury. Be aware that the impact mark on the windshield can also be made by an air bag that was deployed during the crash.
Rear-End Impact

In a rear-end impact (Figure 27-11), the patient's head and neck are immediately whipped back. The body is propelled forward by the seat, while the head and neck, following the law of inertia, tend to remain at rest. Additionally, because the weight of the body exceeds that of the head, the body keeps moving while the head slows (Figure 27-12a).

If there is a headrest that has been properly positioned and seat belts are worn, injury is minimized. However, if the vehicle does not have headrests or they are improperly positioned, the neck is hyperextended and the anterior spinal ligaments are often stretched or torn. This is often referred to as a "whiplash" injury. An improperly positioned headrest that is pushed all the way down to restrain just the neck and not the head can actually contribute to the severity of the injury by creating a fulcrum against which to bend the neck backward.

The injuries to be expected include the initial neck injury followed by either the frontal up-and-over or down-and-under injuries once the vehicle comes to a complete stop and the occupant jolts forward (Figure 27-12b).

Lateral Impact. When a vehicle is struck laterally, or directly on the side, it can be crushed inward, impinging on the occupants (Figure 27-13). Injuries may occur to the head, neck, chest, abdomen, pelvis, and extremities. You need to ask yourself who took the brunt of that collision and very carefully examine the side of the patient's body that bore the brunt of the lateral impact (Figure 27-14).

Head and Neck. As the energy of the impact is absorbed, the body is pushed laterally, out from under the head. This causes the head to move in the opposite direction. The structures in the lateral areas of the neck are not as strong as in the anterior/posterior portion of the neck, thus resulting in more frequent muscle tears and ligament injuries. The vertebrae are not designed for extreme lateral movement, and vertebral fractures are common. If there is more than one person in the passenger compartment, head injuries are frequently caused when heads collide. The skull is also thinnest in the temporal region, leading to fractures across the path of the middle meningeal artery.

Chest and Abdomen. Injuries occur when the door strikes the side of the chest and abdomen. If the impact is on the shoulder, the energy traveling in a straight line may dissipate at the curve in the clavicle, resulting in a fracture. If the arm is caught between the door and chest, or if the door hits the chest, fractured ribs and flail
During a rollover, the vehicle hits the ground multiple times and in various places (Figure 27-16 ■). The occupant changes direction every time the vehicle does (Figure 27-17 ■). Vehicles with a high center of gravity, such as sports utility vehicles and vans, are more prone to rollovers. Every protruding object in the vehicle, including the rearview mirror, the headrest, and the door handles, becomes a potentially lethal object.

While a specific pattern of injury is impossible to predict in a rollover, there are a few common characteristics. First, multiple systems injury is common. Second,
ejection is common if the occupant was not restrained. Finally, crushing injuries to ejected occupants are common. Following the laws of motion, if you go straight through the windshield into the ditch, so does your vehicle, right into the ditch on top of you. Sometimes patients are thrown into other lanes of traffic too fast for oncoming vehicles to avoid.

Vehicle-Pedestrian Collision

When a vehicle hits a pedestrian, the extent of injury depends on how fast the vehicle was going, what part of the pedestrian’s body was hit, how far the pedestrian was thrown, the surface the pedestrian landed on, and the body part that first struck the ground. There are likely to be different patterns of injury in children than in adults. This is because adults are larger and have a different weight distribution. Also, children and adults react to an impending collision differently.

A child who is about to be hit by a vehicle—whether the child is walking or riding a bicycle—generally turns toward the oncoming vehicle, so injuries from the impact are generally to the front of the body. A common pattern in a child struck by an auto is the combination of injuries to the femur, chest, abdomen, and head. Because a child is small and has a low center of gravity, a child struck by a vehicle is usually thrown in front of the vehicle, and is often subsequently run over by the same vehicle that hit him. A child struck by the bumper may be thrown onto the hood and then, when the vehicle stops, may be thrown off the car.

An adult, on the other hand, usually turns away from an oncoming vehicle, so the most common impact is to the side of the body. The bumper generally strikes the lower leg, typically causing fractures of the tibia and fibula. As the legs are propelled forward from the force of the vehicle, the adult generally falls backward and lands on the hood, resulting in injuries to the back, chest, shoulders, arms, and abdomen. If the adult continues across the hood and collides with the windshield, serious head and neck injuries are possible. Finally, the force of the moving vehicle throws the adult off the hood and to the ground.

Restraints: A Cause of Hidden Injuries

Hidden injuries may occur from the use of restraints in motor vehicles, including air bags and seat belts (Figure 27-18). Lap belts, when worn properly,
Frontal and side air bags do not work well in multiple collision events or in rear-end or rollover collisions. Air bags are most effective when used with seat belts. In fact, the air bag may not be effective without a seat belt.

Because the air bag deflates immediately after the impact, the driver may still hit the steering wheel. In any collision involving an air bag, the manufacturers of air bags recommend that rescuers lift the deployed air bag and check for deformation of the steering wheel. Any visible deformity of the steering wheel indicates potentially serious internal injury.

An air bag, especially when used without lap and shoulder restraints, may be the cause of injury. If the air bag is deployed in close proximity to the head, neck, or chest, usually 10 inches or less, significant injury may result from the deployment. Head, spine, eye, facial, and arm injuries are associated with air bag deployment. The individuals most prone to injury resulting from air bags are older adults, short adults (less than 5’ 2”), and infants and children less than 12 years of age. As noted in the next section, any child who is less than 12 years of age should ride in the rear seat of the vehicle; an infant in a safety seat must be placed in the rear seat of any vehicle that has a front passenger air bag. There have been a number of deaths associated with air bag deployment; however, the benefits of the air bags far outweigh the risks.

Considerations for Infants and Children. The properly secured car seat restrains a child at three points (overhead or T-shield seats) or at five points. During a collision, any part of the body that is not restrained continues forward at the same speed the vehicle was traveling prior to the impact. As the child's head snaps forward, the neck is stretched against the resistance of the shoulder restraints. The result can be a spinal cord injury without injury to the vertebrae, which are pliable in children. This condition is referred to as a spinal cord injury without radiologic abnormality (SCIWORA).

Even if the seat is facing backward, the same kind of injury can happen if the car seat is rotated into a reclining position. To prevent head snapping, the proper position for the car seat is to face backward and reclined to a 45-degree angle. To completely avoid injury from air bag deployment, children should always be restrained in the back seat of the vehicle and not in the front passenger seat.

Motorcycle Collisions

Motorcycle collisions account for a significant number of motor vehicle collisions on and off our nation’s highways (Figure 27-19). The incidence of morbidity (illness or injury) and mortality (death) is greatly affected by whether the rider is wearing a helmet. There are three main types of impact in motorcycle collisions: head-on, angular, and ejection. Ejection is most often associated with the head-on impact.
Head-On Impact. When this kind of impact occurs, the motorcycle tends to tip forward because of the location of its center of gravity. This causes the rider to travel into the handlebars at the same speed the bike was traveling. Depending on what part of the rider’s anatomy strikes the handlebars, a variety of injuries may occur.

Angular Impact. In angular motorcycle impacts, the rider strikes an object, usually a protruding object, at an angle. The object impacts whatever body part it comes into contact with, usually breaking or collapsing in on the rider. Examples include the edges of signs, outside mirrors on motor vehicles, or fence posts. The result can be severe avulsion injuries or even traumatic amputations.

Ejection. After any motorcycle collision, ejection occurs if the rider clears the handlebars. Ejection continues until a body part impacts with the object of the collision, the ground, or both. Boots, leather clothing, and a helmet help to protect against soft tissue damage, commonly called “road rash,” and against head and facial injuries (Figures 27-20 and 27-21). If the rider is not wearing a helmet, the incidence of severe head injury and death increases 300 percent, the same as that for auto ejections.

“Laying the Bike Down.” This is an evasive action on the part of the rider, designed to prevent ejection and separation of the driver from the bike in an impending collision. The bike is turned sideways and “laid down” with the driver’s inside leg dragging on the pavement or ground. The driver tends to lose speed faster than the bike, thus moving the bike out from under the driver.

Abrasions can range from superficial abrasions, involving only the epidermis, to full-thickness abrasions, which extend through the subcutaneous tissue and, in severe cases, to the covering over the bone. Abrasions can be complicated by particles embedded in the tissue such as dirt, grass, or asphalt.

Burns are most often sustained when the inside leg does not clear the bike. The leg becomes caught between the exhaust pipe and the ground. The longer the contact with the hot pipe, the worse the burn.

All-Terrain Vehicles. ATVs are very problematic since they are easily tipped over (Figure 27-22). The three-wheel versions have been pulled off the market.
Even the four-wheel ATVs are quite unstable and can easily cause collisions similar to motorcycle collisions.

**Falls**

Falls are the most common mechanism of injury. The severity of trauma depends on the distance, surface, and body part that impacted first. Associated factors are objects that interrupt the fall prior to landing.

In general, the greater the distance of the fall the more severe the injury, because increased height increases the velocity at impact. Some experts believe that the surface is more of a determining factor of injury than the height. A fall of 20 feet, which is equivalent to two stories of a building, onto an unyielding surface is considered severe for an adult, and a fall of more than 10 feet, or 2 to 3 times the height of the child, can cause severe injuries in a child. Internal organ damage is frequent, and you should have a high index of suspicion regardless of how the patient looks at first.

The pattern of trauma injuries also depends on the body part that impacts first. As we pointed out earlier, energy travels in a straight line until it is forced to curve. At that point, energy changes form to dissipate, and injury occurs.

**Feet-First Falls**

A feet-first landing causes energy to travel up the skeletal system. Fractures of the heels and fractures or dislocations of the ankles are common (Figure 27-23). If the knees are flexed at the time of impact, the majority of energy will be dissipated at the knees and will preserve the rest of the skeletal system. If the person lands flat-footed with knees locked, however, energy will be transmitted up through the femurs to the hips and pelvis, possibly causing fractures.

If energy remains, the spine will absorb the force at every curve of the lumbar, midthoracic, and cervical spine. The patient who fell three times his height or more will probably have a spinal injury resulting from the transmission of energy up through the legs and hips and into the spine.

In falls of more than 20 feet, the internal organs are likely to be injured from deceleration forces: The liver, spleen, kidney, aorta, and heart may be affected.

Extending the arms to break the fall as the body is thrown forward is natural. The first point of energy dissipation is at the wrist. A fracture of the wrist bones known as a Colles, or “silver fork,” fracture is common. The elbow and shoulder are the next points of potential injury. If the body is thrown backward, the most common injuries are to the head, back, and pelvis.

**Head-First Falls**

In head-first falls, the pattern of injury begins with the arms and extends up to the shoulders. The head may be forcibly hyperextended, hyperflexed, or compressed, all of which can cause extensive damage to the cervical spine. As the body continues its downward motion, the torso and legs are thrown either forward or backward. Chest, lower spine, and pelvic injuries are also common.

**Penetrating Injuries**

Penetrating injuries are caused by any object that can penetrate the surface of the body—such as bullets, darts, nails, and knives. The amount of damage that results depends on the amount of kinetic energy transferred to the tissue and the area of the body it penetrates. Of these two factors, the amount of kinetic energy transferred to the tissue is the greatest indicator of potential damage. For example, if the object is a knife, the low kinetic energy limits the damage to just the immediate site of impact and the underlying structures. The higher kinetic energy of a bullet results in tissue damage extending relatively far from the site of impact. If the kinetic energy produced by the bullet is totally absorbed by the body tissues, the bullet will not exit. If kinetic energy remains with the bullet, however, an exit wound will occur.

Penetrating injuries are classified as low, medium, and high velocity (Figure 27-24).

**Low-Velocity Injuries**

A knife or other object impaled in the body exerts damage to the immediate area of impact and its underlying structures. As the person tries to defend against an
1. **Drag**. The factors that slow a bullet down, such as wind resistance, constitute drag.

2. **Profile**. The impact point of the bullet is its profile. The greater the size of the impact point, the more energy is transferred.

3. **Cavitation**. Sometimes called pathway expansion, cavitation is the cavity in the body tissues formed by a pressure wave resulting from the kinetic energy of the bullet. Cavitation greatly extends the tissue damage beyond the initial bullet pathway. That is, the hole created in the tissues is larger than the diameter of the bullet. (Cavitation occurs with medium- and high-velocity projectiles but not generally with low-velocity projectiles.) Blown-out tissue caused by cavitation and carried along with the bullet explains why the exit wound is always larger than the entry wound. Always assess for an exit wound. However, EMS personnel should not make judgments about the exact pathway of the bullet or specific organ injury based on entrance and exit wounds. It is not important to determine what penetrating injury is the entrance or exit; however, it is imperative to locate and manage all of the open wounds.

4. **Fragmentation**. A bullet that breaks up into small pieces or releases small pieces upon impact increases the body damage. The fragments increase the frontal impact area and create greater tissue damage with injuries spread over a larger area of the body.

**Medium- and High-Velocity Injuries**

Medium- and high-velocity projectiles are generally pellets or bullets. Most shotguns or handguns fire at medium velocity. High-velocity weapons include high-power, high-speed rifles such as an M-16 or a 30-30 Winchester.

The damage caused by medium- and high-velocity projectiles depends on two factors: trajectory and dissipation of energy. **Trajectory** is the path or motion of a projectile during its travel. Normally, a bullet, once fired, follows a curved trajectory or path. However, the faster the bullet, the flatter the curve of the trajectory and the straighter the path of the bullet.

**Dissipation of energy** is the way energy is transferred to the human body from the force acting on it. In the case of medium- and high-velocity projectile injuries, dissipation of energy is affected by drag, profile, cavitation, and fragmentation.

**Gunshot Wounds**

Of fatal wounds that occur from firearms, 90 percent involve the head, thorax, and abdomen. Wounds also occur to the neck and extremities.
Head. The interior of the skull is a fixed space with little-to-no room for expansion. When the energy from a projectile enters the skull and starts to dissipate, brain tissue is severely compressed.

Gunshot wounds to the face generally result in major soft tissue injuries that immediately threaten the airway. It is very difficult to get a good seal when ventilating the patient who is lacking facial contours. Bleeding is extensive, and the airway is difficult to manage.

Chest. Lung tissue is relatively tolerant of the cavitation caused by projectiles. The numerous air-filled alveoli form a spongy mass that is easily movable. Pneumothorax is a common result of injury to the chest and/or lung, with air or a combination of air and blood escaping into the chest cavity. Associated rib fractures may also occur.

The heart is not as tolerant of projectiles as are the lungs, but the outer covering of the pulmonary vessels, aorta, and heart is tough and elastic. These tissues may be able to seal themselves off from low-velocity projectile wounds, but medium- and high-velocity projectiles are likely to cause significant wounds to the heart and the great vessels that enter and exit the heart.

The lower boundary between the chest cavity and the abdomen is formed by the diaphragm. If a projectile strikes the lower part of the chest or upper abdomen during exhalation, the projectile is more likely to enter below the relaxed diaphragm and cause an abdominal wound. If the projectile strikes the same area during inhalation, the projectile is more likely to enter above the contracted diaphragm and cause a wound to the chest cavity. Suspect both thoracic and abdominal injury if the entrance wound is between the nipple line and the waist.

Abdomen. The abdomen is often secondarily injured when the chest is injured. The abdominal cavity is large and contains structures that are fluid filled (such as the bladder), air filled (such as the stomach), solid (such as the spleen), and bony (such as the pelvic bones). The air-filled and fluid-filled structures are more tolerant of cavitation than are the solid organs. The majority of abdominal wounds are not rapidly fatal, even though a high percentage involving medium-velocity injuries require surgical repair.

Extremities. The extremities contain bone, muscle, blood vessels, and nerves. Bone injury from a projectile results in bony fragments becoming secondary missiles, lacerating surrounding vessels, muscles, and nerves. Muscle expands, resulting in capillary tears and swelling. Vessels can be severed, ripped, buckled, and obstructed. As a result, circulation and motor and sensory function to the extremity may be severely or totally compromised.

Blast Injuries

Blast injuries can occur as a result of explosions from, for example, natural gas, gasoline, fireworks, improvised (man-made) explosive devices, and grain elevators (Figure 27-26). Regardless of the cause, every explosion has three phases: primary, secondary, and tertiary (Figure 27-27). Each causes specific patterns of injury.

- **Primary phase injuries** are due to the pressure wave of the blast. These injuries primarily affect the gas-containing organs, such as the lungs, stomach, intestines, inner ears, and sinuses. Severe damage and death may occur from this phase without any external sign of injury.

- **Secondary phase injuries** are due to flying debris propelled by the force of the blast, or blast wind. In contrast to the injuries in the primary phase, the injuries of this phase are obvious. Most common are lacerations, impaled objects, fractures, and burns.

- **Tertiary phase injuries** occur when the patient is thrown away from the source of the blast. Injuries are much the same as would be expected from ejection from a vehicle. The pattern is dependent on the distance thrown and the point of impact.

Injuries sustained during the secondary and tertiary phases are the most obvious and are more easily accessed and treated. Injuries of the primary phase are most often ignored or unsuspected and, therefore, go untreated. Unfortunately, injuries of the primary phase are just as severe as, if not more severe than, those obtained during the other phases. In general, the index of suspicion on all blast injury patients must remain high, regardless of the initial presentation.

**THE MULTISYSTEM TRAUMA PATIENT**

Approximately 90 percent of trauma patients have a simple or single injury that involves only one body system, such as a fractured tibia or a soft tissue laceration with no major bleeding. A multisystem trauma patient
has multiple injuries or involvement of more than one body system. The body systems may include the central nervous, pulmonary, cardiovascular, gastrointestinal, urinary, reproductive, musculoskeletal, and integumentary systems. Multiple organ injuries are considered to be multisystem trauma, even though they may be part of the same body system, such as the small intestine or the liver. For example, a patient with a chest injury involving the lung (the pulmonary system and the lung as the organ) may also have a head injury (the central nervous system and the brain as the organ), or a patient with an abdominal injury (the gastrointestinal system and the small intestine as the organ) may also have a pelvic fracture (the musculoskeletal system).

Multisystem trauma carries a high incidence of morbidity and mortality. It requires the EMT to respond quickly, provide a rapid assessment to identify immediately life-threatening injuries, manage any life threats, rapidly prepare the patient for transport, and expeditiously transport the patient to an appropriate facility that can provide trauma care (Figure 27-28). It is important to follow your local, regional, or state destination protocols when making a transport decision for a trauma patient.

**THE GOLDEN PERIOD AND PLATINUM TEN MINUTES**

The “golden period” has been established as a parameter for emergency care because severely injured patients have the best chance for survival if intervention takes place as quickly as possible from the time of injury. This was once referred to as the “golden...
on the scene. The patient should be loaded into the ambulance and transport begun within 10 minutes after arriving on the scene of a severely injured or multisystem trauma patient. However, you must not go to the scene, load the patient, and transport without performing an assessment and providing emergency care. You must assess for life-threatening injuries, provide emergency care for the life threats, and prepare the patient for transport within those 10 minutes.

If a patient is not severely injured (or is without any life-threatening medical problems), more time can and should be devoted to completing normal on-scene assessment and emergency care before transport is undertaken.

The key is determining whether the patient is or is not (possibly) severely injured. It is to the patient’s potential benefit to err on the side of overestimating, rather than underestimating, the extent or severity of injuries. The harm that can be done by delaying transport when it is needed outweighs the good that can be done by completing on-scene assessment and care at a more deliberate pace. That is why EMTs are taught to maintain a “high index of suspicion”—a presumption that a patient has severe injuries if there is any indication at all that this is possible, which is often based on findings at the scene as to the mechanism of injury and the amount of force that may have been delivered.

As you have learned in this chapter, a patient involved in trauma may have hidden, internal injuries. These may be far more serious than any of the external injuries that you can observe. In some cases, there can be internal injuries with no external injuries that you can detect.

In instances of trauma, you must evaluate and rely on the patient’s assessment findings and indicators of critical injuries or instability as well as the mechanism of injury in your priority decision. (See Table 27-1.)

THE TRAUMA SYSTEM

The trauma system was designed to provide immediate surgical intervention for patients with internal trauma. Although this accounts for a small percentage of patients, approximately 10 percent, this care dramatically reduces the morbidity and mortality of these patients.

The trauma system requires significant resources and is expensive to maintain and operate. Hospitals with certain recognized capabilities are considered to be part of the trauma system and are recognized as trauma centers (Figure 27-29). A common designation of trauma centers according to the American College of Surgeons Committee on Trauma is:

- **Level I—Regional Trauma Center.** Can manage all types of trauma 24 hours a day, 7 days a week.
- **Level II—Area Trauma Center.** Can manage most trauma with surgical capabilities 24 hours a day, 7 days a week. They are capable of stabilizing more
of center focuses on stabilizing the seriously injured trauma patient and then transferring to a higher-level center.

- **Level IV—Trauma Facility.** Is typically a small community hospital in a remote area capable of stabilizing seriously injured trauma patients and then transferring them to a higher-level trauma center.

In addition to the aforementioned trauma centers, some facilities carry a specialty center designation. These centers have personnel capable of managing special types of trauma, such as spinal cord injuries or burns. Specialty centers may include neurocenters, burn centers, spinal cord injury centers, pediatric trauma centers, and limb reimplantation centers.

EMS interfaces with and is an integral component of the trauma system. It is crucial that EMS personnel triage patients accurately for transport to an appropriate trauma center. See Figure 27-30 for field triage criteria regarding transport of trauma patients to an appropriate trauma facility, as developed by the Centers for Disease Control.

### GOLDEN PRINCIPLES OF PREHOSPITAL TRAUMA CARE

The golden principles of prehospital trauma care apply to all patients who have experienced some type of injury but especially those with multisystem trauma or critical injuries. The principles are:

- Ensure at all times the safety of the EMS personnel, patients, and bystanders.
- Quickly determine the need for additional resources at the scene.
- Determine the mechanism of injury and kinematics involved in producing real or potential injuries.
- Provide a primary assessment to identify and manage immediate life threats.
- Establish and maintain spinal stabilization for patients suspected of having a vertebral or spinal cord injury.
- Establish and maintain a patent airway.
- Establish and maintain adequate oxygenation in the patient with an adequate rate and adequate tidal volume by keeping the SpO2 reading greater than 95%.
- Provide positive pressure ventilation with a high concentration of oxygen connected to the ventilation device in the patient with an inadequate respiratory rate or inadequate tidal volume.
- Control external hemorrhage with direct pressure followed by a tourniquet if direct pressure is ineffective.
- Treat for shock by maintaining a normal body temperature and splinting fractures when appropriate.
- Consider application of the pneumatic antishock garment (PASG) for decompensated shock (systolic blood pressure less than 90 mmHg) associated with

---

**TABLE 27-1** Indications for On-Scene Time of 10 Minutes or Less and Rapid Transport

- Airway occlusion or difficulty in maintaining a patent airway
- Respiratory rate <10 or >29/minute
- Inadequate tidal volume
- Hypoxia (SpO2 <95%)
- Respiratory distress, failure, or arrest
- Suspected skull fracture
- Flail chest
- Suspected pneumothorax, hemothorax, or tension pneumothorax
- Pelvic fracture
- Two or more proximal long-bone fractures
- Crushed or mangled extremity
- Uncontrolled external hemorrhage
- Suspected internal hemorrhage
- Signs and symptoms of shock
- Significant external blood loss with controlled hemorrhage
- Glasgow Coma Scale score 14 or less
- Altered mental status
- Seizure activity
- Sensory or motor deficit
- Any penetrating trauma to the head, neck, anterior or posterior chest or abdomen, and above the elbow or knee
- Amputation of an extremity proximal to the finger
- Trauma in a patient with significant medical history (myocardial infarction, chronic obstructive pulmonary disease, congestive heart failure), >55 years of age, hypothermia, burns, or pregnancy
- Multisystem trauma
- Open or depressed skull fracture
- Suspected brain injury
- Paralysis

**FIGURE 27-29** A St. Louis Fire Department ambulance pulls up at the Charles F. Knight Emergency and Trauma Center.

specialized trauma patients and then transferring them to a level I center.

- **Level III—Community Trauma Center.** Has some surgical capability and specially trained emergency department personnel to manage trauma. This type
2011 Guidelines for Field Triage of Injured Patients

Measure vital signs and level of consciousness
- Glasgow Coma Scale: ≤3
- Systolic Blood Pressure (mmHg): <90
- Respiratory Rate: ≤10 or ≥29 breaths per minute, or need for ventilatory support
- <20 in infant aged <1 year

1. Assess anatomy of injury
   - All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee
   - Chest wall instability or deformity (e.g., flail chest)
   - Two or more proximal long bone fractures
   - Crushed, dislocated, mangled, or amputated extremity
   - Amputation proximal to wrist or ankle
   - Pelvic fractures
   - Open or depressed skull fracture
   - Paralysis

2. Assess mechanism of injury and evidence of high-energy impact
   - Falls
     - Adults: ≥20 feet (one story is equal to 10 feet)
     - Children: ≥10 feet or two or three times the height of the child
   - High-risk auto crash
     - Impalement, including roof: ≥12 inches occupant site; ≥18 inches any site
     - Ejection (partial or complete) from automobile
     - Death in same passenger compartment
     - Vehicle telemetry data consistent with a high risk of injury
   - Auto vs. pedestrian/bicyclist thrown, run over, or with significant (>20 mph) impact
   - Motorcycle crash >20 mph

3. Assess special patient or system considerations
   - Older adults
     - Risk of injury/death increases after age 55 years
     - SBP <110 may represent shock after age 65
     - Low impact mechanisms (e.g., ground level falls) may result in severe injury
   - Children
     - Should be triaged preferentially to pediatric capable trauma centers
   - Anticoagulants and bleeding disorders
     - Patients with head injury are at high risk for rapid deterioration
   - Burns
     - Without other trauma mechanism: triage to burn facility
     - With trauma mechanism: triage to trauma center
   - Pregnancy >20 weeks
   - EMS provider judgment

4. When in doubt, transport to a trauma center.

Transport to a trauma center. Steps 1 and 2 attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the defined trauma system.

Transport to a trauma center, which, depending upon the defined trauma system, need not be the highest level trauma center.

Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.

National Center for Injury Prevention and Control
Division of Injury Response

Find the plan to save lives, at www.cdc.gov/fieldtriage

FIGURE 27-30 Guidelines for Field Triage of Injured Patients.
suspected pelvic fracture, intraabdominal bleeding, or retroperitoneal bleeding.
• Maintain manual spinal stabilization until the patient is completely immobilized on a backboard.
• Transport critically injured or multisystem trauma patients within 10 minutes to the appropriate trauma facility according to the trauma triage criteria. Always follow your local, regional, or state destination protocols.
• Obtain a history from the patient, relatives, or bystanders.
• Perform a secondary assessment to identify all other life-threatening and non-life-threatening injuries and manage each according to priority.

Special Considerations in Trauma Care

The following are special considerations in the trauma patient. Many of these considerations also apply to the medical patient:

• Your personal safety is of utmost importance when arriving on scene and throughout the entire time you are with the patient. You must always remain alert for potential scene hazards. These might involve traffic on the roadway, hazardous materials, hostile environment, unsecured crime scene, and sudden changes of patient behavior. An injured EMT is no longer able to provide care and requires additional resources at the scene.

• Airway management and adequate ventilation and oxygenation are key elements in managing the trauma patient. Shock from blood loss results in an inadequate delivery of oxygen to the cells. This causes the cells to convert from aerobic to anaerobic metabolism resulting in little energy production, acid accumulation, and eventual cellular dysfunction and death. Thus, ensuring the patient has an adequate airway, ventilation, and oxygenation contributes to managing and reversing the shock state.

• Stop significant bleeding. If a patient is losing a significant amount of blood, the delivery of oxygen and glucose to the cells is impaired. Hemoglobin in the red blood cell is the primary mechanism for oxygen transport. With any type of bleeding, red blood cells and hemoglobin are being removed from the vessels and decreasing the oxygen-carrying capability of the blood. The result is shock. To prevent or reverse shock, you must stop the bleeding as quickly as possible by direct pressure. If this is not effective, a tourniquet is then applied.

• Assessment of the trauma patient is conducted in a sequence that promotes a systematic approach to the patient. There are times when you must deviate from the sequence to provide emergency care for a life threat. As an example, airway always is assessed before circulation in the sequence. However, if you identify a major bleed (arterial or venous) during the general impression, you must first control the bleeding prior to moving on in the assessment. Adhering rigidly to a sequence when presented with obvious life threats may contribute to the deterioration of the patient.

• Rapid transport of the severely injured patient is essential to his survival. The definitive care for many seriously injured trauma patients is surgery. On-scene time should be limited to 10 minutes if at all possible. Rapid extrication should be used to remove the patient from a vehicle. Use the triage transport criteria to determine the need for rapid transport and the most appropriate medical facility. Consider intercepting with an advanced life support unit or transport by air medical if ground transport is excessive. Notify the receiving facility of the patient’s condition and estimated time of arrival.

• A backboard can serve to secure suspected fractures in an unstable patient who requires rapid transport. En route, if time or the patient’s condition permits, further stabilization of fractures can be accomplished through splinting. Taking the time at the scene to splint suspected fractures will delay transport and may contribute to the deterioration of the patient.

• Do not develop tunnel vision and become focused on dramatic injuries or dramatic patients. An open humerus fracture with a bone protruding from the skin at a 90-degree angle will attract your attention. However, if the patient is alert and screaming in pain, you must assume that he has an adequate amount of energy, good perfusion, and an adequate amount of oxygen and glucose delivered to the cells. On the other hand, the patient sitting next to him who barely nods his head in response to your question of “Are you okay?” likely is lacking energy from inadequate perfusion. It may be prudent to assess the quiet patient first. The most obvious injuries are not necessarily the most lethal. Often, the lethal injuries are occult and can be easily missed without a systemic and thorough assessment.
SUMMARY

Mechanism of injury generally refers to how a person was injured. Knowing the mechanism of injury may increase your suspicion that the person might have suffered certain injuries. However, your patient assessment is the most valuable method to determine what injuries the patient has sustained. Mass and velocity determine the amount of kinetic energy applied to the body in various types of mechanism of injury. The change in the kinetic energy is responsible for producing injury.

A force applied to the body will usually result in blunt or penetrating trauma. Blunt trauma is from a force applied to the body in which there is no penetration of the body by an object (for example, a blow to the chest with a baseball bat). Penetrating trauma will produce a break in the continuity of the skin by the object (for example, a knife or a bullet). Vehicle collisions frequently cause blunt trauma and create some typical injury patterns based on the type of impact: frontal, rear-end, lateral, rotational, or rollover. Even though vehicle safety restraints and air bags have saved a large number of lives, they also can produce injuries, such as bruising, fractures, and face and eye trauma. Motorcycle, all-terrain vehicle, and other recreational vehicle crashes produce various typical injury patterns in patients.

The severity of a penetrating trauma injury commonly depends on the mass and the velocity of the object as it strikes the body. The greater the mass and the higher the velocity, the greater the kinetic energy that is produced and the more severe the resulting injury. Velocity has a greater effect than mass. High-velocity weapons are particularly prone to producing massive bodily injury. Blast injuries, resulting from an explosion, are associated with three phases of injury: primary phase injuries (pressure injuries), secondary phase injuries (debris impacts), and tertiary phase injuries (from the person being thrown by the force of the blast).

Trauma systems have been developed to allow for rapid intervention in the injured patient. There are different designations of trauma facilities with various levels of care. Trauma triage criteria have been developed to assist the EMT in recognizing the need for rapid transport of an injured patient and determining the most appropriate facility to transport to.

Case Study Follow-up

Scene Size-up
Your initial call was for a minor collision with one patient complaining of knee pain. The police officer greeted you and explained that he was taking a report from the driver of a car that was struck from behind when he began to complain of the pain. He estimates the collision occurred at around 30 mph. He tells you that the other driver has been driven to the hospital by a friend.

The scene size-up reveals no obvious hazards; both vehicles have been moved off the road into a parking lot. You see only slight denting to the rear of your patient’s vehicle. There is only one patient, and since his car wasn’t damaged enough to interfere with the operation of the doors, gaining access to the patient is easy and will not require a rescue unit. You put on your disposable gloves and approach the vehicle.

Primary Assessment
You introduce yourself to the patient and ask him his name, and he says, “Call me Mike.” You explain that, as a safety measure, your partner will get into the back seat and reach from behind to hold Mike’s head still. There are no dents or damage to the steering wheel and no cracks in the windshield.

Your general impression is of a 40-year-old male in no obvious severe distress. Mike’s chief complaint is pain in the knees, and he tells you privately that he did not have his seat belt on and went down and under the dashboard during the impact. He is alert and oriented. The airway, breathing, oxygenation, and circulation status are all adequate. Because the mechanism of injury is not significant—and your general impression is that Mike is not badly injured—you determine that he is a low priority for immediate transport and that you will conduct the secondary assessment at the scene.

You maintain a high index of suspicion, however, and will be ready to change your priority decision if you find out that the mechanism of injury was more severe than seems true at this point, if any potential life threats are identified, or if there is any deterioration in Mike’s condition.

Secondary Assessment
You proceed with a rapid secondary assessment and find no signs of injury. The knees, which Mike says continue to hurt, show no evidence of bruising, swelling, or deformity. A quick check of all four extremities reveals no loss of pulses or sensory or motor function. You obtain a set of baseline vitals, which are all within normal ranges. Rapid extrication technique is not warranted in this case, so you work with your partner and a police Emergency Medical Responder to apply a continued
cervical spine immobilization collar and a KED immobilization vest, then transfer and immobilize Mike to a long spine board.

Once he is secured, you reassess Mike’s pulses and motor and sensory function in all four extremities. In the ambulance, you proceed to ask Mike history questions and find out he now also has an ache in his lumbar spine, is allergic to sulfa drugs, takes medication for allergies to environmental substances, has a history of asthma that has not been bothering him recently, and last ate and drank at breakfast 2 hours ago. Mike states he was just waiting for the oncoming traffic to clear so he could make a left turn when suddenly the other car struck him from behind.

Reassessment
Because Mike is stable, you conduct a reassessment every 15 minutes on the way to the hospital. You repeat the primary assessment and vital signs. You check to be sure that he is securely immobilized with no loss of function to the extremities. To help him feel a little more comfortable, you apply a cold pack to his knees. You arrive at the hospital, transfer Mike to the care of the emergency department staff, and prepare your ambulance for the next call.

IN REVIEW

1. Based on the formulas for kinetic energy and force, explain how the following are likely to affect the severity of an injury: (a) mass and velocity; (b) acceleration and deceleration.
2. Name and describe, in sequence, the three impacts that take place in a vehicular collision.
3. Name and describe four types of motorcycle collision.
4. Describe the path of energy and possible patterns of injury for each of the following kinds of falls: (a) feet first; (b) landing on outstretched hands; (c) head first.
5. Define cavitation and tell which of the following kinds of weapons would be likely to produce it: knife, handgun, M-16 rifle.

6. Explain the cause of each of the following phases of blast injury: primary, secondary, and tertiary.
7. Name mechanisms of injury that should cause the EMT to have a high index of suspicion of significant injury.
8. List the various types of trauma centers.
9. List anatomical criteria for rapid transport of a trauma patient.
10. List mechanism of injury criteria for rapid transport of a trauma patient.
11. List physiological criteria for rapid transport of a trauma patient.

CRITICAL THINKING

You arrive on the scene and find a 62-year-old male patient who, while driving on the freeway, struck a cement barrier head-on. The police estimate he was traveling at 65 mph upon impact. The windshield has an impact mark on the driver’s side, the air bag deployed, and the headrest is completely down. The patient was wearing his lap and shoulder restraints. The patient is unresponsive.

1. Based on the mechanism of injury, what injuries do you suspect the patient possibly has suffered?
2. What type of impact was involved in the collision?
3. What two different pathway patterns of injury may be involved in this collision?
Bleeding and Soft Tissue Trauma

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • Trauma (Content Areas: Bleeding; Soft Tissue Trauma)

COMPETENCY • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES • After reading this chapter, you should be able to:

28-1. Define key terms introduced in this chapter.
28-2. Explain the importance of recognizing and providing emergency medical care to patients with soft tissue injuries to control bleeding, prevent or treat shock, and to prevent contamination of wounds.
28-3. Recognize the severity and type of external bleeding.
28-5. Describe the assessment-based approach to external bleeding, including emergency medical care.
28-6. Explain why bleeding from the nose, ears, or mouth is of special concern and describe the appropriate care for bleeding from the nose, ears, or mouth.
28-7. Recognize indications of the severity of internal bleeding and describe the assessment-based approach to internal bleeding, including medical care to maintain perfusion and treat for shock.
28-8. Explain factors that may increase bleeding.
28-9. Define hemorrhagic shock and describe the assessment-based approach to hemorrhagic shock, including emergency medical care.
28-10. List types of closed soft tissue injuries and describe the assessment-based approach to closed soft tissue injuries, including emergency medical care.
28-11. List types of open soft tissue injuries and describe the assessment-based approach to open soft tissue injuries, including emergency medical care.
28-12. Explain special considerations and appropriate care for chest injuries, abdominal injuries, impaled objects, amputations, and large neck injuries.
28-13. Describe various types of dressings and bandages, including the purpose and methods of applying pressure dressings, and discuss general principles of dressing and bandaging.

KEY TERMS • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

abrasion p. 788
air embolism p. 795
amputation p. 789
avulsion p. 788
bandage p. 795
closed injury p. 787
contusion p. 787
crush injury p. 787
dressing p. 785
dressing p. 787
echymosis p. 787
episiotomy p. 779
eschar p. 793
hematoma p. 787
impaled object p. 794
laceration p. 789
occlusive dressing p. 793
open injury p. 788
penetration/puncture p. 790
sterile p. 795
Case Study

The Dispatch
EMS Unit 101—respond to Riverside High School at 1434 River Street for a reported stabbing—time out 1645 hours.

You ask the dispatcher if the police have been alerted. He doesn’t know but will check. You and your partner decide that if the police are not on the scene, you will stage at the minimart down the street until the scene is secure.

The dispatcher comes back and advises you that the police are at the scene and have one person in custody. He says your patient is a male with a stab wound to the left upper abdomen with profuse bleeding.

Upon Arrival
You and your partner have put on your gloves and eye protection. As you pull into the high school parking lot, you notice a crowd of teenagers and adults gathered around a young male lying on the ground. You notify dispatch that you are “on arrival.” Time is 1651.

A police officer approaches your unit. Your partner asks if the scene is secure. The officer states it is, and tells you they have one teenager in custody. You note that there is only one patient.

As you exit the vehicle and approach the patient, you see the young male, who appears to be a teenager, lying supine on the ground with a large penetrating wound to the left upper quadrant of the abdomen. The wound is bleeding profusely. There is no impaled object. No weapon is visible near the patient.

How would you proceed with this patient?
During this chapter, you will learn about bleeding and shock. Later, we will return to the case study and put in context some of the information you learned.

INTRODUCTION
Bleeding can be a significant, life-threatening emergency. As an EMT you must be able to recognize obvious or external bleeding problems, as well as not-so-obvious internal bleeding problems. If either type of bleeding is left untreated, it has the potential to lead to rapid patient deterioration, shock, and death.

Control of severe external bleeding is performed during the primary assessment. Only airway and breathing have a higher priority; however, if major bleeding is recognized during the general impression it should be immediately managed. Internal bleeding and shock are treated immediately following the primary assessment. An important element of the emergency care of bleeding associated with signs and symptoms of shock is to transport the patient to a medical facility as rapidly as possible.

Injuries to the soft tissues—the skin, muscles, and nerves—are often dramatic but rarely life threatening. However, they are serious if they involve large vessels or organs or if they lead to airway or breathing compromise, uncontrolled bleeding, or shock.

In general, emergency medical care emphasizes controlling bleeding, preventing further injury, and reducing the risk of infection. Unless an injury is life threatening, care is usually accomplished after the primary assessment and prior to lifting and moving. Failure to recognize and provide care for soft tissue injuries may lead to severe, uncontrolled bleeding, possible additional injury including hemorrhagic shock, or further contamination of the wound and increased risk of infection.

EXTERNAL BLEEDING
Standard Precautions must be taken routinely to avoid exposure of skin and mucous membranes to blood and other body fluids. Wear personal protective equipment, including gloves and eyewear, and wash your hands before and after each run. Standard Precautions are your best defense against transmission of infectious disease. (For more details, see Chapter 2, “Workforce Safety and Wellness of the EMT.”) This is true for all EMS calls, but especially in the presence of trauma with external bleeding (Figure 28-1 ■).

Severity
The severity of blood loss is dependent on several variables:

- Amount of blood loss
- Rate of blood loss
- Other injuries or existing conditions
- Patient's existing medical problems
- Patient's age

The severity of bleeding relative to the amount of blood loss is dependent on the patient. A 500-mL blood loss may not be as severe in a large patient as it would be in a child or smaller adult. An adult patient has 70 mL/kg of blood volume. An average-sized adult is considered to be 154 lb, which is 70 kg. Thus, an average-sized adult has 4,900 mL or 4.9 liters of blood volume (70 mL × 70 kg = 4,900 mL). A loss of 15 percent of blood volume or more is considered significant and can lead to shock. In the 154-lb patient, a loss of 735 mL of blood can lead to a shock state. Infants and young children typically...
have 80 mL/kg of blood volume. A 22-lb infant (10 kg) would have a total blood volume of 800 mL (10 kg × 80 mL = 800 mL). A 15 percent blood loss would be 120 mL (800 mL × 15% = 120 mL). A 200-mL blood loss in an average-sized adult would represent only a 4 percent blood loss, whereas a 200-mL blood loss in a 10-kg infant would represent a 25 percent blood loss.

To conclude that a loss of 500 mL of blood is not significant in an adult would be wrong, since the severity of that volume of blood loss is relative to the patient’s weight. The estimate of blood loss must be made based on the patient’s signs and symptoms (Table 28-1) and not on what appears to be on the floor, soaked into the patient’s clothing, in the toilet, or elsewhere on the scene.

The natural response of the blood vessels to bleeding is vessel constriction and clotting. However, a serious injury can prevent that defense mechanism from working, resulting in uncontrolled bleeding. A vessel that has been cut across, or perpendicular to the vessel, will have a tendency to retract and clot off. A cut along the length of the vessel will cause the vessel to open wider when it contracts. This will cause the vessel to bleed more severely. Remember: Uncontrolled bleeding or significant blood loss can lead to hemorrhagic shock and quite possibly to death.

**Pathophysiology Pearls**

The middle layer of a blood vessel is made up of smooth muscle (tunica media) that gives it the ability to constrict when injured. A transverse (across) cut of a vessel will cause the vessel to retract, thickening the smooth muscle layer at the cut end of the vessel and reducing the diameter of the vessel, which reduces blood flow and allows clotting to occur more easily.

**Types of Bleeding**

There are three types of bleeding: arterial, venous, and capillary. Each type can be life threatening. Each has its own characteristics (Figure 28-2 ■):

- **Arterial bleeding.** Bright red, spurting blood from a wound usually indicates a severed or damaged artery. The blood is bright red because it is rich in
oxygen. Spurting generally coincides with the pulse or contraction of the heart. Arterial bleeding can be more difficult to control than any other type of bleeding because of the higher pressure in the arteries, although the muscular walls may assist in hemostasis. As the patient’s blood pressure decreases, the spurting may also decrease and present as a steady flow of blood instead.

- **Venous bleeding.** Dark red blood that flows steadily from a wound usually indicates a severed or damaged vein. When blood is dark red, it is depleted of oxygen. A steady flow usually indicates venous bleeding, because veins are under less pressure than arteries. Venous bleeding may be profuse, but it is usually easier to control than arterial bleeding because of its lower pressure.

- **Capillary bleeding.** Slowly oozing blood that is a dark or intermediate color of red usually indicates damaged capillaries (Figure 28-3 ▶). In most cases, capillary bleeding is easily controlled. This type of bleeding often clots spontaneously. However, if a large body surface is involved, bleeding may be profuse and the threat of infection great.

### Methods of Controlling External Bleeding

#### Direct Pressure

The first method for controlling bleeding is direct pressure (EMT Skills 28-1A to 28-1C). This is usually accomplished by placing a sterile gauze pad or dressing over the injury site and applying fingertip pressure directly to the point of bleeding. Large, gaping wounds may require packing with sterile gauze and the application of direct hand pressure, if fingertip pressure fails (EMT Skills 28-1D). If, during the primary assessment, you find a major bleed, apply pressure to the site with your gloved hand until dressings can be applied.

If severe bleeding persists while direct pressure is being applied over dressings, remove the dressings and apply direct pressure to the point of bleeding, typically directly to the vessel that is bleeding. If diffuse bleeding is discovered, apply additional pressure. A pressure dressing can be applied to the wound to control hemorrhage. (See the section on pressure dressings later in the chapter.)

If major bleeding is occurring around an impaled object, apply direct pressure on either side of the object to control the bleeding. Never apply pressure to the object and never remove the object.
**Tourniquets**

If bleeding is not controlled with direct pressure, the next step is to apply a tourniquet. Many commercial tourniquets are now available (Figures 28-4a and 28-4b). To apply a tourniquet, follow these directions (EMT Skills 28-2A to 28-2D):

1. Use a bandage or commercial device that is 4 inches wide. If using a bandage rather than a commercial device, it should be four to six layers thick.
2. Wrap the tourniquet around the extremity at a point just proximal to the bleeding but as distal on the extremity and as close to the injury as possible. Do not cover the wound with the tourniquet.
3. Tighten the tourniquet until the hemorrhage ceases.
4. Secure the tightening rod or device.
5. Write the time of tourniquet application on tape and secure it to the tourniquet (for example, TK 13:32). Never cover the tourniquet or site of bleeding. Continuously reassess the wound for recurrent bleeding.
6. Notify the receiving medical facility that a tourniquet has been applied.
7. Document the use of the tourniquet and the time it was applied in the prehospital care report.

In some cases, an inflated blood pressure cuff may be used as a tourniquet until bleeding stops (Figure 28-5). Typically, the cuff will be inflated to 20 mmHg beyond the patient’s systolic blood pressure. If this technique is used, the cuff needs to be monitored to maintain pressure.

When using any type of tourniquet, consider the following guidelines:

- **Always use a wide bandage 4 inches or greater; never use wire, a belt, or any other material that may cut the skin or underlying soft tissue.**
- **Once it is applied, secure the tourniquet tightly. Do not loosen or remove it unless you are directed to do so by medical direction or local protocol. Prolonged transport, typically greater than 2 hours, may be an indication to loosen the tourniquet. Follow your local protocol.**
- **Apply the tourniquet as close to the injury as possible. However, never apply a tourniquet directly over any joint, and do not apply the tourniquet over the wound itself.**
- **Always make sure the tourniquet is in open view.**
- **Document the time of application on a piece of tape and affix it to the tourniquet.**
- **The tightness needed for a tourniquet to control hemorrhage in a leg is typically greater than that needed to control hemorrhage in an arm.**

**PATHOPHYSIOLOGY PEARLS**

If a tourniquet applied to an extremity does not completely stop arterial blood flow, the arterial blood will continue to flow into the extremity but the venous blood will not be able to flow out. This will build up arterial and venous pressure in the wound and actually increase the amount of bleeding. Be sure the tourniquet completely stops the arterial blood flow once it is applied.

**Elevation**

There is no evidence showing that elevation is an effective method to control or slow bleeding. However, there is also no evidence that shows it is harmful to the
patient. Thus, elevation would not be harmful after direct pressure is applied to the wound on the extremity. Elevation can only be considered if it is done in conjunction with direct pressure. Never use elevation alone and never elevate an extremity with a suspected fracture that has not been splinted.

**Splints**

Bleeding can be life threatening in an extremity with a suspected fracture. If left unsplinted, movement of broken bone ends or bone fragments can continue to damage surrounding tissues and blood vessels. Also, movement of the extremity may cause the clots that have formed to be broken, which will allow the vessels to continue to bleed. Splinting the extremity may assist with control of bleeding associated with a possible fracture because the splint will decrease movement at the site of the bleeding wound.

The source of bleeding in some fractures is the bone itself and not the surrounding vessels. This is especially true of the pelvis and femur. When the femur is fractured, it allows the surrounding muscle and tissue to lose tension and increase the diameter of the thigh. Basically, the cylindrical size of the thigh is increased. This allows more bleeding to occur within the thigh. The application of a traction splint serves not only as a splint but also as a method of bleeding control. The traction splint that is applied to a suspected fractured femur attaches to the ankle and at the level of the hip. Traction is applied to the ankle, which pulls the femur back in line. In turn, the traction increases the tension of the muscle and tissue surrounding the femur. This decreases the cylindrical size of the thigh and decreases the space into which the femur and surrounding vessels can bleed. The smaller-sized thigh may tamponade the bleeding with the increased pressure around the femur.

Apply splints on scene to extremity fractures only if the patient is stable and there are no life threats. If the patient is unstable, has any life threats, or exhibits signs of hemorrhagic shock, place the patient on the backboard and align the extremity fractures. Begin rapid transport. If time and the patient’s condition permit, splint individual fractures en route to the medical facility. See Chapter 30, “Musculoskeletal Trauma and Nontraumatic Fractures,” for more information on splints and splinting.

**PATHOPHYSIOLOGY PEARLS**

Up to 1,500 mL of blood can be lost around each femur and 500–750 mL around the tibia and fibula.

**Topical Hemostatic Agents**

Hemostatic agents are designed to improve clotting and control life-threatening hemorrhage that can’t be controlled with direct pressure. These agents come in two forms: (1) a dressing that is impregnated with the hemostatic agent and packed into the wound and (2) a powder or substance that is poured directly into the wound.

The hemostatic dressing may have fibrinogen and thrombin, chitosan, or other substances on the surface of the dressing to promote clotting and stop bleeding when applied to wounds. These dressings have shown dramatic results when applied to wounds with major arterial and venous bleeding. Hemostatic agents that are poured directly into the wound at the site of bleeding cause clotting to occur (Figure 28-6). These agents are used with pressure dressings to control arterial and venous bleeding.

The use of hemostatic agents is usually reserved for prolonged transport times. They do have associated complications such as burn injury to the wound from heat being produced in the chemical reaction that promotes clotting and embolization of granules in the vascular system. Be sure to follow your local protocol.

**Assessment-Based Approach: External Bleeding**

**Scene Size-up, Primary Assessment, and Rapid Secondary Assessment**

Based on dispatch information, begin preparing for the call while still en route to the scene by putting on gloves and eye protection. If you are responding to a known scene of violence or to an accident, make certain that the appropriate support agencies have been notified (police have secured the scene, for example, or special extrication teams have been notified).

Upon arrival, make sure the scene is safe before you enter, and take notice of any potential mechanism of injury. Also note the number of patients at the scene. If more than one patient has profuse bleeding, more resources may be required to effectively treat them.
As you approach the patient, begin to gather a general impression. Note the posture of the patient and whether he is alert or appears to have an altered mental status. An altered mental status is a sign of poor perfusion and shock. Note any significant bleeding. Significant bleeding is characterized as arterial or venous bleeding or bleeding that flows freely and steadily and is not controlled. If you note significant bleeding as you approach the patient, the first immediate action should be to control the bleeding with direct pressure. As that is being done, you or your partner should continue with the primary assessment.

Ensure that the patient has a patent airway. Assess the breathing rate and tidal volume to determine if breathing is adequate. Assess for adequate oxygenation. If the breathing is adequate and the patient is exhibiting signs and symptoms of poor perfusion, administer supplemental oxygen via a nonrebreather mask at 15 lpm to maintain an SpO\(_2\) of 95% or greater. If the breathing is inadequate, begin positive pressure ventilation with supplemental oxygen attached to the ventilation device. Assess the central and peripheral pulses, skin, and capillary refill.

External bleeding has a tendency to be very dramatic. Control the bleeding, but continue with the primary assessment. Do not skip the assessment of the airway, breathing, and circulation because you are distracted by a dramatic, bloody patient. Control the bleeding and proceed with the assessment.

After the primary assessment, perform the rapid secondary assessment in any patient who has suffered significant bleeding, who has an altered mental status, who presents with multiple injuries, or who has suffered a significant mechanism of injury. The rapid secondary assessment will reveal any other potential life threats and will provide further information about the stages of shock. Since bleeding is a serious condition, the rapid secondary assessment should not, if possible, take more than 90 seconds to perform.

Be sure to obtain a set of baseline vital signs for two reasons: (1) The vital signs will indicate the seriousness of the blood loss. (2) The baseline vital signs can be compared to a series of later vital sign measurements to determine if the patient’s condition is deteriorating, remaining the same, or improving. Keep in mind that vital signs may be deceiving and may not indicate the seriousness of the condition. Also assess signs of perfusion or hypoperfusion.

**Emergency Medical Care**

Severe external bleeding should be controlled during the primary assessment, following these steps:

1. **Take the necessary Standard Precautions.**
2. **Apply direct pressure** to the site of the bleeding. Apply a pressure dressing if possible.
3. If direct pressure fails to control the bleeding, **apply a tourniquet.** Be sure to note the time when the tourniquet is applied.
4. **Provide care for shock by administering supplemental oxygen** via a nonrebreather mask at 15 lpm to maintain an SpO\(_2\) of 95% or greater for adequate breathing or via positive pressure ventilation with supplemental oxygen if breathing is inadequate. Keep the patient warm, and transport immediately.
5. **Immovilize injured extremities.**

**Reassessment**

During the reassessment, ensure that the bleeding is still under control. Be alert for wounds that may suddenly begin to bleed again. Repeat the primary assessment, and obtain a set of vital signs every 5 minutes if the patient appears to be unstable. The patient would be considered unstable if any abnormal vital signs are noted, such as persistent tachycardia. Serial vital sign assessments are important to monitor the level of shock and blood loss. Provide additional emergency care and assessment as necessary.

**Bleeding from the Nose, Ears, or Mouth**

The EMT may encounter patients who are bleeding from the nose, ears, or mouth (Figure 28-7 ■). These special areas may be cause for concern, because they can indicate a serious condition. Possible causes of bleeding from the nose, ears, or mouth include the following:

- Skull injury
- Facial trauma
- Digital trauma (nose picking)
- Sinusitis and other upper respiratory tract infections
- Hypertension (high blood pressure)
- Clotting disorders
- Esophageal disease

**Figure 28-7** Bleeding from the nose, ears, or mouth could be a sign of serious illness or injury.
Any time you observe bleeding from a patient’s ears or nose associated with trauma, suspect a possible skull fracture. If the patient has experienced a head injury, you should not attempt to stop the flow of blood, which could create pressure inside the skull, causing even more damage. Instead, place a loose dressing around the area to collect the drainage and limit exposure to sources of infection.

Epistaxis, or nosebleed, is bleeding from the nose, which may result from injury, disease, or the environment. Usually this type of bleeding is more of an annoyance than a threat to life. However, in cases of extreme blood loss, hemorrhagic shock can develop.

To provide emergency medical care for nosebleed, place the patient in a sitting position and have him lean forward. Apply direct pressure by pinching the fleshy portion of the nostrils together (EMT Skills 28-3A and 28-3B). Keep the patient as calm and as still as possible. Apply ice or a cold pack over the bridge of the nose, if possible.

---

**INTERNAL BLEEDING**

Internal bleeding may result from a variety of causes, including blunt trauma, abnormal clotting, rupture of a blood vessel or vascular structure, and certain fractures (especially pelvic fractures). Because it is not visible and seldom obvious, internal bleeding can result in severe blood loss with rapid progression of hemorrhagic shock and death—all in a matter of minutes.

**Severity**

The severity of internal bleeding depends on the patient’s overall condition, age, other medical conditions, and source of the internal bleeding. The two most common sources of internal bleeding are injured or damaged internal organs and fractured extremities, especially fractures of the femur or pelvis. Always suspect internal bleeding if there are penetrating wounds to the skull, chest, abdomen, or pelvis.

A hematoma is a contained collection of blood. A hematoma the size of the patient’s fist equates to approximately 10 percent of the blood volume. A significant amount of internal bleeding can be associated with fractures. A fracture of the tibia, fibula, or humerus can cause a loss of 500–750 mL of blood in the average-sized adult patient. A loss of 1,500 mL of blood can occur around a femur fracture. Body cavities can hold much larger amounts of blood. Approximately 3,000 mL of blood can be lost in the thorax.

The severity of internal bleeding should be estimated based on signs and symptoms. Always suspect internal bleeding in cases of unexplained signs and symptoms of hemorrhagic shock.

---

**Assessment-Based Approach: Internal Bleeding**

**Scene Size-up and Primary Assessment**

During your scene size-up, look for and evaluate potential mechanisms of injury. Your suspicion of internal bleeding may be based on the mechanism of injury you identify. Ask yourself questions such as Did the patient fall? Is there a weapon or other item that might have caused trauma? If, for example, the emergency involves a fall, motorcycle or automobile collision, pedestrian impact, or blast, suspect blunt trauma and internal bleeding. Remember that penetrating injuries can result in both external and internal bleeding.

After ensuring that the scene is safe, approach the patient. During your general impression, look for any obvious external bleeding that is considered to be major. If you find a major bleed, immediately control it with direct pressure. As you continue with the primary assessment, assess the patient’s mental status. A decreasing mental status is a sign of both hypoxia and shock. As the patient continues to lose blood, the mental status will continue to deteriorate.

Assess the airway and ensure that it is patent. If it is not, open the airway with either a jaw-thrust or head-tilt, chin-lift maneuver, depending on whether a spinal injury is suspected. Assess the respiratory rate and tidal volume. Assess for adequate oxygenation. If both the respiratory rate and tidal volume are adequate, and the patient is exhibiting signs and symptoms of poor perfusion, administer supplemental oxygen via a nonbreather mask at 15 lpm to maintain an SpO2 reading of 95% or greater. If either the respiratory rate or the tidal volume is inadequate, immediately begin positive pressure ventilation with oxygen connected to the ventilation device. The respiratory rate may provide some early clues in your assessment of blood loss. As the patient loses blood, the poor perfusion state, cell hypoxia, and the sympathetic nervous system will cause an increase in the rate and depth of respiration. In the patient with tachypnea, carefully inspect, palpate, and auscultate the chest during the rapid secondary assessment since the rapid breathing may also indicate a chest injury.

After assessing the airway, breathing, and oxygenation, assess the pulses, skin, and capillary refill. The quality of the pulse is usually the first thing to indicate a blood loss, even before an increase in the pulse rate. The pulse will become weak and throbbing as the bleeding continues, tachycardia will then develop. Depending
on how much blood the patient lost before you arrived on the scene, you may find both a weak and thready pulse and tachycardia. If no radial pulse is found, this is an indication of severe hemorrhagic shock. It indicates that the vessels in the extremities have become severely constricted in an attempt to shunt blood to the core of the body, and the volume of blood is significantly decreased.

The skin will become pale, cool, and clammy in a hypoperfusion state. This is also seen as a result of the sympathetic nervous system causing the peripheral vessels to constrict (vasoconstriction) and shunt the blood to the core of the body. As the warm, red blood gets shunted to the core of the body, the skin becomes cooler and paler. The sympathetic nervous system will cause the skin also to become clammy or diaphoretic (sweaty). The capillary refill will be delayed. Be aware of environmental and disease conditions that may affect the capillary refill status. In infants, children, and adult males, capillary refill is typically less than 2 seconds. Adult females have a normal capillary refill of less than 3 seconds. Geriatric patients have a normal capillary refill of less than 4 seconds.

**PATHOPHYSIOLOGY PEARLS**

When blood loss occurs, almost immediately the nervous system sends signals from the brain to increase the heart rate, strengthen its contraction, and constrict vessels. The brain also stimulates the adrenal glands to secrete epinephrine and norepinephrine, which occurs within a few minutes. The epinephrine and norepinephrine will produce a sustained effect on the heart and vessels. The alpha properties in the epinephrine and norepinephrine will cause the vessels to constrict, creating the pale appearance and coolness of the skin. Alpha will also stimulate the sweat glands, causing the clammy, or diaphoretic, presentation. The effects of alpha stimulation are to constrict the vessels and increase the systemic vascular resistance in an attempt to raise the blood pressure.

The information collected in the primary assessment is important in determining if the patient’s condition is improving, deteriorating, or remaining the same. Based on this quick assessment, the information gained regarding the mental status; respiratory rate and depth; pulse rate and quality; skin color, temperature, and condition; and capillary refill is enough to make a judgment that the patient is in shock. You would then proceed to a rapid secondary assessment to identify any other life threats and to attempt to determine where the patient is bleeding.

**Secondary Assessment**

If the potential mechanism of injury and your general impression of the patient suggest internal bleeding, proceed to a rapid secondary assessment following the primary assessment. If there is evidence of contusions, abrasions, deformity, impact marks, swelling, or other trauma, treat the patient for internal bleeding. This is a priority patient; prepare for immediate transport following the rapid secondary assessment and initial emergency care.

**Signs and Symptoms.** Internal bleeding is not visible and may not be easily detectable. In some patients, by the time obvious signs and symptoms are present, the patient may have lost a significant amount of blood. Be on guard for subtle signs and symptoms and changes in the patient’s condition. Signs and symptoms of internal bleeding include the following:

- Pain, tenderness, swelling, or discoloration of suspected site of injury
- Bleeding from the mouth, rectum, vagina, or other orifice
- Vomiting bright red blood or blood the color of dark coffee grounds
- Dark, tarry stools, or stools with bright red blood
- Tender, rigid, or distended abdomen

**ASSESSMENT TIPS**

There can be internal bleeding with no obvious distention; 1 to 2 liters may distend the abdomen only 1 inch.

Signs and symptoms of internal bleeding that also indicate hemorrhagic shock are as follows:

- Anxiety, restlessness, combativeness, or altered mental status
- Weakness, faintness, or dizziness
- Thirst
- Shallow, rapid breathing
- Rapid, thready pulse (typically >90/minute in an adult)
- Pale, cool, clammy skin
- Delayed capillary refill
- Narrow pulse pressure (difference between systolic and diastolic pressure)
- Dropping blood pressure
- Dilated pupils that are sluggish in responding to light
- Nausea and vomiting

**PATHOPHYSIOLOGY PEARLS**

As the systolic blood pressure drops from the decrease in blood volume, the systemic vasoconstriction causes the diastolic blood pressure to be maintained or to increase, creating a narrow pulse pressure. A narrow pulse pressure is an indication that a significant amount of blood has been lost.

**Emergency Medical Care**

The goal of all emergency medical care for internal bleeding is to recognize its presence quickly, maintain
the body’s perfusion, treat for shock, and provide rapid transport to an appropriate medical facility.

1. Take Standard Precautions by wearing appropriate personal protective equipment.
2. Maintain an open airway and adequate breathing. Provide positive pressure ventilation if respiratory rate or tidal volume is inadequate.
3. Administer supplemental oxygen by a nonrebreather mask at 15 lpm if the patient is exhibiting signs and symptoms of poor perfusion or to maintain an SpO$_2$ reading of 95% or greater.
4. Control external bleeding with direct pressure. If direct pressure is unsuccessful in controlling the bleeding, apply a tourniquet. Splint any extremity that you suspect is fractured. Initial splinting can be achieved by the long backboard when expeditious transport is critical. Once en route, if time and the patient’s condition permit, fractures can be more specifically managed.
5. Provide immediate transport to critical or unstable patients and those with signs and symptoms of hemorrhagic shock.
6. Provide care for shock, as detailed later in this chapter.

Reassessment
Continually reevaluate the critical patient, performing a reassessment every 5 minutes during transport, or more frequently if needed.

**FACTORS THAT MAY INCREASE BLEEDING**

The following factors may interfere with the clotting process and lead to an increase in the rate of bleeding or the amount of blood lost:

- Movement. Movement can disrupt the clotting process and allow bleeding to continue.
- Low body temperature. A low body temperature may make the clotting process slower and less effective. That is one reason why it is necessary to keep the bleeding and shock patient warm.
- Medications. Coumadin (warfarin) and other anticoagulant drugs, aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs (NSAIDs) will interfere with the clotting process.
- Intravenous fluids. Intravenous fluids may increase the blood pressure, causing clots to break free, or the water or other properties of the fluid may interfere with the clotting process.
- Removal of dressings and bandages. If the bleeding has been controlled, do not remove the dressing to examine the wound. This may disrupt the clotting and cause the bleeding to begin again.

**HEMORRHAGIC SHOCK**

Shock is most often the direct result of inadequate perfusion of tissue from the loss of blood volume. (As you will recall from Chapter 15, “Shock and Resuscitation,” shock from fluid loss is called hypovolemic shock. When the fluid loss results from bleeding, or hemorrhage, it is known as hemorrhagic hypovolemic shock, or simply hemorrhagic shock.) When the cells of the body do not receive the oxygen, glucose, and other nutrients they need, they begin to fail and die. If this condition persists, cell failure, organ failure, and death will follow (Figure 28-8 ■). It is imperative that hemorrhagic shock is recognized and treated promptly. Immediate transport is necessary.

Certain major organs of the body require an adequate blood flow to function properly. When bleeding continues unchecked, there is a reduction in circulating blood volume. In response, blood may be shunted or redirected from less important organs to more important organs. Since these important organs are located in the head and trunk, peripheral perfusion (to the extremities) and perfusion of the skin, for example, are drastically reduced.

Hemorrhagic shock should be suspected in any patient who has suffered or may have suffered trauma (Figure 28-9 ■).

**Assessment-Based Approach: Hemorrhagic Shock**

As in any case with potential for exposure to blood or body fluids, wear the appropriate personal protective equipment. If possible, put it on while en route to the scene to decrease the amount of time it takes to get to the patient.

**Scene Size-up and Primary Assessment**

During scene size-up, take note of any potential mechanism of injury that may have caused external or internal bleeding. Penetrating injuries may prompt you to seek law enforcement resources and to reevaluate scene safety. When it is safe to approach the patient, assess the mental status, airway, breathing, oxygenation, and circulation, noting any abnormalities or signs of shock. Provide high-concentration oxygen if breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the SpO$_2$ is less than 95%; provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

**Secondary Assessment**

If multiple injuries, internal bleeding, or hemorrhagic shock is suspected, or the patient has an altered mental status, perform a rapid secondary assessment. Assess for signs and symptoms of hemorrhagic shock throughout the assessment. Restlessness, anxiety, and thirst may
**CYCLE OF HEMORRHAGIC SHOCK**

**TRAUMA**

Loss of blood volume from the vascular space decreases cardiac output and pressure in the aorta, carotid, and peripheral arteries. Baroreceptors trigger hormone release and sympathetic nervous system stimulation to increase cardiac output, blood pressure, and perfusion.

**Patient becomes unresponsive, heart rate severely increases and then drops dramatically, blood pressure decreases significantly and may not be obtainable, respirations decrease and become inadequate.**

**Brain becomes ischemic and medulla fails, causing a severe drop in perfusion and blood pressure.**

**Continued volume loss overwhelms compensatory mechanisms and blood pressure falls, tachycardia and tachypnea further increase, peripheral pulses are extremely weak or absent, mental status deteriorates.**

**Patient exhibits tachycardia, weak peripheral pulses, decreased mental status, tachypnea, and pale, cool and clammy skin.**

---

**FIGURE 28-8** Continuous cycle of shock.

---

**FIGURE 28-9** Abdominal bruising is a sign of blunt trauma and probable internal bleeding. © Edward T. Dickinson, MD

be the first signs of shock. If the patient exhibits these signs, assess for internal or external bleeding in the chest, in the abdomen, in the pelvis, around the femur, or to the upper extremities.

Monitor for peripheral perfusion and skin color, temperature, and condition. Peripheral blood flow will be decreased as internal bleeding progresses. This may cause weak, thready, or absent pulses in the distal extremities, and also cause the skin to become pale, cool, and clammy.

**Signs and Symptoms.** A blood loss of greater than 15 percent will affect the patient’s vital signs. Establish a baseline as soon as possible. The signs and symptoms of shock are as follows:

- Mental status:
  - Restlessness
  - Anxiety
  - Altered mental status

---

**PATHOPHYSIOLOGY PEARLS**

A decrease in blood perfusion to the brain will decrease the delivery of oxygen and elimination of carbon dioxide, causing the patient to present with restlessness, anxiety, and an altered mental status.

---

**PATHOPHYSIOLOGY PEARLS**

The patient may present with cool skin and a decreasing body core temperature from the lack of heat production associated with a shift from aerobic to anaerobic metabolism.
• Peripheral perfusion and perfusion of the skin:
  • Pale, cool, clammy skin
  • Weak, thready, or absent peripheral pulses
  • Delayed capillary refill
• Vital signs:
  • Increased pulse rate (early sign), with weak and
    thready pulse (early sign)
  • Increased breathing rate (early sign) that may be
    deep or shallow, labored, and irregular
  • Narrow pulse pressure
  • Decreased blood pressure (late sign)
• Other signs and symptoms:
  • Dilated pupils (sluggish reaction)
  • Marked thirst

**PATHOPHYSIOLOGY PEARLS**

When fluid surrounding the cells in the hypothalamus of the
brain moves into the blood vessels to try to increase the blood
volume, the concentration of the particles (electrolytes) in the
fluid changes, causing the patient to experience thirst.

• Nausea and vomiting
• Pallor with cyanosis to the lips

**Note:** Infants and children can compensate, or main-
tain their blood pressure, until their blood volume is
depleted by almost one-third. Then their condition will
suddenly and radically deteriorate. If a child’s blood
pressure is dropping, it is an ominous sign.

**Emergency Medical Care**

The treatment of hemorrhagic shock needs to occur
early in the primary assessment and continue until trans-
fer of care to the receiving medical facility is complete.
The main priority in the care of this patient is to main-
tain perfusion to the vital organs and interrupt any pro-
gression or worsening of shock.

Emergency medical care of hemorrhagic shock is as
follows (EMT Skills 28-4A to 28-4C):

1. **Maintain Standard Precautions** by wearing the ap-
  propriate personal protective equipment, including
  gloves and eye protection.
2. **Maintain an open airway.** If breathing is adequate
  and signs and symptoms of poor perfusion, hypoxia,
  hypoxemia, respiratory distress, or heart failure are
  evident; the patient complains of dyspnea; or the SpO₂
  is less than 95% administer supplemental oxygen via a
  nonrebreather mask at 15 lpm. If breathing is inade-
quate, begin positive pressure ventilation with supple-
mental oxygen connected to the ventilation device.
3. **Control any external bleeding** using the techniques
  described earlier in this chapter.
4. **Apply and inflate the pneumatic antishock garment
  (PASG)** if signs and symptoms of hemorrhagic shock
  are present; if the lower abdomen is tender with a

**Note:** Because of the ability of infants and children
to compensate for shock by maintaining blood pres-
sure, followed by a sudden deterioration into severe
and possibly irreversible shock, it is crucial in infants
and children not to wait for significant signs of shock
suspected pelvic injury (lower abdominal tenderness,
pelvic instability) with a systolic blood pressure of <90
mmHg; if there is suspected intraperitoneal hemor-
rhage with hypotension or suspected retroperitoneal
hemorrhage with hypotension; and if there is no evi-
dence of chest injury, pregnancy, evisceration, or car-
diac arrest. Always apply and inflate the pneumatic
antisock garment (PASG) only in accordance with
local protocols and if approved by medical direction.

See Figure 28-10 and the more detailed section on
the PASG that follows.

5. **Place the patient in a supine position.**
6. **Splint suspected bone or joint injuries.** In the hemor-
hagic shock patient, transport is critical. Thus, the
fractures will be initially stabilized by the long back-
board. En route, if time and the patient’s condition
permit, the fractures can be individually splinted.

7. **Use a blanket to cover any patient suspected of suffer-
ing hemorrhagic shock** to prevent loss of body heat.
Since the patient may have a decreased blood flow
to nonvital organs, the body’s heat regulation may be
impaired. Warm the patient compartment to 85 de-
grees during transport to prevent body heat loss. Re-
move any wet or blood-soaked clothes.

8. **Transport the patient immediately.**

**Note:** Because of the ability of infants and children
to compensate for shock by maintaining blood pres-
sure, followed by a sudden deterioration into severe
and possibly irreversible shock, it is crucial in infants
and children not to wait for significant signs of shock

---

**FIGURE 28-10** A pneumatic antishock garment (PASG).
to appear but to treat the infant or child based on any suspicion of trauma and subtle signs and symptoms of shock. A child’s total blood volume is far less than that of an adult. Even a small loss of blood that would not be considered life threatening for an adult should be considered critical in an infant or child. Immediate transport is crucial.

Remainder of the Assessment
Continue to assess the patient for changes in mental status and vital signs throughout the rapid trauma assessment and reassessment. These may be conducted en route if early transport is initiated because of suspected shock.

Pneumatic Antishock Garment (PASG)
The PASG is a controversial device that is primarily used to control blood loss. Follow your local protocol regarding use of the PASG.

Indications
- Suspected pelvic fracture with hypotension (systolic blood pressure <90 mmHg)
- Suspected intraperitoneal hemorrhage with hypotension (internal abdominal trauma and bleeding)
- Suspected retroperitoneal hemorrhage with hypotension

Contraindications
- Penetrating thoracic trauma
- Splinting of lower extremity fractures
- Eviscerated abdominal organs
- Impaled object in abdomen
- Pregnancy
- Cardiopulmonary arrest
- Congestive heart failure
- Pulmonary edema

For application and inflation of the PASG, see EMT Skills 28-5A to 28-5D. Once inflated, the PASG should not be deflated in the prehospital setting unless ordered by medical direction. If you suspect the patient has suffered a ruptured diaphragm or if he complains of respiratory distress after inflation, contact medical direction to consider deflation.

Summary: Assessment and Care
To review possible assessment findings and emergency care for bleeding and hemorrhagic shock, see Figures 28-11 and 28-12.

Assessment Summary

Bleeding and Hemorrhagic Shock
The following findings may be associated with bleeding and shock.

Scene Size-up
Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Splatters or pools of blood at the scene
- Blood-soaked clothing
- Penetrating trauma
- Blunt trauma

Primary Assessment

General Impression
- Obvious massive external hemorrhage
- Extremely pale color
- Appears weak and ill

Mental Status
- Alert to unresponsive, based on amount of blood loss and shock
- As blood loss continues, mental status decreases

Airway
- May be closed if mental status is altered
- May be bleeding in airway from trauma

Breathing
- Initially fast and normal to deeper volume
- May become shallow and fast or slow as blood loss and shock progress
- May be absent or inadequate if bleeding in chest or associated with chest injury
- May be fast and shallow if abdominal injury is present

Circulation
- Pulses possibly difficult to find because of extreme blood loss
- Increased heart rate that becomes extremely elevated, then suddenly decreases with continued blood loss
- Pulses becoming extremely weak or absent as blood loss and shock continue
- Skin becoming increasingly pale, cool, and clammy as blood loss and shock progress

Status: Priority Patient

Secondary Assessment

Physical Exam
Head, neck, and face:
- External bleeding
- Blood from ear, nose, or mouth
- Pupils dilated and sluggish to respond to light
- Cyanosis
- Pale oral mucosa

Figure 28-11a Assessment summary: bleeding and hemorrhagic shock.
The Skin

Review the description and function of the skin provided in Chapter 7, “Anatomy, Physiology, and Medical Terminology.” You may recall that the skin is one of the most durable and largest organs of the body. It is composed of three layers—the epidermis, the dermis, and a subcutaneous layer. It protects the body from the environment, bacteria, and other organisms, and it helps to regulate the body’s temperature. The skin also senses heat, cold, touch, pressure, and pain, and it aids in the elimination of water and various salts.

The term wound usually refers to an injury to the skin and underlying tissues (EMT Skills 28-6). Wounds...
Emergency Care Algorithm

**BLEEDING AND SHOCK**

- **Mechanism of injury present?**
  - Yes: Consider manual in-line stabilization
  - No: No

- **Major external bleeding?**
  - Yes: Control the bleeding by direct pressure
  - No: No

- **Bleeding controlled?**
  - Yes: Yes
  - No: Tourniquet

- **Alert and able to obey commands**
  - Yes: Consider oxygen
  - No: Assess mental status

- **Assess mental status**
  - Altered: Yes
  - No: Yes

- **Assess breathing**
  - Yes: Yes
  - Inadequate: Suction if necessary
  - Adequate: Head-tilt, chin-lift or jaw-thrust

- **Assess circulation**
  - Adequate: Yes
  - Inadequate: Consider oxygen

- **Rapid secondary assessment**
  - Yes: Spinal injury suspected?
    - Yes: Immobilize to backboard
    - No: No
  - No: No

- **Suspected pelvic fracture with SBP < 90 mmHg**
- **Suspected intraperitoneal or retroperitoneal hemorrhage with hypotension SBP < 90 mmHg**
- **Penetrating chest injury**
- **Eviscerated abdominal organ**
- **Pregnancy**
- **Cardiac arrest**

- **Maintain body temperature**
- **Apply PALS**
- **Transport**
- **Reassessment**

Green = key decision points
Blue = interventions

**FIGURE 28-12** Emergency care algorithm: bleeding and shock.
to the skin are categorized as *closed, open, single, or multiple*. These types of injuries are discussed in detail on the following pages.

### CLOSED SOFT TISSUE INJURIES

A wound in which there is no break in the continuity of the skin is called a *closed injury*. There are three specific types of closed injuries: contusions, hematomas, and crush injuries.

#### Contusions

A *contusion*, or bruise, is an injury to the tissue and blood vessels contained within the dermis (Figure 28-13). This type of injury causes localized swelling and pain at the injury site. The patient may also have some discoloration at the injury site caused by blood leaking from damaged vessels and accumulating in the surrounding tissues. The black and blue discoloration is called *ecchymosis*.

**PATHOPHYSIOLOGY PEARLS**

The ecchymosis (black and blue discoloration) associated with a contusion occurs when the red blood cells in the blood that has leaked out of the capillary or vessel become deoxygenated.

#### Hematomas

A *hematoma* is similar to a contusion, except it usually involves damage to a larger blood vessel and a larger amount of tissue. It is characterized by a large lump with bluish discoloration caused by blood collecting beneath the skin. This blood may also separate tissues and pool in the pockets they form. A hematoma the size of the patient’s fist can be equal to 10 percent blood loss, causing minimal signs and symptoms of hemorrhagic shock.

#### Crush Injuries

A *crush injury* is one in which force great enough to cause injury has been applied to the body. Severe blunt trauma or crushing force can cause serious damage to the underlying soft tissues with associated internal bleeding, and may result in hemorrhagic shock. Internal organs may actually rupture if a severe crush injury is sustained. Crush injuries can fall into either category, open or closed injuries. See “Open Soft Tissue Injuries” later in this chapter for more details.

**Assessment-Based Approach: Closed Soft Tissue Injuries**

**Scene Size-up and Primary Assessment**

During your scene size-up, include a scan for the mechanism of injury. Be sure you have taken all Standard Precautions before you approach the patient, including protective gloves.

When the scene is safe, approach the patient and conduct a primary assessment. If the mechanism of injury and your general impression of the patient suggest a possible spinal injury, establish in-line stabilization of the cervical spine. After assessing the mental status and ensuring an adequate airway, breathing, and oxygenation, check for and treat obvious signs of severe bleeding and shock.

If breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the $\text{SpO}_2$ is less than 95% administer supplemental oxygen. Initiate positive pressure ventilation with supplemental oxygen if breathing is inadequate.

**Secondary Assessment**

Perform a secondary assessment, checking for evidence of trauma. Assess baseline vital signs and obtain a history.

**Signs and Symptoms.** Signs and symptoms of closed soft tissue injury include:

- Swelling, pain, and discoloration at the injury site
- Signs and symptoms of internal bleeding and hemorrhagic shock if the underlying organs are injured

**Emergency Medical Care**

In general, small contusions do not require treatment. They usually heal by themselves. Larger contusions, hematomas, and crush injuries, however, can be an indication of serious underlying internal injuries and blood loss and can lead to compromised blood flow and nerve injury.
Steps to provide emergency medical care for closed soft tissue injuries are as follows:

1. **Take Standard Precautions.** Since blood or body fluids may be present, wear protective gloves, eyewear, and other appropriate personal protective equipment. Wash your hands thoroughly after the call, even if gloves were worn.

2. **Ensure an open airway and adequate breathing and oxygenation.** If breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the $\text{SpO}_2$ is less than 95% administer supplemental oxygen.

3. **Treat for shock, if necessary.** If you suspect significant blood loss, provide emergency care based on the mechanism of injury and the patient’s signs and symptoms.

4. **Splint suspected fractures.** Prevent a closed injury associated with possible bone fracture from becoming an open injury, reduce the amount of bleeding, and relieve the patient’s pain by immobilizing the injured extremity. The injured extremity should also be elevated, if possible.

**Reassessment**

For the reassessment, repeat the primary assessment, reassess and monitor vital signs, and recheck all interventions.

---

**OPEN SOFT TISSUE INJURIES**

When the continuity of the skin is broken, the wound is called an **open injury**. In open injuries the patient is at risk for external bleeding and contamination with dirt and bacteria, which may lead to infection. The open injury may be the first indicator of a deeper, more serious injury, such as a fracture or ruptured or lacerated organ.

There are six general types of open injuries: abrasions, lacerations, avulsions, amputations, penetrations/punctures, and crush injuries (Figure 28-14 ■).

**Abrasions**

An **abrasion** generally is caused by scraping, rubbing, or shearing away of the epidermis, the outermost layer of the skin (Figure 28-15 ■). Even though an abrasion is considered a superficial injury, it often is extremely painful because of the presence of exposed nerve endings. In most cases, blood will ooze from the wound (capillary bleeding), which can be controlled easily with direct pressure.

While small abrasions may not be life threatening, abrasions to large areas of the body surface may be cause for concern. For example, as a result of a motorcycle accident, a patient may slide across the pavement, causing head-to-toe abrasions (“road rash”). Bleeding in such a case may not be a serious threat; however, contamination, infection, and the potential for underlying injuries will be significant.
Lacerations

A break in the skin of varying depth, a laceration may be linear (regular) or stellate (irregular) (Figures 28-16 ■, 28-17a, and 28-17b ■). Lacerations may bleed more than other types of open soft tissue injuries, especially when an artery is involved. Linear lacerations are usually caused by a knife, razor, or broken glass. They usually heal better than stellate injuries because the wound has smooth edges. Stellate lacerations are commonly caused by a blunt object. The edges of the wound will be jagged and healing may be prolonged.

Avulsions

An avulsion is a loose flap of skin and underlying soft tissue that has been torn loose (partial avulsion) or pulled completely off (total or complete avulsion) (Figures 28-18a and 28-18b ■). Bleeding may be severe because of blood vessel injury, although some blood vessels may tamponade (compress) themselves by retracting into the soft tissue. Healing will be prolonged and scarring may be extensive.

Avulsions are most commonly a result of accidents with industrial or home machinery and motor vehicles. They commonly involve the fingers, toes, hands, feet, forearms, legs, ears, and nose. A small amount of blood loss does not negate the possibility of a serious injury. The severity of an avulsion is directly related to the effectiveness of circulation and perfusion distal to the injury.

Amputations

An amputation involves a disruption in the continuity of an extremity or other body part (Figures 28-19a to 28-19c ■). Amputations are the result of ripping or
tearing forces often associated with industrial, agricultural, power tool, or motor vehicle accidents. Bleeding from amputations may be massive. However, in most cases, because of the elasticity of the blood vessels, very little bleeding occurs. An incomplete amputation typically bleeds more than a complete amputation. Always consider shock in cases of amputation.

**Penetrations/Punctures**

A penetration/puncture injury generally is the result of a sharp, pointed object being pushed or driven into the soft tissues (Figure 28-20 ■). The entry wound may appear very small and cause little bleeding. However, such injuries may be deep and damaging and may cause severe internal bleeding. The overall severity of the injury depends on the location, the size of the penetrating object, the depth of penetration, the forces involved, and the structures in the path of the injury. It can be difficult to determine the extent of injury based on the external wound. Therefore, treat these injuries with great caution.

Gunshots may cause both an entrance and an exit wound (EMT Skills 28-7). In general, the entrance wound is smaller than the exit wound and, if the patient was shot at close range, the entrance wound will be surrounded by powder burns. The exit wound is usually larger and will bleed more profusely. Remember to assess for the possibility of multiple gunshot wounds, especially in areas covered with hair.

Stab wounds may be easily detected or may be small and hidden by clothing or body parts, such as an extremity. Expose the patient and carefully inspect all areas of the body so that a potentially life-threatening injury is not missed. Always assess the patient for underlying internal injuries and hemorrhagic shock.
against the body. Then, when released, the blood vessels or internal organs will begin to bleed freely and profusely.

Other Soft Tissue Injuries

Bites

Dog bites are a common type of animal bite. The soft tissue injuries caused by dog bites are usually to the hands, arms, and legs, although some occur on the head and face (Figure 28-22). Complications include infection, cellulitis (inflammation of skin cells), and septicemia (blood infection). Rabies and tetanus (lockjaw) are also a concern, although rare. Human bites may cause hepatitis (inflammation of the liver).

Generally, bite wounds are a combination of penetration/puncture injuries and crush injuries, which may also involve internal organs and bones. Severity of a bite injury is related to the force of the animal’s jaws. The most dangerous bite occurs from injuries over vascular areas. Human bites are probably the most difficult to manage in the long term because of the high rate of infection. (The human mouth carries a greater amount of bacteria.) The most frequent human bite locations are the ears, nose, and fingers.

Emergency care for bites is essentially the same as for other soft tissue injuries. However minor the wound may appear, the bite should be evaluated at a medical facility. Always ensure scene safety first. If possible, arrange for someone to contain or isolate the animal, so that it will not interfere while you provide care to the patient.
Clamping Injuries

A clamping injury is a body part that is caught or strangled by some piece of machinery (Figure 28-23). Most clamping injuries involve a finger or hand caught in an opening (the mouth of a bottle, for example). Time is a factor because the longer a part remains clamped, the more damage there may be. Also, edema makes removal more difficult over time.

In general, if a body part is trapped in a clamping object and the patient is stable, apply a lubricant (K-Y Jelly, for example) and slowly attempt to wiggle the part loose. If possible, elevate the body part above the level of the patient’s head to decrease circulation pressure as you attempt to remove the part.

If a clamping injury causes severe bleeding or shock and if the patient cannot be rapidly disentangled, immediately transport the patient. Lifesaving measures may then be initiated and the clamping object removed later by emergency department personnel. If the clamping object is too large to transport, specialized personnel may be required to cut away parts of the machine or other clamping object and disentangle the patient.

Assessment-Based Approach: Open Soft Tissue Injuries

If you are responding to a known scene of violence or to an accident, check with dispatch to make certain that the appropriate resources have been marshaled (police have secured the scene, for example, or special extrication teams have been notified). Since there is an increased likelihood of exposure to blood or body fluids when you treat a patient with open injuries, be sure to wear the appropriate personal protective equipment, including gloves and eye protection. In cases of potential splattering, a protective mask should be worn.

Secondary Assessment

Conduct a secondary assessment. Assess baseline vital signs, and obtain a history. For patients without a significant mechanism of injury, without an altered mental status, and without multiple injuries, perform a modified secondary assessment, using components of the complete secondary assessment for the specific injury site.

**Signs and Symptoms.** The signs and symptoms of open soft tissue injuries include the following:

- A break in the skin and external bleeding
- Localized swelling, pain, and discoloration at the injury site
- Possible signs and symptoms of internal bleeding and hemorrhagic shock

Emergency Medical Care

Unless bleeding is severe, emergency care for open soft tissue injuries is performed after the primary assessment.

1. **Take Standard Precautions.**
2. **Ensure an open airway and adequate breathing and oxygenation.** If breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the SpO₂ is less than 95% administer supplemental oxygen. Initiate positive pressure ventilation with supplemental oxygen if the tidal volume or respiratory rate is inadequate.
3. **Expose the wound.** In order to completely assess the wound, expose the entire injury site. Cut away clothing and, if necessary, clear the area of blood and debris with sterile gauze, dressings, or the cleanest material available. Thoroughly assess and evaluate the patient for additional wounds or injuries.
4. **Control the bleeding with direct pressure.** Use a tourniquet if bleeding is not controlled with direct pressure.
5. **Prevent further contamination.** Keep the wound as clean as possible. If there are loose particles of
foreign material around the wound, wipe them away with a sterile gauze or similar clean material. Always wipe away from the wound, never toward it. Never pick out embedded particles or debris.

6. **Dress and bandage the wound.** If not already done, apply a dry sterile dressing. Secure it with a bandage. Check distal pulses both before and after applying the bandage to be sure it is not too tight.

7. **Keep the patient calm and quiet.** Remember that an early sign of shock is restlessness and anxiety. The more excited a patient becomes, the higher the heart rate and blood pressure, which may lead to increased bleeding.

8. **Treat for hemorrhagic shock.** If signs and symptoms are present, provide the appropriate care.

9. **Transport.**

**Reassessment**

Perform a reassessment by repeating the primary assessment, monitoring vital signs, and rechecking interventions.

**Special Considerations**

All of the emergency care steps just described apply to the specific injuries discussed in detail in the next sections: chest injuries, abdominal injuries, impaled objects, amputations, and large open neck injuries. In all of these cases, ensure an open airway and adequate breathing and oxygenation. If breathing is adequate and signs and symptoms of poor perfusion, hypoxia, hypoxemia, respiratory distress, or heart failure are evident; the patient complains of dyspnea; or the SpO2 is less than 95% administer supplemental oxygen. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen attached to the ventilation device.

**Chest Injuries.** A chest injury may prevent adequate respiration by causing the lung to collapse. In cases of penetrating chest wounds:

1. **Use an occlusive dressing to prevent air from entering the chest cavity through the wound** (a condition known as an *open pneumothorax*). An **occlusive dressing** (one that can form an airtight seal), such as Vaseline gauze, household plastic wrap, or the plastic bag from a dressing or oxygen mask, should be secured with tape on three sides (Figure 28-24 ■). A commercial device, such as an Asherman chest seal, can also be used to occlude the open wound while creating a flutter valve for air to escape. For an open chest wound, leave one side untaped to allow air to escape as the patient exhales. This will prevent a tension pneumothorax, which is a severe buildup of air in the chest cavity that compresses the lungs and heart toward the uninjured side.

2. **If there is no suspected spinal injury, the patient may assume a position of comfort or any position that allows for easiest chest expansion, usually injured side down.**

**Abdominal Injuries.** Abdominal wounds sometimes result in an **evisceration** (internal abdominal organs protrude through the wound). Follow these guidelines when dealing with such an injury:

1. **Do not touch the abdominal organs or try to replace the exposed organs.** You may cause further damage and increase contamination of the organs and abdominal cavity.

2. **Cover the exposed organs.** Use a sterile dressing moistened with sterile water or saline. The dressing should be large enough to cover all of the protruding organs. Sterile gauze is preferred. Avoid all absorbent materials, such as toilet tissue or paper towels, which may cling to the organs. Then loosely cover the moistened dressing with an occlusive dressing taped on all four sides (Figure 28-25 ■). Maintain

---

**FIGURE 28-24** Open chest injury with occlusive dressing taped on three sides. (© Shout Picture Library)

**FIGURE 28-25** Cover the abdominal organs with a moist sterile dressing and an occlusive covering.
temperature with layers of a more bulky dressing, such as a particle-free bath blanket or towel. Do not apply the PASG if it is used in your system.

3. **Flex the patient’s hips and knees, if they are uninjured and if spinal injury is not suspected.** This will help to decrease the tension of the abdominal muscles. Placing pillows or other materials under the patient’s knees also may be helpful. (However, suspect spinal injury with a significant mechanism of injury to the abdomen.)

**Impaled Objects.** An **impaled object** (an object still embedded in a wound) should never be removed in the field, unless it is through the cheek or the neck where it is obstructing airflow through the trachea (Figure 28-26■).

Emergency medical care for a patient with an impaled object includes the following (EMT Skills 28-8A to 28-8C):

1. **Manually secure the object.** Prevent any motion, which can cause further damage and bleeding.

2. **Expose the wound area.** Remove clothing from around the wound, but be careful to cause no further motion of the object.

3. **Control bleeding.** Apply direct pressure to the wound edges. Avoid putting undue pressure on the impaled object.

4. **Use a bulky dressing to help stabilize the object.** Surround the entire impaled object with dressings. Pack them around the object, and tape it securely in place to avoid motion during transport. A dressing formed into a ring or doughnut shape may be used to stabilize the object. If it is in the abdomen, do not use the PASG if it is used in your system.

**Amputations.** In amputation injuries, you must care for the amputated part, as well as for the patient and the injury site. Your handling of the amputated part can have significant impact on the success of surgical reattachment.

First, provide emergency medical care to the patient. Enlist others to look for any missing body parts. Once a body part is located, follow these guidelines (Figure 28-27■):

1. **Remove any gross contamination by flushing the part with sterile water or saline.** Never immerse the part in water or sterile saline, since this may damage it.

2. **Wrap the part in a dry sterile gauze dressing.** (Check with local medical direction, which may dictate the use of moist dressings instead.)

3. **Wrap or bag the amputated part in plastic.** Place it in a plastic bag or plastic wrap in accordance with local protocol. Label the bag with the patient’s name, date, and time the part was wrapped and bagged.

4. **Keep the amputated part cool.** Place the wrapped and bagged part in a cooler or other suitable container with an ice pack or ice on the bottom to keep

---

**FIGURE 28-26** An impaled object in the cheek may be removed. Dress outside of wound and inside between cheek and teeth.

**FIGURE 28-27** Emergency care for amputated part. Follow local protocol.
the part cool. Do not place the part directly on the ice pack or ice to avoid any possibility of freezing the part. The container should also be marked with the patient’s name, date, and body part.

5. **Transport the part with the patient, if at all possible.** In some cases, however, this may not be possible, especially when the part has not been located. In this instance, arrange for immediate transport of the body part, once it is found, to the same facility to which the patient has been transported.

   **Note:** If an amputation is incomplete and the body part is still partially attached, do not complete the amputation. Care for the wound as previously described, but also make sure that the partially amputated part is not twisted or constricted. Immobilize the injured area to prevent further injury.

**Large Open Neck Injuries.** In addition to severe bleeding from a wound involving the major blood vessels of the neck, there is the danger of air being sucked into a neck vein and carried to the heart, which can be lethal. Bleeding control and prevention of an air embolism (air bubble) are the major goals (Figure 28-28 ■). Assess any neck wound for major blood vessel involvement. Arterial bleeding will be profuse with bright red blood spurting from the wound and is a grave sign. Venous bleeding will be dark red and flowing steadily from the wound.

In general, follow these guidelines for care of a large open neck wound:

1. **Place a gloved hand over the wound to control bleeding.**
2. **Apply an occlusive dressing,** which should extend beyond all wound edges to avoid air or part of the dressing being sucked into the wound. Tape the dressing on all four sides.
3. **Cover the occlusive dressing with a regular dressing.**
4. **Apply only enough pressure to control the bleeding.** Compress the carotid artery only if it is severed and it is necessary to control bleeding.

5. **Once bleeding is controlled, apply a pressure dressing,** taking care not to restrict airflow or compress the major blood vessels in the neck. Such a dressing should not be applied circumferentially around the neck. (Direct pressure is preferred.)

6. **If there is a suspected spinal injury, provide appropriate immobilization.** Spinal injury should always be suspected with any significant injury or mechanism of injury to the neck.

### DRESSINGS AND BANDAGES

**Dressings**

A dressing covers an open wound to aid in the control of bleeding and to prevent further damage or contamination. The dressing should be sterile, or free of any organisms (bacteria, virus, or spore) that may cause infection. Commercially wrapped and packaged dressings are available in various types and sizes.

The following are common types of dressings (Figures 28-29a to 28-29d ■):

- **Gauze pad.** Available in various sizes (2” × 2”, 4” × 4”, 5” × 9”, and so on), a gauze pad is made of layered gauze.

- **Self-adhering dressing.** This type of dressing adheres to itself when overlapped. It is available in various sizes and may also be used as a roller bandage.

- **Universal or multitrauma dressing.** This is a bulky dressing, usually 10” × 36”, and is used on large areas such as abdominal wounds. (Also called abdominal or ABD pads.)

- **Occlusive dressing.** This dressing creates an airtight seal for open abdominal, chest, and large neck injuries. A petroleum-type occlusive dressing is impregnated with petroleum to prevent adhering to the open wound. An improvised occlusive dressing may be made from sterile plastic wrap, plastic bags, or a similar material.

   **Note:** Plastic is preferred over aluminum foil as an occlusive dressing, because foil has been found to cause further damage to exposed internal organs, and it is not as pliable as plastic.

**Bandages**

Once a dressing is applied, a bandage is used to secure a dressing in place (EMT Skills 28-9A to 28-9G). In most cases it is not necessary for a bandage to be sterile, but it should be clean and free of debris. Bandages that may be used as dressings are also available in various types and sizes. The following are common types of bandages:

- **Self-adhering bandage.** This type of bandage adheres to itself when overlapped. It may be used as a dressing or as a roller bandage (EMT Skills 28-10A to 28-10C).
- **Gauze rolls.** Available in various sizes, this bandage is rolled meshed gauze.
- **Triangular bandage.** This bandage is usually a 40-inch square piece of cloth (Figure 28-30). When folded to form a 2- or 3-inch-wide cravat, it may be used as a bandage to secure dressings.
- **Air splint.** This device may be used to hold dressings in place on an extremity (Figure 28-31).

### Pressure Dressings

A pressure dressing can be used to maintain control of bleeding. Apply a pressure dressing in the following way:

1. **Cover the wound with several sterile gauze dressings or a sterile bulky dressing.**
2. **Apply direct pressure** over the wound until the bleeding is controlled.
3. **Bandage firmly** to create enough pressure to maintain control of the bleeding. Check distal pulses to be sure the bandage is not too tight. An air splint or blood pressure cuff can also be used to hold a pressure dressing in place. If you use a blood pressure cuff, be sure that distal pulses are still present after inflation.
4. **If blood soaks through the original dressing and bandage, indicating continued severe bleeding, remove them and apply direct fingertip pressure.** Once the bleeding is controlled, apply dressings and bandage over the wound again.

### General Principles of Dressing and Bandaging

There are no hard-and-fast rules for dressing and bandaging wounds. Often, adaptability and creativity are far more important ingredients. In dressing and bandaging, use the materials you have on hand and the methods you can best adapt, as long as the following conditions are generally met:

- **Dressing materials should be as clean as possible.** Sterile materials are always preferable. When you open dressing packages or handle any materials that you will use as dressings, do so carefully to
Do not bandage a wound too loosely. Bandages should not slip or shift and should not allow the dressing beneath to slip or shift.

Bandage wounds snugly, but not too tightly. Be careful not to interfere with circulation. If the injured part involves the hands or feet, leave the tips of the toes or fingers exposed to allow for distal circulation assessments. For circumferential bandages, check distal pulses and motor and sensory function before and after bandage application.

If you are bandaging a small wound on an extremity, cover a larger area with the bandage. This will help avoid creating a pressure point, and it will distribute pressure more uniformly.

Always place the body part to be bandaged in the position in which it is to remain. Avoid bandaging across a joint, and do not try bending a joint after the bandage has been applied.

Apply a tourniquet if bleeding is not controlled with direct pressure. Once in place, a tourniquet must not be removed in the field.

Summary: Assessment and Care
To review possible assessment findings and emergency care for soft tissue injuries, see Figures 28-32 and 28-33.
**Assessment Summary**

**SOFT TISSUE TRAUMA**

The following findings may be associated with soft tissue injury.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Splatters or pools of blood at the scene
- Blood-soaked clothing
- Penetrating trauma
- Blunt trauma

**Primary Assessment**

**General Impression**
- Obvious massive external hemorrhage
- Extremely pale color
- Open or closed injuries to body

**Mental Status**
- Alert to unresponsive, based on amount of blood loss and shock
- As blood loss continues, mental status decreases

**Airway**
- May be closed if mental status is altered
- May be bleeding in airway from trauma

**Breathing**
- Initially fast and normal to deeper tidal volume
- May become shallow and fast or slow as blood loss and shock progress
- May be absent or inadequate if bleeding in chest or associated with chest injury
- May be fast and shallow if abdominal injury is present

**Circulation**
- Pulses possibly difficult to find if extreme blood loss
- Increased heart rate that becomes extremely elevated, then suddenly decreases with continued blood loss
- Pulses becoming extremely weak or absent as blood loss and shock continue
- Skin becoming increasingly pale, cool, and clammy as blood loss and shock progress

**Status:** Priority patient if uncontrolled bleeding or shock is suspected

---

**Secondary Assessment**

**Physical Exam**

**Head, neck, and face:**
- Look for large laceration to neck that may cause air emboli

**Chest:**
- Open wound to chest

**Abdomen:**
- Rigid, distended abdomen
- Discoloration around umbilicus or in flank area (late)
- Penetrating or blunt trauma
- Pain on palpation
- Abdominal evisceration

**Extremities:**
- Obvious external bleeding
- Swelling, pain, and discoloration at injury site
- Flaps or complete avulsions
- Amputations

**Baseline Vital Signs**
- BP: normal; may decrease or become absent in shock
- HR: normal or increased in shock
- RR: normal or increased in shock
- Skin: normal or pale, cool, clammy, cyanotic in shock
- Pupils: normal or dilated and sluggish to respond in shock

**SAMPLE History**

**Signs and symptoms of closed soft tissue injury:**
- Swelling
- Pain
- Discoloration
- Shock if associated with internal injury

**Signs and symptoms of open soft tissue injury:**
- Abrasions
- Lacerations
- Punctures
- Avulsions
- Amputations
- Obvious external bleeding
- Shock if associated with significant bleeding

---

![FIGURE 28-32a](Assessment summary: soft tissue trauma.)
Emergency Care Protocol

SOFT TISSUE TRAUMA

1. Establish manual in-line stabilization if spinal injury is suspected.
2. Control any major life-threatening bleeding.
3. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
4. Suction secretions as necessary.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 95% and no signs or symptoms of hypoxia, respiratory distress, or shock are present, oxygen may not be necessary. If signs of hypoxia, respiratory distress, or shock are present, or the SpO2 reading is less than 95%, administer oxygen to maintain the SpO2 at >95%.
7. If there is an open chest injury, apply a nonporous dressing taped on three sides.
8. Control bleeding with direct pressure (use fingertip pressure).
9. Apply a tourniquet if bleeding is not controlled with direct pressure.
10. Apply sterile dressings and bandages.
11. Splint suspected fractures.
12. Maintain body temperature.
13. Consider PASG if indicated.
14. Place the patient supine.
15. If spinal injury is suspected, immobilize the patient to a backboard.

16. Manage specific soft tissue injuries as follows:
   - Abdominal evisceration: Apply a moist sterile dressing over the wound and cover with a nonporous dressing taped on four sides. Position the patient supine and flex knees.
   - Large laceration to neck: Apply direct pressure to stop bleeding. Apply a nonporous dressing taped on all four sides.
   - Open chest wound: Apply a nonporous dressing taped on three sides.
   - Impaled object: Apply dressings to the wound and stabilize in place. Remove the object only if impaled in the cheek or obstructing ventilation in the neck.
   - Avulsion: Do not complete avulsion. Rinse the wound to clean off debris if necessary. Apply dressing and bandages to keep the avulsed tissue in place. Splint the extremity to limit movement.
   - Amputation (partial): Do not complete a partial amputation. Realign the extremity to as normal a position as possible. Apply sterile dressings. Splint to immobilize and limit movement. Be prepared to control bleeding.
   - Amputation (complete): Clean debris. Apply direct pressure to the stump to control bleeding. Apply sterile dressings and bandages. Wrap the amputated part in a dry, sterile gauze dressing. Then wrap or bag the amputated part in plastic and place on a cold pack or ice. Do not freeze. Transport with the patient, if possible.
17. Transport.
18. Perform reassessment every 5 minutes if unstable and every 15 minutes if stable.
Emergency Care Algorithm

OPEN SOFT TISSUE TRAUMA

Mechanism of injury present?

Yes

Manual in-line stabilization

Yes

Major external bleeding?

No

Control the bleeding by direct pressure

No

Tourniquet

Yes

Bleeding controlled?

No

Alert and able to obey commands

Assess mental status

Altered

Consider oxygen therapy

Assess circulation

Secondary assessment

Yes

Airway open?

No

Suction if necessary

Head-tilt, chin-lift or jaw-thrust maneuver

Oro- or nasopharyngeal airway

Yes

Assess breathing

Adequate

Administer oxygen

Inadequate

PPV with O₂

Assess circulation

Rapid secondary assessment

Spinal injury suspected?

Yes

Immobilize to backboard

No

Abdominal evisceration

Laceration to neck

Open chest wound

FIGURE 28-33  Emergency care algorithm: open soft tissue trauma.
EMT SKILLS 28-1

Bleeding Control by Direct Pressure

28-1A  Bleeding from a wound to the forearm.

28-1B  Apply gloved fingertip pressure over a dressing directly on the point of bleeding.

28-1C  If the bleeding does not stop, remove the dressing and apply direct pressure with gloved fingertips to the point of bleeding.

28-1D  Pack large, gaping wounds with sterile gauze and apply direct pressure.

EMT SKILLS 28-2

Application of a Tourniquet

28-2A  First attempt to control bleeding by direct pressure.

28-2B  If direct pressure is ineffective, apply direct pressure over a thick dressing while preparing the tourniquet.

continued
Apply the tourniquet proximal to the wound but not over a joint.

Pack large, gaping wounds with sterile gauze and apply direct pressure. Twist the rod to tighten the tourniquet to the extent necessary to control bleeding and secure the tightening rod. Write the time of tourniquet application on tape and apply it to the tourniquet, leaving the tourniquet exposed to view, and notify the receiving facility that a tourniquet has been applied. Continuously reassess the wound for recurrent bleeding. Do not loosen or remove the tourniquet unless directed to do so by medical direction or local protocol.

EMT SKILLS 28-3

**Controlling a Nosebleed**

Have the patient sit and lean forward.

Pinch the fleshy part of the nostrils together.
Emergency Care for Shock

**EMT SKILLS 28-4**

- **28-4A** Take all necessary Standard Precautions.
- **28-4B** Administer supplemental oxygen or positive pressure ventilation as indicated.
- **28-4C** Cover the patient to prevent loss of body heat.

**EMT SKILLS 28-5**

- **28-5A** Place the PASG on the spine board, then the patient on the PASG. Position so the top of the garment is three finger-widths below the bottom of the rib cage.
- **28-5B** Apply the garment.

*continued*
Soft tissue injuries can occur in a variety of ways, as shown in these photos.

28-6A During a street altercation, one participant struck the other with a tire iron—blunt trauma resulting in an open soft tissue injury to the arm.

28-6B (1) and (2) This patient, a salesman in a sporting goods store, was demonstrating a bow with a carbon fiber arrow. During the demonstration, the apparatus broke, releasing the arrow that penetrated the patient’s hand. (© Charles Stewart MD MDM MPH)
Gunshot Wounds

■ **28-7B.1** Gunshot entrance wound to the chest. (© Edward T. Dickinson, MD)

■ **28-7B.2** Gunshot exit wound from the shoulder. (© Edward T. Dickinson, MD)
**EMT SKILLS 28-8**

Stabilizing an Impaled Object

- **28-8A**  An impaled kitchen knife.
- **28-8B**  Cut away clothing.
- **28-8C**  Stabilize and bandage the object in place.

**EMT SKILLS 28-9**

Bandaging

- **28-9A**  Head and/or eye bandage.
- **28-9B**  Head and/or ear bandage.
■ 28-9C Cheek bandage (be sure the mouth will open).

■ 28-9D Hand bandage.

■ 28-9E Shoulder bandage.

■ 28-9F Foot and/or ankle bandage.

■ 28-9G Knee bandage.
The Self-Adhering Roller Bandage

- **28-10A** Secure the self-adhering roller bandage with several overlying wraps.
- **28-10B** Overlap the bandage, keeping it snug.
- **28-10C** When the bandage covers an area larger than the wound, secure with tape or tie it in place.

**Chapter Review**

**SUMMARY**

Perfusion is the delivery of oxygen, glucose, and other nutrients to the cells and the elimination of carbon dioxide and other waste products. Perfusion occurs from adequate circulation of blood through the vessels and capillaries. If the perfusion becomes insufficient, it is called hypoperfusion or shock. Hypovolemic shock is most often a result of blood loss. If not treated promptly and effectively, shock can rapidly lead to death.

Bleeding may be external or internal. External bleeding is easy to identify, since it can be seen during the patient assessment, whereas internal bleeding cannot be seen and must be suspected based on the patient's signs and symptoms. Bleeding could be arterial, venous, or capillary. Arterial bleeding is the most difficult to control, followed by venous
bleeding. Methods to control external bleeding include direct pressure and tourniquet if the bleeding is uncontrolled with direct pressure.

Bleeding may lead to shock. The patient will present with a variety of signs and symptoms. Emergency care includes establishing and maintaining an airway, breathing, oxygenation, and circulation; controlling any bleeding; splinting any suspected fractures; keeping the patient warm; and providing rapid transport.

Soft tissue injuries are often dramatic, but rarely are they life threatening unless they involve organs or major vessels. Soft tissue injuries are classified as open or closed. A complication of an open soft tissue injury is the introduction of bacteria and other contaminants into the wound, increasing the risk of infection. The primary step in emergency care of the soft tissue injury is to stop any major bleeding. Other types of injuries involving the soft tissues that are life threatening are open chest wounds, abdominal evisceration, and large and deep lacerations to the neck.

Dressings are sterile and cover the wound directly, whereas a bandage may or may not be sterile and is typically used to hold the dressing in place. An occlusive dressing is used to prevent air from entering the wound. Bandages should be applied in a manner that securely holds the dressing in place but does not compromise the circulation or the wound.

Case Study Follow-up

Scene Size-up
You and your partner have responded to a reported stabbing at Riverside High School. You arrive on the scene to find it has been secured. You approach the patient, an unresponsive male lying supine on the ground with a large penetrating wound to the left upper quadrant of the abdomen. The wound is bleeding profusely. There is no impaled object and no weapon visible.

Primary Assessment
Your general impression of the teenage patient is that he is critical and will require rapid transport to the hospital. You immediately tell your partner to get the stretcher. You begin to assess the patient’s mental status and note that he is unresponsive to verbal stimuli but will grimace to painful stimuli. His airway is patent with rapid and shallow breathing at a rate of 34 per minute. You instruct one of the Emergency Medical Responders to begin bag-valve-mask ventilations at 12/minute and attach supplemental oxygen to the reservoir device.

You cannot feel a radial pulse but you can feel a carotid pulse, which is weak and rapid with a rate of 120 bpm. Dark red blood is flowing profusely from the abdominal wound. You decide to quickly pack the wound with sterile dressings and tape the dressings in place.

Your partner and an Emergency Medical Responder return with the stretcher and a pair of firefighter Emergency Medical Responders who have just arrived on the scene. Since there are no other signs of external trauma, you decide not to use spinal precautions.

Secondary Assessment
Once the patient is on the stretcher and in the ambulance, you conduct a rapid secondary assessment that does not reveal signs or symptoms not already known, other than that the abdomen is rigid to palpation. The patient remains unresponsive.

Your partner obtains a set of vital signs. You notify the hospital via radio of your patient’s condition and expected arrival in 7 minutes.

Your partner informs you that blood pressure is 72/56 mmHg, pulse is 134 bpm, breathing is being assisted at a rate of 12/minute, and skin is pale, cool, and clammy. Although the external bleeding was profuse, you know that, because the wound site is the abdomen, the patient is most likely bleeding internally as well as suffering from hypoperfusion shock. You begin a rapid secondary assessment to find any additional wounds.

Reassessment
Transport time is short. There is time for only one reassessment, which reveals no changes in the patient’s condition. You arrive at the hospital and quickly unload the patient. You give a quick report to the waiting trauma team as you transfer care to them. You then begin the task of documenting the call on yourprehospital care report. Your partner and the firefighters begin to clean and decontaminate the ambulance and equipment used during the call.

On the evening news, you learn that the patient died while in surgery. The next day you get a chance to talk to the emergency physician who explains that the patient had a lacerated splenic artery and an abdomen filled with blood. You ask if you could have done anything different, or better, or faster. The doctor tells you there was nothing anyone could have done for this patient in the prehospital setting that you did not do, and she commends you for your work in attempting to control bleeding, assisting ventilations, and—especially—transporting the patient without delay. The only satisfaction to be gained from this sad case is the knowledge that you gave the young patient the best possible chance.
IN REVIEW

1. Describe arterial, venous, and capillary bleeding.
2. Describe the primary method to control external bleeding.
3. Explain (a) when and (b) how to use a tourniquet to control bleeding.
4. Name the two most common sources of internal bleeding.
5. List the signs and symptoms of internal bleeding, including late signs.
6. Describe emergency medical care of internal bleeding.
7. List the signs and symptoms of hemorrhagic shock.
9. Describe each of the three types of closed soft tissue injuries.
10. Identify the general signs and symptoms of closed soft tissue injuries.
11. Outline the general emergency medical care for closed soft tissue injuries.
12. Describe each of the six types of open soft tissue injuries.
13. Identify the general signs and symptoms of open soft tissue injuries.
14. Outline the general emergency medical care for open soft tissue injuries.
15. Describe the special considerations that must be taken when providing emergency medical care to patients with the following injuries: penetrating chest wounds, abdominal evisceration, impaled object, amputated part, and large open injury to the neck.
16. Describe the purpose of a dressing and name several available types.
17. Describe the purpose of a bandage and name several available types.
18. Describe the purpose of a pressure dressing and outline the steps for applying a pressure dressing.

CRITICAL THINKING

You arrive on the scene of a domestic incident. The police direct you into the kitchen of the home where you find a 52-year-old male patient with a knife impaled in his anterior chest on the right side approximately 2 inches inferior to the clavicle on the midclavicular line. He also has a large, gaping laceration to the left side of his neck with a large, steady flow of blood. He is moaning. His respirations are 46 per minute and severely shallow. His radial pulse is absent. The skin is extremely pale, cool, and clammy. His carotid pulse is 132 bpm.

1. What immediate emergency care would you provide for the patient?
2. How would you manage the wound to the neck?
3. What complications may be associated with the neck wound?
4. How would you manage the knife impaled in the chest?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • **Trauma** (Content Area: Soft Tissue Trauma)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

29-1. Define key terms introduced in this chapter.
29-2. Explain the concept that burns are not just “skin deep.”
29-3. Describe the effects of burns on the following body systems:
   a. Circulatory
   b. Respiratory
   c. Renal
   d. Nervous and musculoskeletal
   e. Gastrointestinal
29-4. Explain the classification of burns by depth and by body surface area involved, for both adult and pediatric patients.
29-5. Discuss considerations of burn depth, location, body surface area involved, the patient’s age, and any pre-existing medical conditions in determining the severity of burn injuries.
29-6. Discuss each of the following types of burns:
   a. Thermal
   b. Inhalation
   c. Chemical
d. Electrical
e. Radiation
29-7. Discuss each of the following mechanisms of burn injuries:
   a. Flame
   b. Contact
   c. Scald
   d. Steam
   e. Gas
   f. Electrical
g. Flash
29-8. Describe the assessment-based approach to burns.
29-9. Describe special considerations in the scene size-up when responding to calls involving burned patients.
29-10. Explain the concept of stopping the burning process.
29-12. Discuss special considerations for dressing burns, including burns to specific anatomical areas.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- superficial burn p. 814
INTRODUCTION

Each year over 2 million people suffer burn injuries. Burn injuries are complicated because, contrary to what most people think, they are not just “skin deep.” In addition to damaging the structure of the skin and compromising its functions, burn injuries impact most of the body’s other systems in some way. For instance, burn injuries can impair the body’s fluid and chemical balance and body temperature regulation, as well as its musculoskeletal, circulatory, and respiratory functions. Burn injuries may also affect a person’s emotional well-being because of possible disfigurement and the need to cope with long healing processes.

In order to properly assess and provide emergency care for burn patients, EMTs need to have a fundamental understanding of the kinds of burns, how burn injuries are classified, and how they affect adult, child, and infant patients.

THE SKIN: STRUCTURE AND FUNCTION REVIEW

To understand how to classify burns, it is necessary first to understand the structure and function of the skin. (Review the information on the skin in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and Chapter 28, “Bleeding and Soft Tissue Trauma,” as well as reading the information in this chapter.)

The skin has a structure of three layers: The outermost layer is the epidermis, which provides a watertight and resilient barrier from the external environment; the second layer is the dermis, which contains small capillary beds as well as the sensory structures of the skin; and the innermost layer is the hypodermis (also called the subcutaneous layer), composed of fatty connective tissue and containing larger blood vessels. The layers range in thickness from one cell to several layers of cells. The skin serves multiple functions. For instance, it:

- Provides a physical barrier against the external environment
- Provides a barrier against infection
- Provides protection from bacteria or other harmful agents
- Insulates and protects underlying structures and body organs from injury
- Aids in the regulation of body temperature
- Provides for sensation transmission (hot, cold, pain, and touch)
- Aids in elimination of some of the body’s wastes
- Contains fluids necessary to functioning of other organs and systems

All of these functions can be impaired or destroyed by a burn injury.

AIRWAY, BREATHING, OXYGENATION, AND CIRCULATION

Most burn patients who die in the prehospital setting will die from an occluded airway, toxic inhalation, or other trauma, and not from the soft tissue trauma of the burn itself. The EMT should first establish and maintain a patent airway, adequate ventilation, and adequate oxygenation, and ensure that any life-threatening bleeding
has been controlled. Only then will the EMT turn attention to further assessment and care of the burn.

**EFFECTS OF BURNS ON BODY SYSTEMS**

Burn injuries can not only impair or destroy the structure and functions of the skin, they can also damage other body systems. This section discusses some of the potential complications from burns to body organ systems other than the skin. The organ systems discussed are all essential for patient survival and successful recovery. Burn injuries that impair any of these functions can have a dramatic effect on the patient’s outcome.

By providing the proper emergency medical care of the airway, preventing further contamination, and providing protection from further injury, you can decrease burn patient mortality considerably.

**Circulatory System**

Burn injuries can cause extreme fluid loss and increased stress on the heart. Burns increase capillary permeability, or the ability of fluid to leak from the vessels, which decreases the fluid volume inside the vessels. As fluid leaks from the damaged tissue cells to areas between the cells, it creates edema (swelling), which can further compromise tissue perfusion to local capillary beds as well as perfusion to distal tissues.

A condition that can occur with moderate to major burns that cover sufficient body surface area (BSA) is called burn shock. Burn shock, which develops only after the first few hours, results from extensive vascular bed damage that allows both fluid and protein molecules in the plasma to leak into surrounding tissues. The loss of plasma proteins causes the normal fluid balance of the rest of the vascular system to become disturbed and, as a result, blood plasma starts to seep from all capillary beds (even those not involved in the burn itself). The end result is a large fluid shift out of the vessels and into the spaces surrounding the cells to a point where the total vascular volume is insufficient to meet the body’s needs. This also explains the extensive swelling seen in the burn patient. In the first 24 hours after a burn injury, as a result of the fluid loss from the vessels into the tissues, the edema may cause the body to swell to double its normal size.

The fluid loss just described can lead to shock (hypoperfusion). Major burns will require large amounts of fluid replacement during the patient’s hospitalization. For example, an average adult patient with a full- or partial-thickness burn area of 50 percent BSA may need as much as 15 liters of fluid in the first 24 hours after a burn injury. However, fluid losses are usually not significant in the early hours of a burn. An EMT who finds a newly burned patient in a state of hypoperfusion should first consider direct blood loss from an associated external or internal hemorrhage.

**Respiratory System**

Burns may affect the respiratory system in a variety of ways. Swelling of the face or throat may cause airway closure. Inhalation of superheated air may cause the lining of the larynx to swell (laryngeal edema) and may cause fluid to accumulate in the lungs. Smoke and toxic gas inhalation may cause respiratory arrest or compromise or poisoning from noxious fumes. If the patient is in an enclosed space, he would have a higher probability of having an inhalation injury. If the chest is circumferentially burned, eschar (tough, leathery burned skin) may restrict chest expansion.

**Renal System (Kidneys)**

The decrease in blood flow from fluid loss caused by a burn (see the prior section on the circulatory system) will, of course, cause decreased blood flow to the kidneys and a consequent decrease in urinary output. Also, the burn injury will cause many wastes to form in the blood because of cell destruction, such as myoglobin from muscle destruction. This is particularly true with electrical burns. Since the kidneys are responsible for filtering the contaminated blood, a blockage in the kidneys may also result. In the end this may cause all or parts of the kidneys to stop functioning.

**Nervous and Musculoskeletal Systems**

Burn injuries can destroy nerve endings in the burn area and cause loss of function to extremities or other body parts. An extremity burn may cause loss of function, long-term muscle wasting, and joint dysfunction because of scarring. Patients who face loss of function, extreme pain, and scarring will also be prone to fear and anxiety. These patients may need both medical and psychological help to aid the healing process.

**Gastrointestinal System**

Although it is a low priority for the EMT, the gastrointestinal system plays an important role in the long-term care and survival of severely burned patients. As blood flow is decreased, blood is rerouted from this system to the rest of the body. Nausea or vomiting are common in burns of greater than 10 percent BSA and can further upset normal chemical balances, and long-term stress may cause ulcers. In order to promote healing and survival of burn patients, the gastrointestinal system must be kept functioning properly to ensure adequate nutritional support for healing.
**ASSESSMENT AND CARE OF BURNS**

**Classifying Burns by Depth**

Burns are classified according to depth of the injury. Burn injuries involving the skin are classified as superficial (first-degree), partial-thickness (second-degree), or full-thickness (third-degree) burns (Figure 29-1 ■). In most cases you can quickly classify the burn as you form your general impression and establish a more detailed evaluation during the secondary assessment. A fourth-degree burn also exists and is commonly associated with electrical injuries.

**Superficial Burns**

Formerly referred to as a first-degree burn, a **superficial burn** involves only the epidermis. Usually a superficial burn is caused by a flash (a sudden occurrence of heat or flame lasting only a few seconds), hot liquid, or the sun. The skin will appear pink to red and will be dry. In some cases there may be slight swelling, but there will be no blisters. The skin will be soft and tender to the touch.

Although superficial in nature (affecting only the epidermis), these types of injuries may be very painful because the pain receptors in the underlying dermis of the skin are still intact. Superficial burns, generally, will take several days to heal but will not require much emergency medical care if only a small area is injured. The injury may cause the epidermis to peel but not cause any scarring. Examples of superficial burns include sunburn or a minor scald injury.

**Partial-Thickness Burns**

Formerly known as a second-degree burn, a **partial-thickness burn** involves not only the epidermis but also portions of the dermis. Partial-thickness burns occur from contact with fire (flame or flash), hot liquids or objects, chemical substances, or the sun. In addition, damage to the small blood vessels causes plasma and tissue fluid to collect between the layers of skin and form blisters. Since pain receptors are still intact, the patient will complain of pain from the burn.

Partial-thickness burns are further classified as **superficial partial-thickness** and **deep partial-thickness** burns. The signs and symptoms are as follows:

**Superficial Partial-Thickness Burns**

- Thin-walled blisters result from superficial dermal layer damage.
- Skin is pink and moist. (The moisture is caused by small leaks in the capillary beds caused by the burn.)
- Skin is soft and tender to touch. (Skin resiliency and hydration are normally preserved, but the skin will be more tender to touch.)
Deep Partial-Thickness Burns
- Thick-walled blisters often rupture. (The more severe nature of the blisters occurs because the dermis is injured at a greater depth, and they tend to rupture with any body motion or accidental friction because of their large size.)
- Skin is red and blanched white. (Deeper levels of the epidermis and dermis are injured.)
- The patient can still feel pressure at the site. (Pain receptors in the dermis may now be damaged and less responsive in some situations, but pressure receptors are found deeper in the dermis and may still be intact.)
- There is poor capillary refill to the burn site. (Increased edema starts to compromise capillary beds in the vicinity of the burn.)

Partial-thickness burns cause intense pain resulting from damage to nerve endings. Examples of partial-thickness burns include thermal flame burns or severe scaldings (EMT Skills 29-1).

Full-Thickness Burns
Formerly known as a third-degree burn, a full-thickness burn involves all the layers of the skin. This type of burn results from contact with extreme heat sources such as hot liquids or solids, flame, chemicals, or electricity. The skin will become dry, hard, tough, and leathery and may appear white and waxy to dark brown or black and charred. The tough and leathery dead soft tissue formed in the full-thickness burn injury is called an eschar.

Most full-thickness burns are not very painful because nerve endings have been destroyed. However, in most such injuries there will be surrounding areas of partial-thickness and/or superficial burns that may cause intense pain. Full-thickness burns are often evident in patients who have been trapped in a confined space with flames or who have been exposed to a high heat source or chemical contact (EMT Skills 29-2).

Some full-thickness burns may also be categorized as fourth-degree burns. A fourth-degree burn is a very deep burn that extends completely through the epidermis and dermis and deep into the tendons, ligaments, muscle, bone, blood vessels, and nerves. These burns are typically associated with electrical injuries and require extensive skin grafting to allow the site to heal.

Determining the Severity of Burn Injuries
The EMT must classify the severity of the burn injury in order to provide the optimal emergency medical care, make the best patient transport decision, and give an accurate report to the receiving facility. The estimate of burn injury severity may be crucial in deciding to which facility the patient will be transported—to a specialized burn center or to a regular hospital, for instance. In general, burns are classified as critical, moderate, or minor.

In addition to the depth of the injury (superficial, partial thickness, or full thickness), you will consider other factors in determining the severity of a burn injury. For instance, you will often want to consider the source or agent of the burn. A small burn caused by an electrical source may give more cause for concern than a small thermal (heat) burn because of the electrical burn’s potential for internal injury. Likewise, a chemical burn will vary in severity depending on the type and strength of the chemical. Inhalation injuries or burns involving the airway are always considered critical.

The most important factors to consider in determining burn severity are (Figure 29-2 and Table 29-1):
- Depth of burn
- Location of the burn
- Patient’s age
- Preexisting medical conditions
- Percentage of body surface area involved

Burn Injury Location
Just as the depth of the burn injury and its body surface area are important, so too is the location of the burn. Injuries to certain body areas are more critical than those to other areas. Burns of the face (Figure 29-3) are considered critical because of the potential for respiratory compromise and long-term cosmetic concerns, as are injuries to the eyes or ears. Hands and feet are also given special consideration because of the potential for loss of function. Burn injuries to the genital or groin region are of concern because of the potential for loss of genitourinary function and increased chances for infection. Finally, burns that occur to regions of the body where there is major joint function (for example, hips and shoulders) may be considered critical because of loss of joint function should the injury not receive appropriate burn care early in the course of recovery.

Circumferential burns, which encircle a body area such as an arm, a leg, or the chest—and especially ones that encircle joint areas—are critical because of the circulatory compromise and nerve damage that result from constriction or from swelling tissues. Burns that encircle the chest may impede respiratory function by limiting expansion of the chest.

Age and Preexisting Medical Conditions
Age of the patient is also a major factor in determining the severity of the burn injury. Children under age 5 and adults over age 55 have less tolerance for burn injuries. Children, in addition to BSA percentage differences, face other challenges of growth process impairment. Because of their relatively larger skin surface in relation to body mass, they have the potential for
CRITICAL BURNS

- Full thickness burns involving hands, feet, face, eyes, ears, or genitalia.
- Burns associated with respiratory injury.
- Full-thickness burns covering more than 10% of body surface.
- Partial-thickness burns covering more than 25% of body surface in adults.
- Partial-thickness burns >20% in children less than 10 years and adults more than 50 years.
- Chemical burns or high-voltage electrical burns.
- Burns complicated by fractures or major trauma.
- Moderate burns in young children or elderly patients.
- Circumferential burns to any body part, such as arm, leg, or chest.

</table>
greater fluid loss in burn injuries than adults. Older adults have prolonged healing processes and may have underlying medical conditions that affect their response to burn injuries.

Any preexisting illness or injury may increase the severity of a burn injury. A patient with an existing respiratory illness or condition may be adversely affected if there is further respiratory compromise from a burn injury. A patient with an existing cardiovascular problem may have increased complications from a burn injury and resulting fluid loss. Diabetes will compromise the patient’s ability to heal from the burns. What may seem like a minor burn in an otherwise healthy adult may be more severe in those patients with preexisting medical conditions. If the patient has experienced other injuries along with a burn injury, the life threat or potential for shock (hypoperfusion) may be increased as well.

**PATHOPHYSIOLOGY PEARLS**

Preexisting cardiovascular, pulmonary, endocrine, or neurological disease may turn a minor or moderate burn into a critical condition in an elderly patient because of the body’s inability to adequately respond to the stress of the burn.

**Special Considerations for Infants and Children.** As mentioned earlier, infants and children have a larger body surface in relation to mass than adults. For this reason, burn injuries can have increased effects on infants and children. Fluid and heat loss are also greater in infants and children than in adults. There is a higher risk for shock (hypoperfusion), airway difficulties, and hypothermia with burn injuries to infants. Further differences in burn injury severity classification for children less than 5 years old are outlined in Table 29-1.

In addition to assessment and emergency medical care considerations, you must consider the possibility of child abuse when a child has a burn injury. (See information about assessing for and reporting child abuse in Chapter 38, “Pediatrics.”)

**Body Surface Area Percentage**

The **rule of nines** is a standardized way to quickly determine the amount of skin surface, or the body surface area (BSA) percentage, of a burn (Figure 29-4). The rule of nines or any other type of body surface area percentage

---

![Figure 29-3](image-url) Burns to the face suggest respiratory tract involvement or injuries to the eyes. (© Edward T. Dickinson, MD)

![Figure 29-4](image-url) The “rule of nines” is a method for estimating how much body surface is burned in the adult or infant patient.
area calculation is only applied to partial-thickness or full-thickness burns. The rule of nines or other BSA calculations are not applied to superficial burns. In an adult, the head and neck together, each upper extremity, the chest, the abdomen, the upper back, the lower back, the anterior of each lower extremity, and the posterior of each lower extremity each represents a BSA of 9 percent. The genital region represents a 1 percent BSA. This rule will guide you in determining the burn severity, categorizing the patient for triage, and alerting the receiving facility as to the severity of the patient.

In infants and children there are different BSA percentages assigned to body regions because of their different proportional dimensions. The infant’s or young child’s head is much larger in relationship to the rest of the body than in adults. Therefore, for infants 1 year of age or less, the head and neck are counted as 18 percent (greater than an adult), the chest and abdomen as 18 percent (same as an adult), the entire back as 18 percent (same as an adult), each upper extremity as 9 percent (same as an adult), and each lower extremity as 14 percent (less than an adult). The rule of nines is altered to allow the head to account for more of the total BSA. The larger percentage of BSA for the head was shifted from the legs because of the disproportionally larger legs. For children over the age of 1 year, for each year beyond 1, add 0.5 percent to each leg and subtract 1 percent for the head. This formula will be used until the adult rule of nines values are reached. For example, for a 3-year-old child you would add 1 percent (0.5% × 2 years beyond 1) to each leg and subtract 2 percent from the head. Thus, the legs in the 3-year-old would equal a total of 15 percent and the head would equal 16 percent.

**ASSESSMENT TIPS**

The head of the infant or child accounts for more of the total BSA than it does in the adult. This is because the head is proportionally larger in younger patients.

An alternative way to determine the BSA estimate is to compare it to the patient’s palm (of the hand) surface area, which equals approximately 1 percent of BSA. This is known as the **rule of ones**, also called the **rule of palms**. For example, if the burn area is equal to “seven palm surface areas,” then the burn would be estimated at 7 percent BSA. You can use this method to estimate a burn area on a patient of any age.

You may find it helpful to use the rule of nines in larger burn injuries and use the palm method for smaller burns. You can begin to estimate BSA during the primary assessment. Do not spend time trying to determine the exact percentage of BSA injured. The BSA percentage is an estimate only, and slight differences in percentage will not affect prehospital medical care.

---

**Types of Burns**

There are five major types of burns:

- **Thermal burns** are associated with heat applied to the body. There are many causes of thermal burns, including flame, hot water, and steam. In general, the severity of the burn is related to the time the patient is exposed to the heat source, the temperature of the heat applied to the body, and the potential for inhalation injury (as described next). Hot water causes thermal burns called scalds. Scalds in children may be a form of child abuse.

- **Inhalation burns** are associated with high-temperature air or steam that is inhaled and causes damage to the mucosa of the upper airway. This will result in edema that may restrict airflow and lead to an airway obstruction. Another complication is the inhalation of toxic gases such as carbon monoxide and cyanide gas. If the patient is in an enclosed area, he is more likely to suffer an upper airway burn and toxic inhalation.

- **Chemical burns** are produced by acids, alkalis, and other heat-generating chemicals. The type of chemical, its concentration, and the duration of exposure to the chemical will determine the severity of the burn. Chemical burns are discussed in more detail later in the chapter.

- **Electrical burns** result from resistance to electrical current flow in the body. The burns are primarily internal. The electricity may interfere with the conduction system of the heart and result in cardiac arrest. Electrical burns are covered in more detail later in the chapter. Lightning is both a medical and traumatic event with typically little burn injury. Lightning injuries are covered in Chapter 24, “Environmental Emergencies.”

---

**Causes of Burns**

Burns may be caused by a variety of mechanisms (Figure 29-5 ▶):

- **Flame burn.** The patient comes into contact with an open flame. The clothing may ignite, causing further burn injury. Natural clothing fibers typically will burn, whereas synthetic fibers will usually melt, which causes a contact burn in addition to the flame burn.

- **Contact burn.** A burn occurs from contact with a hot object. The burn is normally localized to the area of contact. An example would be touching a hot exhaust pipe on a car.
Burns can occur by a variety of mechanisms. This patient was doing commercial painting using a spray gun with oil paint in an enclosed area. A spark ignited the paint vapors, causing an explosion. In addition to the obvious burns to the skin, because of the ignition of vapors in an enclosed space, inhalation injuries are also likely to have occurred. (Both © Charles Stewart MD EMDM MPH)

- **Scald.** Contact with hot liquid causes a scald burn. The more viscous the liquid, the more severe the burn because of a longer contact time. Intentional scalds, often seen in child abuse, typically involve the entire extremity from being immersed and held in the hot water. Accidental scalds will show patches of burns separated by unburned areas caused by splashing.

- **Steam burn.** Hot steam causes severe burns, often more severe than flame burns, because of the high heat capacity of steam. Typically, these types of burns are found in industrial accidents or in those who inappropriately open a car radiator while it is hot. Steam can cause thermal burns to the distal airways in the lungs.

- **Gas burn.** Hot gases may cause upper airway burns; however, it is not likely that the hot gas will cause distal airway burns. Distal airway injury may occur, however, from the by-products of combustion rather than from the hot gas.

- **Electrical burn.** Because bones, muscles, and other tissues offer resistance to the electrical energy passing through them, the by-product is heat, which results in internal burns. With an electrical burn, the clothing may ignite, resulting in a flame burn.

- **Flash burn.** This is a type of flame burn but is the result of a flammable gas or liquid that ignites quickly. Areas of the body covered by clothing normally are not burned. Inhalation injury may occur if the flash occurs in a closed space. There is a lesser incidence of inhalation injuries when the event occurs outside. A typical flash burn would occur from throwing gasoline on smoldering charcoal to reignite it.

### Assessment-Based Approach: Burns

#### Scene Size-up

Your first priority is to determine whether the scene is safe to enter. Do not enter scenes for which you are not trained. If the patient is in an unsafe environment, such as a fire-engulfed building, and you do not have the proper equipment or training to enter, you must wait until properly equipped and trained personnel can safely remove the patient. Once the scene is safe to enter, you must take appropriate Standard Precautions and then begin assessing the mechanism of injury and number of patients.

#### Primary Assessment

Remember that removing the patient from the burn source does not completely stop the burning process. Burn injuries need to be “cooled down” within approximately the first 10 minutes of injury. Stop the burning process initially by using water or saline. As you work to stop the burning, attempt to remove any smoldering clothing and jewelry, which will still be producing heat and may constrict swollen extremities. If any clothing still adheres to the patient, cut around the area. Do not attempt to remove the adhered portion, since this may cause further damage to the soft tissues. Do not keep the burn immersed, as this may cause hypothermia; cool for 60–120 seconds only.

Once you have stopped the burning process, you can continue your primary assessment and evaluate the patient’s airway, breathing, oxygenation, and circulation. Look for any indications that the airway may
be injured or compromised, such as sooty deposits in the mouth or nose, singed facial or nose hairs, signs of smoke inhalation, or any facial burns. A burn victim’s first reaction when frightened or startled—such as when trapped in a confined space or startled by an explosion—is to inhale deeply. Air in these situations may be superheated and will have an adverse effect on the airway and respiratory function, so you need to consider the likelihood of airway compromise, breathing difficulties, and inhalation of toxic gases. If toxic inhalation is suspected, provide oxygen by nonrebreather mask at 15 lpm or, if breathing is inadequate, provide positive pressure ventilation with supplemental oxygen. The pulse oximeter may provide erroneously high readings as a result of the carbon monoxide content in the blood; therefore, do not base the oxygen administration on the SpO2 reading.

To complete the primary assessment, assess the patient’s circulation and determine whether the patient is a priority for transport. Make a rapid estimate of the severity of the burn, taking into account BSA percentage and any information you have gained about the burn source or agent and any information about the age and medical condition of the patient that you have gained from bystanders or the patient himself. Remember not to spend too long estimating the exact BSA percentage of the burn; you can gather more information later in your assessment.

Most burns do not bleed and are not a cause of early shock. If signs and symptoms of shock are present, look for other sources of blood loss or possible spinal injury. As in all traumatic emergencies, a burn injury patient is a priority for transport if he is unresponsive with no gag reflex or is responsive but not following commands, if he has airway compromise or difficulty breathing, if he shows signs of shock or uncontrolled bleeding, or if he presents with severe pain. A patient with a “critical” burn, as discussed earlier, should also be treated as a priority patient even though he may not present as unstable initially.

Remember that critical burns themselves are not immediately life threatening. Immediate causes of death are airway swelling and inhalation injury.

**Secondary Assessment**

After treating all life-threatening injuries, conduct the secondary assessment, beginning by reassessing the mechanism of injury and chief complaint. Perform a physical exam. Check for evidence of any injury that may have occurred in addition to the burn, and get a more accurate estimate of BSA percentage than the one you determined during the primary assessment. As you examine the patient, continue to remove his clothing and jewelry, but do not attempt to remove debris or any adhered clothing. Record the patient’s baseline vital signs.

---

**ASSESSMENT TIPS**

The determination of an accurate BSA burned can be delayed until the physical exam is completed. Prior to this, the EMT should focus on establishing and maintaining the airway, breathing, oxygenation, and circulation.

Obtain a history from the patient or from family and any bystanders. However, if the patient’s burn is considered critical or if he is a priority for transport for other reasons, you may not have time to obtain the answers to your questions at the scene. If possible, ask the following questions:

- How did the burn happen?
- What caused the burn?
- Was the patient exposed to an explosion or other significant mechanism of injury?
- Did the patient lose consciousness at any time?
- Was the patient confined in an enclosed space or found to inhale copious amounts of smoke?
- How long ago was the patient burned?
- What care was given by bystanders?
- If the burn involved chemicals, what chemical?
- If the burn was a scald, how did it happen? (If a scald or burn injury involves an infant, child, or elderly patient, consider the possibility of abuse.)
- Does the patient have any history of significant heart disease, pulmonary problems, diabetes, or any other condition that might increase the burn severity or complicate treatment?

**Signs and Symptoms.** In addition to estimating BSA and noting location of the burn injuries, watch for the following signs and symptoms of burn depth and possible inhalation injuries:

**Superficial Burns**
- Pink or red, dry skin
- Slight swelling
- Pain and tenderness to touch

**Partial-Thickness Burns**
- White to cherry red skin
- Moist and mottled skin
- Blistering and intense pain

**Full-Thickness Burns**
- Dry, hard, tough, and leathery skin that may appear white and waxy to dark brown or black and charred (eschar)
- Inability to feel pain because of damaged nerve endings
- Pain on peripheral edges of burns

**Inhalation Injuries**
- Singed nasal hairs
- Facial burns
• Burned specks of carbon in the sputum
• A sooty or smoky smell on the breath
• Respiratory distress accompanied by restriction of chest wall movement, restlessness, chest tightness, stridor, wheezing, difficulty in swallowing, hoarseness, coughing, and cyanosis
• The presence of actual burns of the oral mucosa

**Emergency Medical Care**

There are many ways to care for burn injuries. Check with your local medical director to determine the most appropriate emergency medical care for burn injuries in your region. The following steps in emergency medical care for burn injuries represent a general protocol in providing care. Particular attention is paid to preventing further contamination and injury.

1. **Remove the patient from the source of the burn and stop the burning process.** As mentioned earlier, you should not attempt to enter an unsafe environment and extricate the patient unless you have the proper training and equipment. Once the patient has been removed from the source of the burn, you can stop the burn process by using water or saline (Figure 29-6a), but do not keep it immersed. If the burn source is a semisolid or liquid (e.g., tar, grease, or oil), cool the burn with water or saline to stop the burning process but do not attempt to remove the substance since this could cause further tissue damage. Dry chemicals should be brushed away before flushing with copious amounts of water. Remove any smoldering clothing and any jewelry. If any clothing remains adhered to the patient, cut around the area (Figure 29-6b). Do not attempt to remove the adhered portion.

2. **Establish and maintain an airway, and adequate breathing and oxygenation.** Pay particular attention to evidence of inhalation injury to the patient’s upper airway. Maintain an open airway and administer oxygen by nonrebreather mask at 15 lpm, if inhalation of toxic gases is suspected. If toxic inhalation is not suspected, administer oxygen if the SpO₂ is <94%, if the patient complains of dyspnea, or exhibits signs or symptoms of respiratory distress, hypoxia, hypoxemia, poor perfusion, or heart failure. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 breaths per minute in an adult and 12–20 per minute in an infant or child.

3. **Classify the severity of the burn and transport immediately if critical.** Take into account the factors mentioned earlier: BSA percentage, source or agent of the burn, location of the burn, age of the patient, and preexisting medical conditions. (Review Table 29-1.)

4. **Cover the burned area with a dry sterile dressing** (Figure 29-6c) or a sterile, particle-free disposable

**burn sheet** or an approved commercial burn dressing. A clean white sheet is acceptable if no burn sheet is available. Continual use of a wet or moist dressing may cause hypothermia because of the loss of heat regulation in the burned area. However, some EMS systems may use a moist dressing on a 10 percent BSA or less partial-thickness burn. Check with local medical direction regarding the use of wet or moist dressings.

---

**Emergency Medical Care**

There are many ways to care for burn injuries. Check with your local medical director to determine the most appropriate emergency medical care for burn injuries in your region. The following steps in emergency medical care for burn injuries represent a general protocol in providing care. Particular attention is paid to preventing further contamination and injury.

1. **Remove the patient from the source of the burn and stop the burning process.** As mentioned earlier, you should not attempt to enter an unsafe environment and extricate the patient unless you have the proper training and equipment. Once the patient has been removed from the source of the burn, you can stop the burn process by using water or saline (Figure 29-6a), but do not keep it immersed. If the burn source is a semisolid or liquid (e.g., tar, grease, or oil), cool the burn with water or saline to stop the burning process but do not attempt to remove the substance since this could cause further tissue damage. Dry chemicals should be brushed away before flushing with copious amounts of water. Remove any smoldering clothing and any jewelry. If any clothing remains adhered to the patient, cut around the area (Figure 29-6b). Do not attempt to remove the adhered portion.

2. **Establish and maintain an airway, and adequate breathing and oxygenation.** Pay particular attention to evidence of inhalation injury to the patient’s upper airway. Maintain an open airway and administer oxygen by nonrebreather mask at 15 lpm, if inhalation of toxic gases is suspected. If toxic inhalation is not suspected, administer oxygen if the SpO₂ is <94%, if the patient complains of dyspnea, or exhibits signs or symptoms of respiratory distress, hypoxia, hypoxemia, poor perfusion, or heart failure. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 breaths per minute in an adult and 12–20 per minute in an infant or child.

3. **Classify the severity of the burn and transport immediately if critical.** Take into account the factors mentioned earlier: BSA percentage, source or agent of the burn, location of the burn, age of the patient, and preexisting medical conditions. (Review Table 29-1.)

4. **Cover the burned area with a dry sterile dressing** (Figure 29-6c) or a sterile, particle-free disposable

**burn sheet** or an approved commercial burn dressing. A clean white sheet is acceptable if no burn sheet is available. Continual use of a wet or moist dressing may cause hypothermia because of the loss of heat regulation in the burned area. However, some EMS systems may use a moist dressing on a 10 percent BSA or less partial-thickness burn. Check with local medical direction regarding the use of wet or moist dressings.
Reassessment

Perform the reassessment. Monitor vital signs and check interventions every 5 minutes for unstable patients and every 15 minutes for stable patients. Continually evaluate the airway, especially if there are any burns to the face.
Note: Swelling or closure of the airway may be rapid, and emergency medical care will need to be quickly accomplished. Always consider advanced life support (ALS) response when dealing with airway complications in burn injuries, but do not delay transport.

**Chemical Burns**

Chemical burns require immediate care, since the longer the chemical is in contact with the skin the greater the potential for injury (Figure 29-9). In many cases, emergency medical care may be started by people at the scene. Industrial sites may have special response teams or Emergency Medical Responders and equipment available to provide initial emergency medical care. However, you should follow these rules when dealing with chemical burn injuries:

- **Protect yourself first.** As with other burn emergencies, never enter an unsafe scene. Chemical burns may involve a hazardous material incident that you may not be prepared to handle or that may cause you to become exposed. Wear gloves and eye protection at a minimum. In cases of a large exposure you may have to wear an impervious (fluid-proof) gown or suit to prevent further contamination from the chemical(s).
- **Dry chemicals (e.g., dry lime) should be brushed off before flushing with water** (Figure 29-10). Most chemical burns can be flushed with copious amounts of water (Figure 29-11). Always ensure that the chemical is one that may be diluted with water. (Consult a hazardous materials guidebook.) Some chemicals may produce combustion when they come into contact with water. Minimize further wound contamination by making sure fluid runs away from the injury and not toward any uninjured areas. Remove all clothing and jewelry as in other burn injuries. Continue to flush while en route to the hospital.

**Electrical Burns**

Electrical burns, including those caused by electrical currents and lightning, can cause severe damage not only to soft tissues but to the body as a whole.

Electrical energy will always seek to flow to the ground. As the energy enters the body, it will seek the path of least resistance to exit the body. All tissues between the entrance and exit of the current will potentially be injured due to the extreme heat created by the resistance of body structures to the electricity (Figure 29-12 and EMT Skills 29-3). Since the body, especially the heart, produces its own electrical energy from chemical reactions, electrical injuries can disturb or destroy these functions, causing irregular heartbeat or even cardiac arrest.

Scene safety is crucial in electrical burn injuries because of the extremely hazardous nature of the electrical source. Always assume the electrical source is still charged unless you have received reliable information that the power source has been completely shut down.
Establish and maintain a patent airway and adequate breathing. If the tidal volume or respiratory rate is inadequate, initiate positive pressure ventilation at a rate of 10–12/minute in the adult and 12–20/minute in the infant or child.

Administer supplemental oxygen if indicated. Administer supplemental oxygen if the SpO₂ is <94%, or the patient complains of dyspnea, or exhibits signs or symptoms of respiratory distress, hypoxia, hypoxemia, poor perfusion, or heart failure.

Monitor the patient for cardiac arrest. Cardiac dysrhythmias are common after a major electrical injury. Be prepared to administer CPR and apply an automated external defibrillator (AED) if the patient deteriorates to cardiac arrest.

Assess the patient for muscle tenderness with or without twitching and any seizure activity.

Always assess for an entrance and exit burn injury. All tissue in between is suspect for injury even if not readily visible. Emergency medical care for entrance and exit injuries is the same as for other thermal burns.

Transport the patient as soon as possible. Most electrical burn injuries have a slow onset, and underlying tissue or organ damage may not be readily apparent. These patients should be assumed to have critical injuries, even if burns appear insignificant.

Summary: Assessment and Care
To review possible assessment findings and emergency care for burn emergencies, see Figures 29-13 and 29-14.

When caring for electrical burn injuries:

- Never attempt to remove a patient from an electrical source unless trained and equipped to do so.
- Never touch a patient still in contact with the electrical source.
# Assessment Summary

## BURN EMERGENCY

The following findings may be associated with a burn emergency.

### Scene Size-up

Pay particular attention to your own safety. Look for:
- Burning structures or material
- Chemicals
- Electrical sources
- Confined spaces
- Burned clothing
- Obvious burns to patient’s body
- Evidence of explosion
- Other blunt or penetrating trauma

### Primary Assessment

#### General Impression

Stridor or crowing from upper airway
Obvious burns to body and clothing
Burns to neck and face
Singed hair, nasal hair, eyebrows, and other facial hair
Carbonaceous (black) sputum

#### Mental Status

Alert to unresponsive

#### Airway

Stridor (indicates upper airway burn)
Edema to oral mucosa and tongue
Burns around neck and face
Black inside mouth

#### Breathing

Normal to increased if airway or respiratory tract is not involved
Increased or decreased, labored, and shallow if airway or respiratory tract burns

#### Circulation

Increased; may be decreased if severely hypoxic
Skin normal in unburned areas; may be cool, clammy, and pale

#### Status: Priority patient if large body surface area burns, airway or respiratory tract is involved, critical burns are apparent, or burns involve hands, feet, face, genitalia, or major joint locations

### Secondary Assessment

#### Physical Exam

**Head, neck, and face:**
- Burns
- Singed hair, eyebrows, facial and nasal hair
- Dark black (carbonaceous) sputum
- Swelling of tongue and oral mucosa

**Chest:**
- Burns
- Wheezing
- Circumferential burns around thorax may impede ventilation
- Blunt or penetrating trauma if explosion or fall involved

**Abdomen:**
- Burns
- Blunt or penetrating trauma if explosion or fall involved

**Extremities:**
- Burns (the appearance of the burn is largely determined by the burning mechanism, for example, thermal versus chemical)
- Circumferential burns may reduce distal circulation
- Swelling, pain, and discoloration if explosion or fall involved

#### Baseline Vital Signs

- BP: normal, may decrease with severe burns after a few hours (if BP decreased at the scene, look for evidence of other trauma)
- HR: normal or increased
- RR: normal; increased and labored if respiratory tract burn involved
- Skin: normal in unburned areas (if pale, cool, clammy immediately after burn may indicate shock from other trauma)
- Pupils: normal
- SpO₂: may be less than 94% if inhalation injury or toxic inhalation has occurred

#### History

- Signs and symptoms of superficial burns:
  - Skin that is pink or red, and dry
  - Slight swelling
  - Pain
- Signs and symptoms of partial-thickness burns:
  - Skin that is white to cherry red
  - Moist and mottled
  - Blisters
  - Intense pain
- Signs and symptoms of full-thickness burns:
  - Skin that is dry, hard, tough, and leathery
  - White and waxy, dark brown, or charred
  - No pain in burned area
  - Usually pain around the site of full-thickness burn

### Signs and symptoms of inhalation injury:
- Facial burns
- Singed nasal and facial hair and eyebrows
- Black sputum
- Respiratory distress with labored breathing
- Coughing, hoarseness, cyanosis, stridor

---

*FIGURE 29-13a*  Assessment summary: burn emergency.
Emergency Care Protocol

BURN EMERGENCY

1. Remove the patient from the source of burn and stop the burning process.
2. Establish manual in-line stabilization if spinal injury is suspected.
3. Establish and maintain an open airway; insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
4. Suction secretions as necessary.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If breathing is adequate, administer oxygen by non-rebreather mask at 15 lpm if inhalation of a toxic gas or upper airway burn is suspected. If the burn is isolated to an area of the body and does not involve the face or a possible inhalation injury or toxic exposure, base your oxygen administration on the SpO₂ reading and signs of hypoxia. Administer oxygen to maintain the SpO₂ at 95% or greater.
7. Estimate body surface area burn (percent BSA) using the rule of nines.
8. Determine depth of burn: superficial, partial thickness, or full thickness.
9. Apply sterile dressings and bandages or a burn sheet.
10. If the burn is less than 10 percent BSA, dress wet per protocol. Dress all other burns dry.
11. Maintain body temperature.
12. Manage other associated injuries as appropriate.
13. If spinal injury is suspected, immobilize the patient to a backboard.
14. Manage specific burns as follows:
   - **Dry chemical burn:** Remove affected clothing, brush off dry chemical, then irrigate with large amounts of water.
   - **Liquid chemical burn:** Remove affected clothing; irrigate with large amounts of water if the chemical is one that does not react to water.
   - **Burns to the hands and feet:** Remove all rings and jewelry; dress between digits.
   - **Chemical burns to the eyes:** Flush with large amounts of water and continue to flush en route.
   - **Thermal burns to the eyes:** Do not attempt to open eyelids; apply dry, sterile dressing to both eyes.
   - **Electrical burns:** Carefully monitor pulse and respiration; inspect for entrance and exit wounds; assess for muscle tenderness; apply AED if patient is in cardiac arrest.
15. Transport.
16. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

*FIGURE 29-13b* Emergency care protocol: burn emergency.
Emergency Care Algorithm

BURN EMERGENCY

Mechanism of injury present?
- Yes
  - Manual in-line stabilization
- No
  - Patient still in contact with source of burn?
    - Yes
      - Remove from source of burn, protect yourself, extinguish burning clothes
    - No
      - Assess mental status

Alert and able to obey commands
- Yes
  - Consider oxygen administration
- No
  - Assess circulation

Secondary assessment
- Determine the %BSA and depth of burn
- Apply sterile dressings, bandages, and burn sheet
- Burn less than 10% BSA?
  - Yes
    - Dress wet
  - No
    - Spinal injury suspected?
      - Yes
        - Immobilize to backboard
      - No
        - Dress dry

Maintain body temperature
- Manage other associated injuries
- Manage specific burns

Dry chemical
- Brush off chemical
- Irrigate for 20 minutes

Liquid chemical
- Hands and feet
- Chemical eye
- Thermal eye
- Electrical
- Dress source and ground wounds, perform CPR, and apply AED if in cardiac arrest

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

Electrical Burns and Lightning Injuries

- **29-3A** Electrical burn, entrance and exit wounds. (© Edward T. Dickinson, MD)
- **29-3B** Electrical burn caused by chewing on an electrical cord.
- **29-3C** Burn associated with lightning injury.
- **29-3D** Abnormal skin pattern associated with lightning injury.
SUMMARY

Although burns are not the most common mechanisms of trauma that EMTs see in the prehospital setting, they usually present with a dramatic clinical presentation. While the obvious manifestations of burns are frequently impressive, the EMT must remember that these patients may have associated injury leading to compromise to the airway, breathing, oxygenation, or circulatory system that is of greater risk to life and limb, initially, than is the burn. Only after ensuring that all life threats found during the primary assessment are properly managed should the EMT focus attention on the burn injury itself. Initial management at the scene (and during transport) is the prime determinant of survival for any type of burn.

Inhalation burns are of significant concern, because if the patient is not properly assessed, is not provided with adequate airway or ventilatory management, or is not oxygenated as needed, the inhalation injury will easily contribute to patient morbidity and mortality. The EMT must be aware of the unique metabolic and cardiovascular problems that accompany burn injuries. Although some of these concerns cannot be initially managed by the EMT, these factors will have important implications, especially in respect to transport.

Providing care for the critically injured burn patient will include the use of many of the EMT’s assessment and management skills, and the quality of prehospital care rendered during the first hours after a burn injury will have a major impact on long-term outcome. By being vigilant in the evaluation and management of these patients, particularly with regard to airway management and ventilatory support, the EMT can provide the patient with the greatest chance of a meaningful recovery and return to a functional life. It is important to understand your destination protocols and to transport the patient to a burn center, when indicated, to improve the patient’s chance of survival and recovery.

Case Study Follow-up

Scene Size-up

You and your partner have been dispatched to a reported structural fire. You have arrived on the scene of a fully involved structure fire with one patient trapped on the second floor. You have donned your gloves, mask, and eye protection. Since this is a “working” fire with one known patient already, you have called for additional units for assistance.

As you arrive, you spot a firefighter carrying the reported patient down the ladder. Your partner readies the back of the ambulance as you go to the patient.

Primary Assessment

You begin your assessment by noting that the patient, a male, has severe charring and other burns on the right half of his body and that he is unresponsive. His airway is open but breathing is shallow and rapid. His face is somewhat blackened. You immediately place him in the back of the ambulance on the stretcher. His pulse is weak and rapid and you consider him a high-priority patient.

Your partner has inserted an airway adjunct and set up the bag-valve unit for positive pressure ventilation with supplemental oxygen. He begins ventilations while you stop the burning process. You pour sterile saline over the patient’s burned areas and at the same time begin to assess the severity of the burn. There are full-thickness burns over the patient’s right chest and abdomen both front and back, right arm, and leg. There is singed nasal hair and blackened areas around the face. You quickly estimate this to be a full-thickness burn over approximately 50 percent BSA and classify the patient as critical in terms of burn severity.

You begin to remove clothing and jewelry, continuing to stop the burning process, then immediately begin transport to the local trauma center.

Secondary Assessment

The patient remains unresponsive as you begin to further assess and treat him. You have cooled the burn down and now cover the patient with a sterile burn sheet and place sterile dressings between his fingers and toes. You also cover the patient with several blankets to keep him warm. Your partner is continuing to ventilate the patient. You do a physical exam, checking for any further injuries, but do not find any. You assess the patient’s vital signs, and they are BP 98/68 mmHg, pulse 124 bpm and rapid and weak, respirations assisted at 12 breaths per minute. The SpO₂ is 87%. Upon auscultation of the lungs you discover wheezing in all lung fields. You radio the hospital to advise them of the patient’s status and estimated time of arrival. You are unable to obtain a history because the patient is unresponsive and his critical condition did not allow you time to question bystanders at the scene.

Reassessment

Since transport time is short, you conduct only one reassessment. There is essentially no change in the patient’s status and the positive pressure ventilations seem to be helping. At the hospital, you give a quick report to
1. Define and list the characteristics of superficial, partial-thickness, and full-thickness burns.

2. Define the rule of nines and describe how it is used on both adult and infant or child burn injury patients.

3. Using the rule of nines, name the percentage of body surface area (BSA) burned if (a) a 4-year-old child has superficial burn injuries to the front and back of both legs as well as the chest, abdomen, and back, and (b) an adult has partial-thickness burn injuries to the front of one lower extremity and to the front and back of the other lower extremity.

4. Determine the burn severity classification for patients “a” and “b” in question 3.

5. Describe the basic emergency care steps for burn injuries.

6. List the three things an EMT should not do when applying dressings to a burn injury patient.

7. List the emergency medical care guidelines for chemical burns.

8. List the emergency medical care guidelines for electrical burns.

You next begin the task of completing the prehospital care report as your partner readies the vehicle. The dispatcher advises you that you will be required back at the fire scene as quickly as possible.

**CRITICAL THINKING**

You are called to a local university where a female student was working on an experiment under the protective hood in her chemistry lab. When she was removing a beaker of solution from under the hood, the beaker bumped the edge of the sash and splashed her face and chest with an alkali chemical, ammonium hydroxide. Although the student was wearing safety glasses, the solution splashed behind her glasses and soaked into her lab jacket and clothing underneath.

The laboratory assistant immediately got her to the safety shower and began the flushing process before calling 911. By the time you arrive, the patient is sitting down on a chair with a wet towel wrapped around her bare chest, and she is holding her hand over her closed eyes in an attempt to shield them from the bright light in the laboratory. Upon assessment and questioning, she complains only of a severe burning to her eyes. She has no observable burns to her face or oral cavity, and the chemical that splashed onto her chest did not seem to penetrate to her skin.

1. Would these burns be considered mild, moderate, or severe?

2. What is your rationalization for your answer to question 1?

3. How are the eye injuries best managed while en route to the hospital?

4. What is the process recommended for flushing chemical eye injuries?

5. If there was a community hospital within 2 minutes of the university, and a regional burn/trauma center within 15 minutes of the university, which facility should the EMT elect to transport to?
Musculoskeletal Trauma and Nontraumatic Fractures

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARDS** • Trauma (Content Area: Orthopedic Trauma; Content Area: Nontraumatic Musculoskeletal Disorders)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

30-1. Define key terms introduced in this chapter.
30-2. Describe the structures and functions of the musculoskeletal system, including:
   a. Bones
   b. Skeletal muscle
   c. Tendons
   d. Ligaments
   e. Cartilage
   f. Joints
30-3. Describe each of the following types of injuries and their associated signs and symptoms:
   a. Fractures
   b. Strains
   c. Sprains
   d. Dislocations
30-4. Give examples of direct, indirect, and twisting forces that can produce musculoskeletal injuries.
30-5. Explain why fractures of the femur and pelvis are considered to be critical fractures.
30-6. Describe the assessment-based approach to bone and joint injuries.
30-7. Establish the priority for assessing and treating musculoskeletal injuries with respect to a patient’s overall condition.
30-8. Discuss the significance of assessing a musculoskeletal injury for each of the following findings:
   a. Pain
   b. Pallor
   c. Paralysis
   d. Paresthesia
   e. Pressure
   f. Pulses
30-9. Explain the rationale for splinting musculoskeletal injuries.
30-10. Compare and contrast the characteristics and uses of various types of splints, including:
   a. Rigid splints
   b. Pressure (air or pneumatic) splints
   c. Traction splints
   d. Formable splints
   e. Vacuum splints
   f. Sling and swathe
   g. Spine board
   h. Improvised splints
30-11. Discuss hazards of improper splinting.
30-12. Discuss special considerations in splinting long bone injuries, splinting joint injuries, and traction splinting.
30-13. Discuss special considerations in splinting pelvic fractures.
30-14. Describe the basic pathophysiology of compartment syndrome.
30-15. Describe the pathophysiology of nontraumatic fractures.
30-16. Describe the management of nontraumatic fractures.
Injuries to muscles, joints, and bones are some of the most common emergencies you will encounter in the field. They can range from simple and non-life-threatening injuries (such as a broken finger or sprained ankle) to critical and life-threatening injuries (such as a fracture of the femur or spine). Regardless of whether the injury is mild or severe, your ability to provide emergency care efficiently and quickly may prevent further painful and damaging injury and may even keep the patient from suffering permanent disability or death.

**INTRODUCTION**

The two main parts of the musculoskeletal system, as is obvious from its name, are the muscles and the skeleton. The functions of the musculoskeletal system are:

- To give the body shape
- To protect the internal organs
- To provide for movement
- To store salts and other materials needed for metabolism
- To produce red blood cells necessary for oxygen transport

The musculoskeletal system was presented in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” which you may wish to review. Some major points about the musculoskeletal system are summarized in the following sections.

**KEY TERMS**

- compartment syndrome p. 849
- crepitus p. 840
- direct force p. 838
- indirect force p. 838
- nontraumatic fracture p. 849
- osteoporosis p. 837
- paresthesia p. 847
- splint p. 842
- twisting force p. 838

**Case Study**

The Dispatch

Medic One—respond to the Peninsula High football field—you have a 17-year-old male patient complaining of leg pain. Time out is 1634 hours.

Upon Arrival

You are met by the football coach. He tells you his quarterback was tackled very hard. The patient cries out in pain, “My leg, my leg!”

**The Muscles**

There are three kinds of muscles: voluntary (skeletal), involuntary (smooth), and cardiac. Involuntary muscles are found in the walls of organs and help move food through the digestive system. Cardiac muscle is found only in the walls of the heart.

The kind of muscle that is pertinent to the topic of this chapter, musculoskeletal injuries, is voluntary muscle. Voluntary muscles are those that are under control of a person’s will. They make possible all deliberate acts, such as walking, chewing, swallowing, smiling, frowning, talking, or moving the eyeballs. Often referred to as skeletal muscles, most voluntary muscles are generally attached at one or both ends to the skeleton.

The voluntary muscles form the major muscle mass of the body. Movements of the body are the result of work performed by the muscles. What enables muscle tissue to work is its ability to contract—to become shorter and thicker—when stimulated by a nerve impulse. In addition to enabling us to move, muscles help give our bodies their distinctive shapes.

Muscles can be injured in many ways. Overexerting a muscle may break fibers, and muscles subjected to trauma can be bruised, crushed, cut, torn, or otherwise injured, even if the skin is not broken. Muscles injured in any way tend to become swollen, tender, painful, or weak.

**Tendons and Ligaments**

Tendons and ligaments (Figure 30-1) are, in a sense, the glue that holds the body together. Composed of...
specialized connective tissue, tendons connect muscle to bone while ligaments connect bone to bone. Tendons and ligaments, as well as muscles, can be bruised, crushed, cut, or torn, and are included in the category of musculoskeletal injuries.

**Cartilage**

Cartilage is an extension of the bone end and is composed of connective tissue. It is a strong, smooth, flexible, compressible, and slippery substance found at the point of articulation of two bones (Figure 30-2). Cartilage allows the bones to ride over each other during movement with relatively little friction. Cartilage also acts somewhat as a shock absorber between the bone surfaces. Cartilage can be injured, leading to joint pain.

**The Skeletal System**

The skeletal system (Figure 30-3) supports the body, allowing it to stand erect. Without its bones, the body would collapse. As the body’s structural framework, the skeleton must be strong to provide support and protection, jointed to permit motion, and flexible to withstand stress. A major element in motion is the body’s joints, or places where bones meet. Joints allow for several different types of motion:

- **Flexion.** Bending motion that moves the extremity toward the body
- **Extension.** Bending motion that moves the extremity away from the body
- **Adduction.** Movement of a body part toward the midline of the body
- **Abduction.** Movement of a body part away from the midline of the body
- **Rotation.** Turning along the axis of the bone or joint
- **Circumduction.** Movement through an arc of a circle or in a circular motion from a central point

The skeletal system has six basic components: the skull, spinal column, thorax, pelvis, lower extremities, and upper extremities.

The axial skeletal system is composed of the head, thorax, and vertebral column. Injury to these structures is covered in detail in Chapter 31, “Head Trauma,” Chapter 32, “Spinal Column and Spinal Cord Trauma,” and Chapter 34, “Chest Trauma.”

The appendicular skeletal system is made up of the bones in the extremities, to include the shoulder girdle and the pelvis. Injuries to these bones are the focus.
Musculoskeletal Trauma and Nontraumatic Fractures

Chapter 30

• The appendicular skeleton can be divided into bones of the upper extremity and bones of the lower extremity.

Upper Extremity

The upper extremity (Figure 30-4) consists of the shoulder girdle, arm, forearm, and hand. Bones of the upper extremity are:

- Clavicle (collarbone)
- Scapula (shoulder blade)
- Humerus
- Radius
- Ulna (including the olecranon)
- Carpal bones
- Metacarpals
- Phalanges

The humerus is the bone of the upper arm. The radius and ulna are the bones of the lower arm. The carpals, metacarpals, and phalanges are the bones of the wrist, hand, and fingers, respectively. The olecranon, which is the bump at the back of the elbow, is the proximal end of the ulna.

Lower Extremity

The lower extremity (Figure 30-5) is made up of the pelvis, thigh, leg, and foot. Bones of the lower extremity are:

- Pelvis (including the ilium, ischium, and pubis)
- Femur
Types of Injuries

Several kinds of musculoskeletal injuries are possible. The first to come to mind is a fracture or, simply, a broken bone (Figure 30-6 ■). Although many of the signs and symptoms are similar, the injury may not involve a fracture but may be a strain, sprain, or dislocation.

- Patella (kneecap)
- Tibia
- Fibula
- Calcaneus (heel bone)
- Tarsals
- Metatarsals
- Phalanges

The pelvis is made up of the ilium, ischium, and pubis. The large flat bone is the ilium. The iliac crest is what is palpated on the anterior-lateral body at the belt line. The ischium and pubis form the floor of the pelvis.

The acetabulum is a hollow depression in the lateral pelvis where the head of the femur (the thighbone) fits, creating a joint. All of the bones create the pelvic girdle. The greater trochanter is a process of the proximal femur. It is the bony projection that is felt on the lateral upper thigh, often referred to as the hip.

The femur is the bone of the upper leg, while the tibia and fibula are the bones of the lower leg. The patella covers the joint where the femur and tibia meet. Condyles are protuberances at the sides of the tibia and femur where they meet. The calcaneus, or heel bone, is the largest bone of the foot. The tarsals, metatarsals, and phalanges are the bones of the ankle, foot, and toes, respectively.
Fracture

A fracture is a break in the continuity of a bone. Fractures occur as a result of a variety of mechanisms of injury, including direct force, indirect force, and twisting force. These forces are discussed later in the section.

A fracture is generally categorized as open or closed. An open fracture is a fracture with an associated open wound. The open wound may have been caused by the bone end punching through the muscle, soft tissue, and skin, or it may have been caused by the force that caused the fracture, such as a bullet. If there is no break in the skin, the fracture is considered to be closed. An open fracture is additionally complicated by the introduction of bacteria and other contaminants that may lead to infection.

If the bones become displaced, there may be damage to surrounding nerves, blood vessels, muscles, ligaments, and tendons.

Signs and symptoms of a fracture may include:

- Pain
- Tenderness
- Deformity
- Discoloration
- Paresthesia distal to the fracture site (tingling or abnormal sensation; may indicate nerve injury)
- Anesthesia distal to the fracture site (loss of feeling; may indicate nerve injury)
- Paresis (weakness; may indicate nerve injury)
- Paralysis (loss of muscle control; may indicate nerve injury)

There are several types of fractures (Figure 30-7■). You can distinguish the type of fracture only through an X-ray. A hairline fracture is a small crack in the bone that doesn’t create instability. The patient may present only with pain and tenderness. Complications that may result from a fracture include hemorrhage from the bone itself, instability of the extremity leading to an increased incidence of tissue, nerve, or vessel damage; surrounding tissue damage; infection associated with an open fracture; and interruption of distal blood supply.

Geriatric patients are especially prone to fractures because of changes in their bone structure. After 40 years of age, bones start to become less flexible, more brittle, and more easily fractured. Osteoporosis is a degenerative bone disorder associated with an accelerated loss of minerals, primarily calcium, from the bone. This condition dramatically weakens the bones and makes them susceptible to fracture. Osteoporosis typically affects women more than men and occurs most often after menopause.

Strain

A strain is an injury to a muscle or a muscle and tendon, possibly caused by overextension, or overstretching. Overstretching tears muscle fibers and causes pain that
typically increases with the muscle use. A strain may also occur as a result of extreme muscle stress or fatigue associated with overuse. Because there is no bleeding, the injury does not present with edema or discoloration. Typically, the patient complains of pain on palpation, usually localized to a specific site, and pain or weakness with use of the muscle.

**Sprain**
A sprain is an injury to a joint capsule, with damage to or tearing of the connective tissue, and usually involves ligaments. The shoulder, knee, and ankle are the joints most vulnerable to sprains. The patient typically experiences immediate pain and tenderness at the joint upon injury. The joint then becomes inflamed and swollen. Discoloration usually occurs over time but not for several hours after the injury.

**Dislocation**
A dislocation is the displacement of a bone from its normal position in a joint (Figure 30-8). The joint is found in an abnormal position with obvious deformity and usually swelling. The patient will complain of pain and tenderness at the site of dislocation and typically is unable to move the extremity. A dislocation is dangerous because it can damage blood vessels and nerves by compression or tearing. A dislocation usually occurs from the joint being forced well beyond its normal range of motion; thus, the patient is likely to also have ligament or joint capsule injury. Dislocations are often found in association with fractures.

Dislocations may occur at the following joints:
- Hip
- Knee
- Ankle
- Foot
- Metatarsal-phalangeal

**General Injury Considerations**
All of the injuries just discussed—fracture, strain, sprain, and dislocation—may present with similar signs and symptoms: swelling, pain, or deformity. Sometimes there will be discoloration. Sometimes broken bones will break through the skin. Some fractures do not produce any obvious signs or symptoms.

Musculoskeletal injuries are usually associated with external forces such as falls or vehicle collisions, though some may occur through disease (e.g., bone degeneration), particularly in elderly patients. The force applied to the body may cause injuries to the surrounding soft tissues (e.g., nerves and arteries), and even to body areas distant from the injury site. In assessing and treating injuries to the bones and joints, it is important to determine the mechanism of injury as well as the signs and symptoms of the injury itself.

**Mechanism of Injury**
As you approach a patient with an injured extremity, you can get a good idea of how much damage may have occurred by determining the mechanism of injury. The forces that may cause bone and joint injury include direct force, indirect force, and twisting force.

**Direct Force**
The injury from direct force, or a direct blow, occurs at the point of impact. For example, a man in an automobile accident who is not wearing a seat belt is thrust forward, the knees hitting the dashboard. As a result, the patella may be fractured.

**Indirect Force**
With indirect force, the force impacts on one end of a limb, causing injury some distance away from the point of impact. For instance, a woman is thrown from a horse and lands on two outstretched hands. One arm sustains a fractured wrist, while the clavicle (collarbone) at the end of the other arm is fractured.

**Twisting Force**
In twisting force, one part of the extremity remains stationary while the rest twists. Take the case of the child running across a field who steps into a hole. The child’s foot is rammed snugly into the hole and stays stationary while her leg twists, fracturing the tibia.
and/or fibula. Bone and joint injuries from twisting force occur commonly in football or skiing accidents.

Critical Fractures: The Femur and the Pelvis

Most fractures are not considered critical injuries and can be managed with standard splinting procedures. However, two specific fractures are associated with a high incidence of serious bleeding and the potential for the patient to develop shock. A fracture to the femur or pelvis is considered a critical injury and must be managed not only to immobilize the bones but also to reduce the associated bleeding. The bones of both the femur and the pelvis contain a large blood supply (Figure 30-9 ■). When fractured, the bones have a tendency to bleed heavily. Also, the bones are in close proximity to other large vessels that may be lacerated by the bone ends, leading to serious bleeding.

**PATHOPHYSIOLOGY PEARLS**
Severe bleeding associated with a fractured pelvis or femur often occurs from the bone itself and not from a lacerated vessel outside of the bone. ■

When the femur fractures, the bone bleeds heavily. A patient can easily lose approximately 1,500 mL, or 1.5 liters, of blood around each femur. Furthermore because the tension on the muscles in the thigh is lost, the diameter of the thigh is allowed to increase. This permits a larger volume of blood to be housed within the thigh, and it also allows the bone to bleed more freely. A principle in splinting a fractured femur is not only to immobilize the bone ends but also to reduce the amount of bleeding. A traction splint, which is discussed in detail later in the chapter, is applied to accomplish two goals: (1) The bone ends will be realigned, which will help prevent further injury and reduce pain, and (2) the size (diameter) of the thigh will be decreased, which will allow less blood to accumulate and will also indirectly put pressure on the bleeding bone ends.

**PATHOPHYSIOLOGY PEARLS**
A traction splint is thought to reduce the compartment size that the femur can bleed into, thereby decreasing the amount of blood loss associated with the fracture. ■

The pelvis, like the femur, has a rich blood supply. If it is fractured, a large amount of bleeding will occur from the fractured pelvic bone. There is also a rich group of veins found in the sacral area that can bleed as well from injury.

Two liters of blood can be lost within the pelvic cavity. Application of the pneumatic antishock garment, which will be discussed in more detail later in the chapter, will not only stabilize the fracture but also decrease the size of the compartment into which the pelvis can bleed, which may tamponade the bleeding pelvis.

**Assessment-Based Approach: Bone or Joint Injuries**

**Scene Size-up and Primary Assessment**

As you approach the patient with a possible bone or joint injury, take appropriate Standard Precautions and consider the mechanism of injury. During your scene size-up, ask questions of bystanders, family, and the patient. Is the cause of the injury a fall, ejection from a vehicle, high-speed collision, or some other traumatic force? Try to imagine the forces the patient’s body was subjected to and the direction in which those forces propelled the body.

During the primary assessment, your general impression of the patient’s injury helps determine the priority of care and whether your patient has a life-threatening emergency. Joint and bone injuries are often dramatic but rarely life threatening. However, you should check for obvious signs of severe hemorrhage and treat for shock. Any force significant enough to cause a major musculoskeletal injury can also cause internal injuries. When severe hemorrhage is not obvious, bleeding may be internal to the injury site. This is often the case during blunt trauma. If the mechanism of injury is severe, look for signs and symptoms of shock.
Pulselessness or cyanosis distal to an injured extremity is a serious condition. If this is apparent, immobilize the injury immediately, then transport immediately following your secondary assessment. Absent pulses sometimes indicate arterial compromise, which may cause impaired tissue perfusion, possible tissue death, and loss of the limb.

If the patient has a life-threatening condition that requires immediate transport but is not directly related to or caused by the extremity injury (e.g., intraabdominal trauma), you will initiate transport and, if time and the patient’s condition permit, immobilize the extremity injury en route. If the patient is immobilized to a spine board, this will provide temporary stability to the injured extremity.

**Secondary Assessment**

If the patient is unresponsive or there are multiple injuries or the mechanism of injury is significant, conduct a rapid secondary assessment. If the patient is responsive and oriented, multiple injuries are not suspected, and the mechanism of injury is not significant, conduct a modified secondary assessment, inspecting and gently palpating the injured bone or joint. Assess the joints above and below any bone injury or the bones above and below any joint injury. As you examine the patient, be gentle and reassuring because musculoskeletal injuries can be frightening for the patient. Check for deformity, contusions, tenderness, swelling, discoloration, and open wounds at the injury site. Assess the skin temperature, color, and condition; assess the pulse amplitude; and check the capillary refill time distal to the site of injury. Keep in mind that a fracture must be suspected in the field by these signs; a fracture can only be definitively diagnosed by X-rays at the hospital (Figure 30-10) unless obvious bone ends are protruding from the skin.

**ASSESSMENT TIPS**

The severe pain associated with a fracture to an extremity may distract the patient from complaining of other significant pain, such as abdominal pain or spinal pain. For this reason, fractures are referred to as distracting injuries.

Assess the baseline vitals and obtain a history from the patient. Don’t forget to ask such basic questions as:

When did the injury occur?
What happened?
Where does it hurt?
What did you feel at the time of injury?

Most patients with significant musculoskeletal injury will complain of pain localized to the area of injury. The patient may also report feeling or hearing something snap.

**Signs and Symptoms.** Bone and joint injuries can be one of two types, closed or open (Figure 30-11):

- **Closed.** In which the overlying skin is intact (Figure 30-12).

- **Open.** In which an open wound is associated with the fracture; bone may or may not protrude through the wound (Figure 30-13).

The signs and symptoms of bone and joint injury may include (Figure 30-14):

- Deformity or angulation (When compared to the normal extremity, there is a difference in the size or shape of the injured extremity.)
- Pain and tenderness
- Grating, or crepitus, the sound or feeling of broken fragments of bone grinding against each other
- Swelling
- Disfigurement (either an indentation where tissues have separated or swelling indicating contracted tissue)
- Severe weakness and loss of function
- Bruising (discoloration)
- Exposed bone ends
- Joint locked into position

When assessing an extremity for the possibility of a fracture or dislocation, remember to evaluate the six “Ps”:

- **Pain.** Pain may be on palpation (tenderness), with movement, or without movement.
- **Pallor.** The skin distal to the injury site may be pale and capillary refill delayed if an artery is compressed or torn. If a vein is blocked by the fracture, the distal extremity may appear warm, red (flushed), and swollen.
Closed and open injuries.

*FIGURE 30-11* Closed and open injuries.

A closed fracture has no associated open wound. (Shown here, a Colles fracture to the wrist, also called a silver fork deformity because the deformed wrist looks like an inverted fork.) (© Charles Stewart MD EMDD MPH)

An open fracture presents with an open wound, often with a bone end protruding through the skin.

*FIGURE 30-12* A closed fracture has no associated open wound. (Shown here, a Colles fracture to the wrist, also called a silver fork deformity because the deformed wrist looks like an inverted fork.) (© Charles Stewart MD EMDD MPH)

*FIGURE 30-13* An open fracture presents with an open wound, often with a bone end protruding through the skin.

- **Paralysis.** The patient is unable to move the extremity. This may be from nerve, muscle, tendon, or ligament damage.
- **Paresthesia.** The patient may complain of numbness or a tingling sensation. This may indicate nerve damage.
- **Pressure.** The patient may complain of a pressure sensation within the extremity. This may be associated with swelling from damaged tissue or blood loss within the muscle and surrounding structures.
- **Pulses.** The pulse distal to the injury may be absent or have a decrease in amplitude. This may indicate damage to an arterial vessel.

It is often not possible to diagnose the nature of the injury in the prehospital setting. Do not waste time trying to figure out which kind of injury it is. Any painful, swollen, or deformed extremity should be given the emergency care that is outlined next.

**ASSESSMENT TIPS**

Suspect a dislocation when deformity and pain are found at a joint.
Emergency Medical Care

In some cases, the bone injury is the chief complaint. If the patient has a life-threatening condition caused by or directly related to the extremity injury, such as a femur or pelvic fracture with hypotension or an open fracture with severe bleeding, you will immobilize the injured extremity during your primary or secondary assessment if the appropriate resources are available and it does not cause a delay in transport of the patient, and transport immediately. If the patient has a life-threatening condition not directly related to the extremity injury (e.g., intraabdominal trauma), you will initiate transport immediately and immobilize the extremity en route if time and critical patient care permit.

Perform the following steps to immobilize a suspected fracture:

1. **Use proper Standard Precautions**, such as disposable gloves, before you approach the patient.
2. **Establish and maintain an adequate airway and ventilation if necessary.**
3. **Assess and maintain adequate oxygenation. If the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen.** If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxia are present, a non rebreather mask at 15 lpm could be used.
4. **Maintain in-line spinal stabilization** if spinal injury is suspected.
5. **Splint bone and joint injuries.** Check the patient’s distal pulses, motor function, and sensation both before and after splinting. Document your findings in the prehospital care report. Specifics on splinting are detailed in the next section.
6. **Apply cold packs to the painful, swollen, or deformed extremity to reduce pain and swelling.**
7. **Elevate the extremity** (if spinal injury is not suspected) and keep it elevated throughout transport.
8. **Transport.**

**Reassessment**

Perform the reassessment, including a recheck of the patient’s vital signs and interventions. Is the injured extremity properly immobilized? Make sure that the patient’s distal pulses, motor function, and sensation have improved or have not deteriorated as a result of immobilization.

**Summary: Assessment and Care**

To review possible assessment findings and emergency care for musculoskeletal injuries, see Figures 30-15 and 30-16.

**BASICS OF SPLINTING**

Any device used to immobilize a body part is a splint. A splint can be soft or rigid. It can be commercially manufactured or it can be improvised from virtually any object that can provide stability.

There are two basic reasons for splinting a bone or joint injury. First, splinting prevents movement of any bone fragments, bone ends, or dislocated joints,
Assessment Summary

MUSCULOSKELETAL INJURY

The following findings may be associated with a musculoskeletal injury.

Scene Size-Up

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Ejection from a vehicle
- High-speed collision
- Sports injury
- Fall
- Crushing force
- Gunshot wounds
- Evidence of other trauma

Primary Assessment

General Impression
- Major bleeding associated with suspected fracture
- Open fracture sites
- Obvious deformity to extremities

Mental Status
- Alert to unresponsive based on other injuries

Airway
- Clear and open unless associated with facial fractures or other injuries

Breathing
- Normal; increased if extreme pain or associated with shock or other injury

Circulation
- Pulse is normal; may be increased in response to pain or shock
- Skin is normal; may be cool, clammy, pale, and cyanotic in extremity if bone injury disrupts distal blood flow

Status: Priority patient if distal pulses are not present or if bone injury is associated with other life-threatening injuries such as severe blood loss, shock, or internal injuries

Secondary Assessment

Physical Exam
Pelvis:
- Pain
- Instability on compression
- Deformity

Extremities:
- Pain
- Deformity
- Tenderness on palpation
- Crepitus
- Loss of function distal to injury
- Open wounds
- Discoloration
- Exposed bone ends
- Abnormal inward or outward rotation of foot and leg (hip dislocation or femur fracture)

Baseline Vital Signs
- BP: normal, or may be decreased if there is other trauma and shock
- HR: normal, or may be increased in response to pain or other injuries, bleeding, or shock
- RR: normal, or may be increased in response to pain, other injuries, bleeding, or shock
- Skin: normal, or may be pale, cool, clammy, and cyanotic if the bone injury is interfering with distal circulation or associated with bleeding and shock
- Pupils: normal or may be dilated and sluggish if associated with bleeding and shock

History
- Signs and symptoms of an open fracture:
  - Pain, deformity, swelling to long bone
  - Open wound associated with suspected fracture site
  - Exposed bone ends
- Signs and symptoms of a closed fracture:
  - Pain, deformity, swelling to long bone
- Signs and symptoms of a dislocation:
  - Pain, deformity, swelling to a joint
  - Abnormal rotation of foot and leg (hip dislocation)

reducing the chance for further injury. Second, splints usually reduce pain and minimize the following common complications from bone and joint injuries:

- Damage to muscles, nerves, or blood vessels caused by movement of bone fragments or bone ends
- Conversion of a closed fracture to an open fracture (by breaking through the skin)
- Restriction of blood flow as a result of bone ends or dislocations compressing blood vessels
- Excessive bleeding from tissue damage caused by movement of bone ends
- Increased pain associated with movement of bone ends or dislocated bones
- Paralysis of the extremities resulting from a damaged spine

General Rules of Splinting

Regardless of where you apply the splint, follow these general rules (EMT Skills 30-1):

- Both before and after you apply the splint, assess the pulse, motor function, and sensation distal to the
Emergency Care Protocol

MUSCULOSKELETAL INJURY

1. Establish manual in-line stabilization if spinal injury is suspected.
2. Establish an open airway, and insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 95% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. If signs of hypoxia or respiratory distress are present, or the SpO2 reading is less than 95%, administer the oxygen to maintain the SpO2 at 95% or greater.
6. Control any major bleeding.
7. If a priority patient, splint suspected fractures and dislocations en route to the medical facility.
8. If a spinal injury is suspected, immobilize the patient to a backboard.
9. Follow the general rules of splinting:
   a. Assess pulses and motor and sensory function distal to injury before and after splinting.
   b. Immobilize joints above and below in a long bone injury, and bones above and below in a joint injury.
   c. Dress and bandage all open wounds before splinting.
   d. If a suspected fracture is grossly deformed or no distal circulation is present, apply gentle traction and attempt to realign. If excruciating pain or resistance is met, stop and splint in the position found.
   e. Splint suspected dislocations in position found unless distal pulses are absent. If no distal pulses, apply gentle traction and realign unless extreme pain or resistance is met. Splint in position found.
   f. Cold can be applied to the deformity to reduce swelling and pain.
   g. Elevate the extremity slightly to reduce swelling. Remove all jewelry and constrictive clothing on the affected extremity.
   h. Reassess pulses and motor and sensory function.
10. Suspected fractures or dislocations requiring special equipment or procedures:
    Hip Dislocation or Fracture:
        Pad between legs and bind legs together or apply long board splints; place the patient on a backboard.
    Pelvis:
        Apply PASG if the SBP is <90 mmHg and inflate all three sections to splinting pressure, or pad between legs and bind legs together; place the patient on a backboard. A pelvic binder or an improvised pelvis wrap can be applied.
    Femur:
        Apply a traction splint; place on a backboard.
    Shoulder:
        Sling and swathe if in a relatively normal position.
        Vacuum splint, wire ladder splints, or board splints if severely deformed.
    Clavicle:
        Sling and swathe.
11. Transport.
12. Perform reassessment every 5 minutes if unstable and every 15 minutes if stable.

injury. (Keep the mnemonic PMS for pulse, motor function, and sensation in mind as you manage a suspected fracture.) You should evaluate these signs every 15 minutes after applying the splint to make sure the splint is not impairing circulation to the extremity.

- Immobilize the joints both above and below a long bone injury. (If the forearm is fractured, immobilize the wrist and the elbow.) Immobilize the bones above and below a joint injury. (If the elbow is injured, immobilize the humerus of the upper arm and the radius and ulna of the forearm.)
- Remove or cut away all clothing around the injury site with a pair of bandage scissors so you won’t accidentally move the fractured bone ends and complicate the injury. Remove all jewelry around the injury site, especially distally, because it may become entrapped by swelling. Bag the jewelry and either give it to a family member or see that it is transported with the patient. Carefully document the disposition of the patient’s jewelry.

- Cover all wounds, including open fractures, with sterile dressings before applying a splint, then gently bandage. Avoid excessive pressure on the wound.
- If there is a severe deformity or the distal extremity is cyanotic (bluish) or lacks pulses, align the injured limb with gentle manual traction (pulling) before splinting. As a general rule, make one attempt to align the extremity. If pain, resistance, or crepitus increase, stop. Generally, you should not try to align a wrist, elbow, knee, hip, or shoulder—major nerves and arteries close to these joints increase the chance of causing further damage. Follow local protocol.
- Never intentionally replace protruding bones or push them back below the skin. (Occasionally, during realignment, these will be drawn into the wound.)
- Pad each splint to prevent pressure and discomfort to the patient.
- Apply the splint before trying to move the patient. Do not release manual traction until after the splint has been applied.
Emergency Care Algorithm

MUSCULOSKELETAL INJURY

Mechanism of injury present?

Yes

Manual in-line stabilization

No

Any major bleeding?

Yes

Control bleeding

No

Assess mental status

Yes

Alert and able to obey commands

Consider oxygen administration

No

Assess circulation

Secondary assessment

Priority patient?

Yes

Immobilize to backboard if necessary and transport

No

Splint suspected fractures or dislocations prior to transport

Splint suspected fractures and dislocations en route

Manage other associated injuries

Manage specific bone injuries

Hip dislocation or suspected fracture

Pelvis

Femur

Shoulder dislocation or suspected fracture

PPV = positive pressure ventilation

Cream = assessment

Green = key decision points

Blue = interventions

CHAPTER 30 • Musculoskeletal Trauma and Nontraumatic Fractures
Pressure (Air or Pneumatic) Splints

The main type of pressure splints are air or pneumatic splints. Air splints are soft and pliable before being inflated but rigid once they are applied and filled with air. Air splints cannot be sized, may impair circulation, may interfere with the ability to assess pulses, and may lose or gain pressure with temperature and altitude changes. Seek medical direction and follow local protocol regarding their use.

Traction Splints

Traction splints (Figure 30-18) provide a counterpull, alleviating pain, reducing blood loss, and minimizing further injury. Traction splints are not intended to reduce (correct) the fracture, but simply to immobilize the bone ends, reduce the diameter or container size of the thigh, and prevent further injury. Several types of traction splints are available, and procedures vary according to the manufacturer. Specifics about traction splinting are detailed later in this chapter.

Formable Splints

Formable splints are a type of rigid splint that is malleable enough to form to a deformed or angulated extremity. The splint is shaped to the deformed extremity instead of making the extremity fit the splint. Once shaped to the injured extremity, it is fixed in place with cravats or Velcro straps. Formable splints are typically made of wire, thin aluminum, or another metal that can bend.

Vacuum Splints

Vacuum splints (EMT Skills 30-2) are soft, pliable splints that are easily formed to deformed extremities. The air is then sucked out of the splint, causing it to become rigid in its position of placement. Vacuum splints are considered to be a type of formable splint.

Sling and Swathe

A sling and swathe is often used to provide stability to a painful and tender shoulder, elbow, or upper humerus...
injury. A sling is a triangular bandage. The sling supports the patient’s arm, while a swathe of cloth holds the patient’s arm against the side of the chest. This minimizes the pain and further injury associated with arm and shoulder movement. (See instructions for applying a sling and swathe under “Splinting Specific Injuries” later in this chapter.)

**Spine Board**

A long spine board is a full body splint. In the case of a critical injury when extremity fractures cannot be splinted at the scene, placing the patient on a long spine board will provide some stabilization through the limitation of movement. This is not an ideal method of splinting; however, uncomplicated fractures are not a priority in critically injured or unstable patients. Rapid transport will take precedence over splinting extremity injuries. A short spine board or vest-type immobilization device may also be used as a splint. A vest-type immobilization device is sometimes used to splint a suspected pelvic injury when turned upside down.

**Improvised Splints**

You may be forced to improvise at the scene. Improvised splints can be made from a cardboard box, cane, ironing board, rolled-up magazine, umbrella, broom handle, catcher’s shin guard, or any similar object. An effective improvised splint must be:

- Light in weight, but firm and rigid
- As wide as the thickest part of the fractured limb
- Long enough to extend past the joints and prevent movement on either side of the fracture
- Padded well so the inner surfaces are not in contact with the skin

An ordinary bed pillow or blanket roll (Figures 30-19a and 30-19b) can be an effective improvised splint when wrapped around the area and secured with several cravats.

**Hazards of Improper Splinting**

For all their obvious benefits to the patient with a bone or joint injury, splints can also cause complications if they are applied in the wrong manner. Improper splinting can:

- Compress the nerves, tissues, and blood vessels under the splint, aggravating the existing injury and causing new injury
- Delay the transport of a patient who has a life-threatening injury
- Reduce distal circulation, compromising the viability of the extremity
- Aggravate the bone or joint injury by allowing movement of the bone fragments or bone ends or by forcing bone ends beneath the skin surface
- Cause or aggravate damage to the tissues, nerves, blood vessels, or muscles from excessive bone or joint movement
- Cause damage to the skin from improper padding

**Splinting Long Bone Injuries**

Special considerations must be taken into account when splinting long bones or joints. Remember that some long bone injuries may lead to serious internal bleeding. As you assess for evidence of trauma, look for the following signs and symptoms of long bone injury:

- Exposed bone ends
- Joints locked in position
- Paresthesia, a pricking or tingling feeling that indicates some loss of sensation
- Paralysis
- Pallor of the injury site
- Loss of distal pulse

Assess the pulse and motor and sensory function below the injury site. Assess the radial pulse for an upper extremity, the dorsal pedal or posterior tibial pulse for a lower extremity. Sensation is intact if the patient can tell you, without looking, which finger or toe you are touching and can feel painful stimuli. If the injury...
involves an upper extremity, motor function is intact if the patient can make a fist, spread the fingers, and make a hitchhiking sign with the thumb. If the injury involves a lower extremity, motor function is intact if the patient can tighten the kneecap (patella) and move the foot up and down as if pumping an automobile accelerator.

### Assessment Tips

If the foot or ankle is injured, having the patient push down and pull back with the great (big) toe will give you the same results as if the entire foot were tested.

If the limb is severely deformed, is cyanotic, or lacks distal pulses, align it with gentle traction. Provide steady, gentle pressure along with traction. If pain or crepitus increases, stop.

For specific guidelines on splinting a long bone injury, see EMT Skills 30-3. In EMT Skills 30-3E, you will see that the hand (or foot) must be immobilized in the position of function. The position of function for a hand is with the fingers curled as if holding a ball. You can put a roll of bandage in the patient’s hand to support this position. The position of function for the foot is at a 90-degree angle to the leg with the foot bent at the normal angle to the leg, not pushed downward or upward toward the shin.

### Splinting Joint Injuries

A common joint injury is the displacement of a bone end from the joint, or dislocation. In a dislocation, the ligaments holding the bones in proper position are often stretched and sometimes are torn loose. Dislocations cause serious pain because the joint surfaces are rich in nerves.

The principal signs and symptoms of any type of joint injury are pain, swelling, deformity, and possible immobility and loss of function. As with long bone injuries, assess the pulse and motor and sensory function below the injury site. Look for paresthesia or paralysis. If the distal extremity is cyanotic (bluish) or lacks pulses, align the joint with gentle traction. If pain or crepitus increases, stop. Do not spend time trying to differentiate a joint injury from a bone injury since it may be difficult to distinguish between the two; for both you will need to splint and transport.

For specific guidelines on splinting a joint injury, see EMT Skills 30-4.

### Traction Splinting

Fractures of the femur can be successfully immobilized with a traction splint. A fractured femur is complicated because of the amount of bleeding that can occur from the fractured bone. A fractured femur is also complicated because the large muscle mass of the thigh contracts and pulls the fractured femur ends so that they override, or pass each other. This allows the thigh to increase in diameter, which permits more blood loss to occur within the thigh, causing great pain in addition to a lot of internal soft tissue injury.

Traction splinting reduces the diameter of the thigh, decreases the space in which bleeding can occur, and realigns the fractured femur. This helps to tamponade the bleeding, relieve pain, and reduce the incidence of internal injuries that would occur if the patient were transported without immobilization. Remember that you don’t have to be certain the femur has actually been fractured. If the thigh is painful, swollen, or deformed, you should treat as if the femur is fractured.

In general, you should not use a traction splint if:

- The injury is within 1–2 inches of the knee or ankle.
- The knee itself has been injured.
- The hip has been injured.
- The pelvis has been injured.
- There is partial amputation or avulsion with bone separation, and the distal limb is connected only by marginal tissue. (In such a case, using a traction splint would risk separation.)

See EMT Skills 30-5 for instructions on applying a bipolar traction splint. See EMT Skills 30-6 for instructions on applying a unipolar traction splint.

### Splinting Specific Injuries

Special techniques may be applied to the splinting of suspected bone and joint injuries to specific sites. Splinting techniques are illustrated in EMT Skills 30-7 for the shoulder and EMT Skills 30-8 for the upper arm, elbow, forearm, wrist, hand, fingers, pelvis, hip, thigh, knee, lower leg, ankle, and foot.

### Pelvic Fracture

Pelvic fractures may be associated with significant pain and bleeding. The pneumatic antishock garment (PASG) is a device that can be used to splint the pelvis and decrease the compartment size to reduce bleeding (Figure 30-20a □). Another method to stabilize the fracture and tamponade the bleeding is to use a commercial pelvic splint (Figure 30-20b □). If a PASG or commercial pelvic splint is not available, an improvised pelvic wrap may be applied. To apply an improvised pelvic wrap:

1. Fold a sheet lengthwise to approximately an 8-inch width.
2. Slide it under the small of the back and then down under the pelvis until it is centered and the ends of the sheet are of equal length on both sides of the patient.
3. Cross the tail ends over the patient and twist the ends until the sheet is tightly secured around the pelvis.
4. Tuck the sheet ends under the patient or tie the ends into a square knot.
5. Place the patient on a backboard or rigid device.
Emergency care focuses on treating any life-threatening injuries first. Immobilize and splint the affected extremity. Elevate the extremity and apply a cold pack or ice. It is extremely important to transport the patient, since he may lose the limb if compartment syndrome is not treated quickly and effectively.

**Compartment Syndrome**

Compartment syndrome may occur when an extremity is fractured or injured. It may also occur in the buttocks and abdomen of the body. When an injury occurs, swelling and bleeding in the space between the tissues is usually present. If the pressure in the space around the capillaries exceeds the pressure needed to perfuse the tissues, the blood flow is cut off and the cells become hypoxic, leading to **compartment syndrome**. The hypoxic cells release chemicals that cause the capillaries to leak, leading to further swelling. If the pressure continues, the cells eventually die, resulting in the loss of muscle, nerves, and vessels in the affected area.

Compartment syndrome usually develops over time as edema around an injured area increases, so it may not be seen at the initial stages of injury. It is commonly associated with fractures, arterial and venous bleeding from penetrating or blunt trauma, crush injuries, and high-energy trauma. Signs and symptoms of compartment syndrome include the following:

- Severe pain or burning sensation
- Decreased strength in the extremity
- Paralysis of the extremity
- Pain with movement
- Extremity feeling hard to palpation
- Distal pulses, motor, and sensory function possibly normal

Emergency care for the nontraumatic fracture is the same as for a fracture caused by trauma. During the assessment, ensure the underlying medical condition is not producing any life threats that must be managed. Otherwise, splint the fracture according to the same guidelines used for traumatic fractures.
EMT SKILLS 30-1

General Splinting Rules

- **30-1A** Assess the distal pulse and motor and sensory function.
- **30-1B** Cut away clothing to expose the injury site.
- **30-1C** Place a sterile dressing over the open wound.
- **30-1D** Align the extremity with gentle traction if there is severe deformity, absence of distal pulses, or cyanosis.
- **30-1E** Pad the splint to prevent discomfort and unnecessary pressure. The correct size splint will immobilize the joint above and below the site of a bone injury.
- **30-1F** Maintain manual traction. Do not release until the splint has been applied. Assess distal pulse and motor and sensory function after the splint has been applied.
If your service uses commercially prepared prepadded splints, skip the padding step, but maintain manual traction in any case.

**EMT SKILLS 30-2**

**Applying a Vacuum Splint**

- **30-2A** Manually stabilize the suspected fracture and assess pulse and motor and sensory function.

- **30-2B** Apply the splint and secure it to the extremity.

- **30-2C** Suction the air out of the splint until it is rigid. Reassess pulse and motor and sensory function.
**EMT SKILLS 30-3**

**Splinting a Long Bone**

- **30-3A** Apply manual stabilization to the injured extremity.

- **30-3B** Assess the distal pulse and motor and sensory function.

- **30-3C** If the deformity is severe, distal pulses are absent, or the distal extremity is cyanotic, align with gentle manual traction.

- **30-3D** Measure the splint for proper length.

- **30-3E** Secure the entire injured extremity. The hand (or foot) must be immobilized in the position of function.

- **30-3F** Reassess the pulse and motor and sensory function.
**EMT SKILLS 30-4**

**Splinting a Joint**

- **30-4A** Manually stabilize the joint in the position found. Then assess distal pulse and motor and sensory function.
- **30-4B** Apply the splint to immobilize the bone above and below the joint.
- **30-4C** Reassess sensory function, pulses, and motor function after the splint is applied.

**EMT SKILLS 30-5**

**Applying a Bipolar Traction Splint**

- **30-5A** Assess distal pulses and motor and sensory function.
- **30-5B** Stabilize the injured leg by applying manual traction.

*continued*
■ **30-5C** Adjust the splint for proper length, using the uninjured leg as a guide.

■ **30-5D** Position the splint under the injured leg until the ischial pad rests against the bony prominence of the buttocks. Once the splint is in position, raise the heel stand.

■ **30-5E** Attach the ischial strap over the groin and thigh.

■ **30-5F** Make sure the ischial strap is snug but not tight enough to reduce distal circulation.

■ **30-5G** With the patient’s foot in an upright position, secure the ankle hitch.

■ **30-5H** Attach the “S” hook to the “D” ring and apply mechanical traction. Full traction is achieved when the mechanical traction is equal to the manual traction and the pain and muscle spasms are reduced. In an unresponsive patient, adjust the traction until the injured leg is the same length as the uninjured leg.
EMT SKILLS 30-6

Applying a Unipolar Traction Splint

30-5I Fasten the leg support straps.

30-5J Reevaluate the ischial strap and ankle hitch to ensure that both are securely fastened.

30-5K Reassess distal pulses and motor and sensory function.

30-5L Place the patient on a long board and secure with straps. Pad between the splint and uninjured leg. Secure the splint to the backboard.

30-6A Assess distal perfusion and motor and sensory function. Place the splint along the medial aspect of the injured leg. Adjust it so that it extends about 4 inches beyond the heel.

30-6B Secure the strap to the thigh.
Apply the ankle hitch and attach it to the splint.

Apply traction by extending the splint. Adjust the splint to 10 percent of the patient’s body weight.

Apply the straps to secure the leg to the splint. Reassess distal pulses and motor and sensory function.

Place the patient onto a long backboard. Strap the ankles together and secure to the board.

---

**EMT SKILLS**

**30-7** Applying a Sling and Swathe

First, place one end of the base of an open triangular bandage across the shoulder of the uninjured side, with the apex behind the elbow of the injured arm. Bend the arm at the elbow with the hand elevated 4–5 inches.

Bring the lower end of the bandage over the shoulder of the injured side. Tie it in a knot at the back of the neck.
Pin the apex to form a pocket at the elbow. Immobilize the injured arm to the body with a swathe.

**EMT SKILLS 30-8**

**Splinting Specific Injuries**

- **30-7C** Fixed splint for humerus injury.
- **30-7D** Application of a fixed splint for a humerus injury to a child.
- **30-8B** Fixation of rigid splint with a sling and swathe.
- **30-8C** Application of a rigid splint with sling and swathe to a child for an elbow injury.
- **30-8D** Application of a rigid splint with a sling and swathe.
Bone injury to the finger splinted with a tongue depressor.

Immobilization of an elbow injury with a vacuum splint in a bent position.

Immobilization of an elbow injury with a vacuum splint in a straight position.

Immobilization of a bone injury to the forearm, wrist, or hand.

Immobilization with a blanket roll splint of a bone injury to the forearm, wrist, or hand.

Common sites of injury to the pelvis.
Use of the PASG is recommended to splint a suspected pelvic injury.

Rigid splint for hip injury.

Immobilized knee injury in straight position.

Immobilization of a lower leg injury with an air splint.

Immobilization of the ankle and foot with a blanket roll.

Injury to shaft of femur with angulation, shortening, and rotation of the limb below the injury site. Apply gentle traction parallel to the normal axis of the injured leg. (For application of bipolar and unipolar traction splints, see EMT Skills 30-5 and 30-6.)
movement and reduce pain. When splinting a joint, be sure to immobilize the bone above and below the joint. When splinting a long bone, you must immobilize the joint above and below the injured bone. Always assess motor and sensory function and distal pulses both prior to and after splinting an extremity.

There are a variety of splints, including rigid, pressure (air or pneumatic), traction, vacuum, improvised, and sling and swathe. Select the proper splint for the injury. Improperly applied splints may aggravate or cause further injury.

**Summary**

A fracture is a break in the continuity of the bone. Some fractures present with obvious signs and symptoms, whereas others may have a more subtle presentation. Fractures can be open or closed. Other associated injuries are dislocations, sprains, and strains. The two main purposes of splinting are to prevent movement and reduce pain. When splinting a joint, be sure to immobilize the bone above and below the joint. When splinting a long bone, you must immobilize the joint above and below the injured bone. Always assess motor and sensory function and distal pulses both prior to and after splinting an extremity.

There are a variety of splints, including rigid, pressure (air or pneumatic), traction, vacuum, improvised, and sling and swathe. Select the proper splint for the injury. Improperly applied splints may aggravate or cause further injury.

**Case Study**

**Follow-up**

You and your partner have just arrived at the high school football field. You have been dispatched to a 17-year-old male patient complaining of leg pain. The scene appears safe as you put on your disposable gloves and remove the stretcher from the ambulance. Your partner grabs the trauma kit. As you wheel the stretcher onto the field you are met by the football coach who tells you his quarterback, Tom Cvitanovic, was tackled. “He can’t move his right leg. He got tackled pretty hard.” The coach’s remarks lead you to believe the mechanism of injury may mean a fracture caused by direct force. You approach Tom and introduce yourself. Your partner asks, “What happened, and where is the pain?”

**Primary Assessment**

Tom complains of severe right leg pain and says his right arm hurts, too. Because he is talking clearly, you assume his airway is open. His breathing is adequate; his radial pulse is strong and 103 per minute. You do not believe he has a life-threatening condition. Tom then lets out a groan, and says, “Oh, man, can’t you do anything for the pain?!!” He seems frightened so you reassure him that he’ll get care quickly. Your partner is at Tom’s head maintaining manual in-line spinal stabilization. He is alert and oriented, is exhibiting no signs of respiratory distress or hypoxia, has no complaints of shortness of breath, and has an SpO2 reading of 99% on room air; therefore, you decide not to place him on oxygen.

**Secondary Assessment**

While your partner continues spinal stabilization, you perform a secondary assessment and assess for signs of injury. Tom denies any neck pain. However, because of the mechanism of injury, you apply a cervical spine immobilization collar as your partner continues to maintain manual stabilization.

You find that Tom’s right arm is tender and swollen. Approximately 6 inches below Tom’s right knee you see bone ends protruding through a fracture site. Pulse, motor, and sensory function are good below both injury sites. You apply a cold pack to Tom’s right arm and then take his baseline vitals. His blood pressure is 142/70 mmHg, respirations are 20 per minute, pulse is 120 per minute, and skin is warm and slightly sweaty. Skin color is normal. You obtain a history and learn that Tom denies any further pain or injury. He says he is allergic to aspirin and doesn’t take any medication. He tells you that 3 years ago he broke the same leg and was hospitalized for almost a week. He had his last meal at noon. Then he describes how he was tackled by two, maybe three, other football players.

Following your local protocols, you decide to apply a vacuum splint to Tom’s right arm. You cover the protruding bone ends below the knee with a trauma pad and note that there is very little bleeding. Following local protocols, and with your partner’s assistance, you apply padded board splints to Tom’s right leg. You recheck the pulse and motor and sensory function of Tom’s injured arm and leg. There is no change. Once Tom is fully immobilized to a backboard, you load him into the ambulance. As you wheel the stretcher from the ambulance, your partner grabs the trauma kit. As you wheel the stretcher onto the field you are met by the football coach who tells you his quarter back the team again next year.
IN REVIEW

1. List three functions of the musculoskeletal system.
2. Explain the difference between an open and a closed bone injury.
3. List the indications that would lead you to suspect a bone or joint injury.
4. Explain the reasons for splinting a bone or joint injury.
5. List the emergency medical care steps for treating a bone or joint injury.
6. Outline the general rules for splinting a bone or joint injury.
7. Describe the complications that can arise from improper splinting of a bone or joint.
8. List contraindications for (reasons for not using) a traction splint on a suspected femur fracture.

CRITICAL THINKING

You arrive on the scene and find a 24-year-old female patient who was riding her bike when she was struck by a car. She was thrown from her bike to the ground. She is alert and moaning loudly. Her airway is open and her respirations are 26 per minute with good chest rise. Her radial pulse is weak and her skin is pale, cool, and clammy. Her heart rate is 128 per minute. During the rapid trauma assessment, you note that her pelvis is unstable and she complains of severe pain when it is palpated. You also note a deformed right lower leg. Her blood pressure is 96/72 mmHg.

1. What initial emergency care would you provide to the patient?
2. What specific injuries do you suspect?
3. How would you manage the possible fractures?
4. What complications would occur with the suspected fractures?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • **Trauma** (Content Area: Head, Facial, Neck, and Spine Trauma)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

---

**OBJECTIVES** • After reading this chapter, you should be able to:

31-1. Define key terms introduced in the chapter.
31-2. Explain the importance of recognizing and providing emergency medical care to patients with injuries to the head.
31-3. Identify the anatomy of the skull.
31-4. Identify the meningeal layers and the spaces into which intracranial bleeding can occur in relationship to the meninges, skull, and brain.
31-5. Associate each of the major anatomical portions of the brain with its functions.
31-6. Explain the pathophysiology and key signs and symptoms of injuries to the scalp, skull, and brain, including:
   - a. Scalp lacerations
   - b. Skull fractures
   - c. Cerebral concussion and diffuse axonal injury
   - d. Cerebral contusion
   - e. Coup/contrecoup injury
   - f. Cerebral and intracranial hematomas
   - g. Cerebral laceration
31-7. Identify and, where possible, manage factors that can worsen traumatic brain injuries, including:
   - a. Hypoxia
   - b. Hypercarbia
   - c. Hypoglycemia
   - d. Hyperglycemia
   - e. Hyperthermia
   - f. Hypotension
31-8. Describe the goals of emergency treatment of patients with traumatic brain injuries.
31-9. Describe the pathophysiology and key signs of increased intracranial pressure and brain herniation.
31-10. Describe the neurological assessment of patients with suspected traumatic brain injury.
31-11. Discuss the focus of history taking and assessment for patients with injuries to the head.
31-12. Assess and provide emergency treatment to patients with injuries to the head.
31-13. Explain the importance of reassessment of the patient with an injury to the head.
31-14. Document information relevant to the assessment and management of patients with injuries to the head.

---

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- anterograde amnesia p. 875
- Battle sign p. 873
- brainstem p. 865
- cerebellum p. 865
- cerebrospinal fluid (CSF) p. 863
- cerebrum p. 864
- concussion p. 866
- consensual reflex p. 872
- contusion p. 867
- Cushing reflex p. 872
- diplopia p. 875
- epidural hematoma p. 867
- extension posturing p. 871
- flexion posturing p. 871
- herniation p. 868
- laceration p. 868
- meninges p. 863
- raccoon sign p. 873
- retrograde amnesia p. 875
- subdural hematoma p. 867
INTRODUCTION

Injuries to the head pose some of the most serious situations you will face as an EMT. The patient is often confused or unresponsive, making assessment of his condition difficult. Drug and alcohol use will also cloud the assessment and make head injury diagnosis difficult. Head injuries to a patient can occur days or weeks before the onset of any signs or symptoms. In addition, many injuries to the head are life threatening. Such injuries are, in fact, a leading cause of death among this nation’s young people. Many patients who survive head injuries suffer permanent disability. The cost of failing to recognize or properly treat such injuries can be very high.

Head injuries must be looked at with concern because the skull encases the structures of the central nervous system. The central nervous system, made up of the brain and the spinal cord, coordinates the functions of other body systems. Injury to it can have severe consequences.

ANATOMY OF THE SKULL AND BRAIN

The skull is the portion of the skeletal system that contains and protects the brain and the portion of the spinal cord that exits from the brain. At this point, you may want to review the information about the skeletal and nervous systems that was presented in Chapter 7, “Anatomy, Physiology, and Medical Terminology.”

The Skull

The brain, which occupies 80 to 90 percent of the space inside the skull, is surrounded by plates of large, flat bones that are fused together to form a helmetlike covering called the cranial skull. The remainder of the skull is made up of facial bones. Composed of 14 irregularly shaped bones, it is made up of the cheek, nose, and jaw bones (Figure 31-1 ■). The basilar skull, or floor of the skull, is made up of many separate pieces of bone and is the weakest part of the skull. Some of its bones are thin and perforated extensively by the spinal cord, nerves, and blood vessels. The basilar skull has many bony ridges that can cause injury to the brain. Also, the skull tightly encloses the brain, severely limiting the swelling and bleeding that can occur around the brain.

The Brain

Within the skull, the brain is cushioned in a dense, serous substance called cerebrospinal fluid (CSF). Produced by the brain, this fluid protects the brain and spinal cord against impact. The cerebrospinal fluid is clear and colorless, circulates throughout the skull and spinal column, and is reabsorbed by the circulatory system. The fluid not only cushions and protects but also performs a function similar to lymph fluid in combating infection and cleansing the brain and spinal cord. When both the skull and the membrane surrounding the brain are broken, cerebrospinal fluid leaks out, often through the nose, ears, or both—a classic sign of basilar skull fracture.

The Meninges

Inside the skull, the surface of the brain is protected from injury by three meninges, or layers of tissue, that enclose the brain (Figure 31-2 ■). The outermost is the dura mater (“hard mother”), composed of a double layer of tough, fibrous tissue. The next layer is the arachnoid. Beneath that, in contact with the brain, is the pia mater (“soft mother”). All three layers enclose not only the brain, but the brainstem and the spinal cord as well. The arachnoid membrane and the pia mater are separated by a lattice of fibrous, spongy

Parts of the Brain

The brain is divided into three anatomical components:

- The cerebrum—The largest part of the brain, the cerebrum, comprises three-fourths of the brain's volume. It is divided into two hemispheres (right and left). Each hemisphere is made up of four distinct lobes: a frontal lobe (anterior), a parietal lobe (middle), an occipital lobe (posterior), and a temporal lobe (side). The cerebrum is responsible for most conscious and sensory functions, the emotions, and the personality. The cerebrum is not attached to the inside of the skull.

tissue filled with cerebrospinal fluid called the subarachnoid space.

Bleeding that occurs between the dura mater and the skull is called epidural and usually involves the brain's outermost arteries. Recognized and treated early, such bleeding may have no permanent consequences. Subdural bleeding, on the other hand, occurs beneath the dura and is usually venous. Bleeding that occurs between the arachnoid membrane and the surface of the brain is called subarachnoid hemorrhage. Any bleeding within the meningeal layers can be fatal within minutes, especially epidural bleeding, which is commonly from a lacerated or ruptured artery.
• The cerebellum—Sometimes called the “little brain,” the cerebellum controls equilibrium and coordinates muscle activity. Tucked underneath the cerebrum, it controls muscle movement and coordination, predicts when to stop movement, and coordinates the reflexes that maintain posture and equilibrium.

• The brainstem—The brain’s funnel-shaped inferior part, the brainstem, is the most primitive and best protected part of the brain. Tethered to the skull by numerous nerves and vessels, it controls most automatic functions of the body, including cardiac, respiratory, vasomotor (blood pressure), and other functions vital to life. The brainstem is made up of the pons, the midbrain, and the medulla, or medulla oblongata, which physically connects the brain to the spinal cord. All of the messages between the brain and the spinal cord pass through the medulla.

## Head Injury

Head injuries can involve the scalp, the skull, the brain itself, or combinations of these.

### Scalp Injuries

The scalp may be injured in the same way as any other soft tissue; it may be contused, lacerated, abraded, or avulsed. Because of the rich supply of blood vessels to the scalp, injuries of the scalp tend to bleed very heavily. In addition, the underlying fascia may be torn while the skin stays intact. Bleeding then occurs under the skin and may be confusing at first as you try to assess the patient. (The presence of blood under intact skin can mimic skull deformity.)

### Pathophysiology Pearls

The vessels in the scalp are not able to constrict as effectively as other blood vessels in the body; thus, they bleed more heavily when injured, which can lead to shock if uncontrolled. The skull is covered by a layer of fascia (fibrous membrane) and then by the scalp. The fascia adheres to the skull loosely, more easily creating a scalp avulsion.

### Assessment Tips

When palpating the skull, you may identify a depressed skull fracture that doesn’t really exist—or fail to detect a depressed skull fracture that actually does exist. The reasons: The fascia, which lies under the scalp but above the skull, can rupture and become depressed and feel, on palpation, like a depressed skull fracture. Conversely, blood may fill the area between a depressed skull fracture and the scalp, making the skull feel normal and not depressed during palpation.

### Skull Injuries

Because of the skull’s spherical shape and thickness, it is generally deformed only if the trauma is extreme.

A linear skull fracture, which is the most common type, resembles a line. There is no gross deformity in a linear fracture and it can only be diagnosed through a radiograph. A depressed skull fracture occurs when the bone ends are pushed inward toward the brain. Typically, the depression can be palpated in the area of fracture. A depressed skull fracture may pose harm if the bone ends damage the brain tissue.

Skull fractures can be open or closed. A closed skull fracture is an injury in which the skull is fractured but there is no open wound to the overlying scalp. An open skull fracture is a fracture of the skull with an associated open wound to the scalp. The open wound allows for the possibility that bacteria and other contaminants will enter the skull and infect the brain. If the dura mater is damaged, cerebrospinal fluid may leak from the open wound.

A basilar skull fracture is a fracture to the floor or bottom of the cranium. This fracture often begins as a linear temporal fracture that extends downward and continues into the base of the skull. Basilar skull fractures often cause leakage of cerebrospinal fluid from the ears, nose, or mouth. Ecchymosis (bruise-type discoloration) around the eyes and behind the ears often occurs with a basilar skull fracture; however, it often takes several hours for the bruising to become apparent.

A skull deformity itself does not cause disability or death; rather, it is any underlying damage to the brain that leads to serious consequences. In short, the skull deformity presents no danger if it is not accompanied by brain injury, hematoma, cerebrospinal fluid leakage, or subsequent infection.

### Pathophysiology of Traumatic Brain Injury

Brain injury may be direct (from penetrating trauma), indirect (from a blow to the skull), or secondary (for example, from a lack of oxygen, buildup of carbon...
Injury to the brain that results from shearing, tearing, and stretching of nerve fibers is called a diffuse axonal injury (DAI). This type of injury interferes with the communication and transmission of nerve impulses throughout the brain. DAI is most common in auto crashes and pedestrians struck by autos. The severe acceleration and deceleration causes the shearing, tearing, and stretching injury. DAI is categorized as mild, moderate, or severe. A concussion is a mild diffuse axonal injury. A severe diffuse axonal injury involves the brainstem.

Specific types of brain injuries include concussion, a temporary loss of the brain's ability to function; contusion, bruising or swelling of the brain; hematoma, pooling of blood within the brain; and laceration, or tearing of the brain tissue.

**Concussion**

A concussion normally causes some disturbance in brain function ranging from momentary confusion to complete loss of responsiveness, and it usually causes headache. If there is a loss of consciousness, it is usually brief (lasting only a few minutes) and does not recur.

A concussion is a mild diffuse axonal injury which, as just noted, involves stretching, tearing, and shearing of brain tissue. As a general rule, a concussion presents with an altered mental status that progressively improves. If the mental status does not improve, if it improves and then worsens, or if it deteriorates from when you arrived on the scene, suspect a type of head injury other than concussion. Concussion patients may lose consciousness immediately following the impact to the head but not minutes or hours after. A loss of consciousness that occurs several minutes or hours after the impact results from some type of injury other than concussion.

Depending on where the force is absorbed by the brain, the signs of simple concussion might include the following:

- Momentary confusion
- Confusion that lasts for several minutes
- Inability to recall the incident and, sometimes, the period just before it (retrograde amnesia) and after it (anterograde amnesia)
- Repeated questioning about what happened
- Mild to moderate irritability or resistance to treatment
- Combativeness
- Inability to answer questions or obey commands appropriately
- Nausea and vomiting
- Restlessness

Remember that the key distinguishing characteristic of concussion is that its effects appear immediately or soon after impact, and then they gradually disappear.
An injury that causes symptoms that develop several minutes after an incident or symptoms that do not subside over time is not a concussion, but a more serious injury.

**Contusion**

A contusion, or bruising and swelling of the brain tissue, can accompany concussion. A contusion causes bleeding into the surrounding tissues and may or may not cause increased intracranial pressure, even in cases of open head injury. Contusion is usually caused by coup/contrecoup or acceleration/deceleration injury.

In coup/contrecoup injury, there can be damage at the point of a blow to the head and/or damage on the side opposite the blow as the brain is propelled against the opposite side of the skull. In acceleration/deceleration injury, typical of a car crash, the head comes to a sudden stop but the brain continues to move back and forth inside the skull, resulting in bruising (possibly very severe) to the brain.

Signs and symptoms of contusion include the initial signs and symptoms of concussion and may include one or more of the following:

- Decreasing mental status or unresponsiveness
- Paralysis
- Unequal pupils
- Vomiting
- Alteration of vital signs
- Profound personality changes

Contusion can lead to swelling of the brain tissue, which can result in permanent disability or death. You may improve the patient’s chances for recovery by aggressive airway management, ensuring adequate ventilation and oxygenation to prevent hypoxia, and reversing and preventing hypotension.

**Subdural Hematoma**

Subdural hematoma is a collection of blood between the dura mater and the arachnoid layer of the brain (Figure 31-5a). It typically is due to low-pressure venous bleeding from small bridging veins that are torn during the impact to the head. Bleeding occurs above the brain. Subdural hematomas are commonly associated with cerebral contusion. Cerebral injury may be caused by pressure that is applied to the brain tissue from the formation of the hematoma and increased intracranial pressure.

There are two types of subdural hematoma:

- **Acute.** Signs and symptoms begin almost immediately after the injury
- **Occult or chronic.** Bleeding continues over time and the signs and symptoms don't become apparent for days to weeks after the injury

Subdural hematoma is the most common type of severe head injury. Approximately 33 percent of patients with severe head injury suffer from a subdural hematoma. Subdural hematoma is more common in patients older than 60 years. The older the patient gets, the more fragile the bridging veins become, making injury more likely when an impact occurs to the head.

Anytime a patient has suffered an impact to the head, you should suspect a subdural hematoma. Patients with a subdural hematoma typically will lose consciousness, but they may not. However, the level of consciousness will progressively deteriorate. An occult (hidden, or not obvious) subdural hematoma may be difficult to identify, since many patients do not remember any impact or injury to the head. These patients, who tend to be older, frequently complain of headache, personality changes, confusion, weakness, paralysis, or other signs of increasing intracranial pressure.

Any patient with an abnormally long blood-clotting time, which prolongs the period of bleeding, is particularly susceptible to subdural hematoma. For example, hemophiliacs are prone to a subdural hematoma, even with minimal impact to the head. Alcoholics have prolonged clotting times and are also more subject to falling and striking their heads. Patients who are taking anticoagulant drugs such as Coumadin or Pradaxa are also prone to subdural hematoma with minimal trauma to the head.

Signs and symptoms of subdural hematoma include the following:

- Weakness or paralysis to one side of the body
- Deterioration in level of responsiveness
- Vomiting
- Dilation of one pupil
- Abnormal respirations or apnea
- Possible increasing systolic blood pressure
- Decreasing pulse rate
- Headache
- Seizures
- Confusion
- Personality change (chronic subdural hematoma)

**Epidural Hematoma**

Epidural hematoma accounts for only about 2 percent of all head injuries that require hospitalization. However,
it is an extreme emergency. It most commonly occurs from low-velocity impact to the head or from deceleration injury. It is almost always associated with a skull fracture, especially in the temporal region because of the location of the meningeal arteries.

In an epidural hematoma, arterial or venous bleeding pools between the skull and the dura (protective covering of the brain) (Figure 31-5b). Bleeding is usually rapid, profuse, and severe. The bleeding expands rapidly in a small space, causing a dramatic rise in intracranial pressure. Approximately 66 percent of the bleeding is arterial.

Signs and symptoms of epidural hematoma include the following:

- Loss of responsiveness followed by return of responsiveness (lucid interval) and then rapidly deteriorating responsiveness (a presentation that occurs in only 20 percent of cases)
- Decreasing mental status (a more common presentation than the classic lucid interval)
- Severe headache
- Fixed and dilated pupil
- Seizures
- Increasing systolic blood pressure and decreasing heart rate
- Vomiting
- Apnea or abnormal breathing pattern
- Systolic hypertension and bradycardia (Cushing reflex)
- Posturing (withdrawal or flexion)

Late signs can include fixed and dilated pupils, absent reflexes, and decreasing vital signs. Immediate surgical repair is needed in cases of epidural hematoma. If it is treated early, the prognosis is generally good, since underlying brain damage is usually minimal.

**Laceration**

Like a contusion, a laceration of brain tissue can occur in either an open or a closed head injury. Often it occurs when an object penetrates the skull and lacerates the brain. It is a permanent injury, almost always results in bleeding, and can cause massive disruption of the nervous system.

Remember that with isolated head trauma, a patient's blood pressure may go up and the pulse rate down (a late finding). If your patient has a subdural or epidural hematoma or laceration, but his blood pressure is dropping, you must consider that he is bleeding somewhere else in the body. If this is the case, treat the underlying shock resulting from blood loss, attempt to maintain the systolic blood pressure above 90 mmHg, and maintain oxygenation at an SpO2 reading of 94% or greater. When providing emergency care to the patient with a traumatic brain injury, it is imperative to understand that the brain injury may be worsened by any one of the following:

- Hypoxia
- Hypercarbia (high level of carbon dioxide)
- Hypoglycemia (blood glucose level <60 mg/dL)
- Hyperglycemia
- Hyperthermia
- Hypotension (systolic blood pressure <90 mmHg)

Emergency care of a traumatic brain injury patient, regardless of the cause or type, should focus on establishing and maintaining:

- A patent airway
- Adequate ventilation
- Adequate oxygenation (SpO2 of 94% or greater)
- A systolic blood pressure greater than 90 mmHg
- A normal body core temperature
- A normal blood glucose level

Seizure activity in the traumatic brain injury patient could lead to worsening of the injury, increased hypoxia and hypercarbia levels, increased hypoglycemia, and an increase in the core body temperature. Seizures must be stopped as quickly as possible. If the patient seizes, consider contacting an ALS unit.

### Brain Herniation

The brain is enclosed in a rigid container: the skull. In addition to the brain, cerebrospinal fluid and blood occupy the limited space. There is very little room for any other mass to collect. If a hematoma or cerebral swelling develops within the cranium, the added mass will cause some other substance or structure to be pushed out. Initially, blood and cerebrospinal fluid are squeezed out of the brain. If the swelling or hematoma continues to develop, pressure inside the skull (called the intracranial pressure, or ICP) rises. With a rise in ICP, the brain is eventually compressed and pushed out of its normal position, downward toward and through the foramen magnum, which is the large opening in the base of the skull or other openings in the tentorium. This process is referred to as herniation.

Compression of the brain will cause it to dysfunction. Pushing the brain downward and out of the foramen magnum or through the tentorium compresses the brainstem, destroying vital functions including the heartbeat, respirations, and blood pressure. Thus, herniation is an extremely serious and potentially deadly condition.
Signs and symptoms specific to brain herniation are:

- Dilated or sluggish pupil on one side
- Weakness or paralysis
- Severe alteration in consciousness
- Abnormal posturing (decorticate, also called flexion; decerebrate, also called extension)—also known as nonpurposeful movement or posturing
- Abnormal ventilation pattern
- Cushing reflex (increased systolic blood pressure and decreased heart rate)

If signs of herniation are evident, controlled hyperventilation of the patient may be considered. A negative effect of hyperventilation is that it has been shown to reduce the blood flow in the brain (cerebral blood flow); thus, it is controversial and may not be included in your protocol. Hyperventilation should not be performed if the patient is hypotensive. Hyperventilation will be discussed in greater detail later in the chapter.

Assessment-Based Approach: Head Injury

You have studied many of the elements of assessment that apply to head injury—for example, the AVPU method of assessing mental status—in earlier chapters. We review and develop these assessment elements on the following pages with particular emphasis on how they apply to a patient who has, or may be suspected to have, a head injury (Figure 31-6).
Nontraumatic injuries to the brain can be caused by clots or hemorrhaging. Such injuries can cause altered mental status and present signs and symptoms similar to those in trauma cases. (See Chapter 18, "Altered Mental Status, Stroke, and Headache.")

### Scene Size-up

Because head injuries can be so serious, always be alert for signs of them during the scene size-up. Unresponsiveness or altered mental status, especially in trauma patients, should always suggest the possibility of head injury. Never assume that mental status changes in a trauma patient are due to drug or alcohol intoxication. Other signs of head injury can be more obvious. These might include bleeding from the scalp or face or an apparent mechanism of injury, such as a fractured windshield at the scene of an automobile crash, a deformed helmet at a bicycling crash, or evidence of a fall (Figures 31-7a and 31-7b ■).

Nontraumatic injuries to the brain can be caused by clots or hemorrhaging. Such injuries can cause altered mental status and present signs and symptoms similar to those in trauma cases. (See Chapter 18, "Altered Mental Status, Stroke, and Headache.")

### Primary Assessment

When performing the primary assessment, be alert for cervical spine injury. Forces applied to the head may have been strong enough to injure the cervical spine as well. Manual in-line stabilization of the spine should be your first step (Figure 31-8 ■).
nonpurposeful pain response, indicating a lower-level brainstem injury.

The lowest level on the AVPU scale is “unresponsive.” A patient at this level exhibits no response at all to verbal or painful stimuli. This is an ominous sign in head injury.

Record your observations of mental status accurately, noting the types of stimuli administered and the patient’s responses. You must determine a baseline for level of responsiveness and check repeatedly for signs of deterioration. For example, a patient who first responds to the loud calling of his name, but later only responds to a shoulder pinch with decorticate posturing, has a deteriorating level of responsiveness. Such deterioration of level of responsiveness in cases of head injury can be a sign of a serious problem.

A useful and more discriminating tool for determining a patient’s level of responsiveness is the Glasgow Coma Scale (Tables 31-1 and 31-2). The scale is a measure of the patient’s eye opening, verbal response, and motor response to different stimuli. In the prehospital setting, the numerical values on the scale are not as important as the types of response to specific stimuli.

Secondary Assessment

When dealing with trauma patients who have head injuries, or suspected head injuries, you will perform a physical exam. A patient with a head injury may not

If the patient is unresponsive or has an altered mental status, establish an airway using a jaw-thrust maneuver while holding in-line spinal stabilization. Keep in mind that head injuries often involve injury to or blockage of the airway (Figure 31-9). Maintain the patient’s airway and provide supplemental oxygen to maintain an SpO₂ of 95% or greater if the breathing is adequate, or positive pressure ventilation with supplemental oxygen if breathing is inadequate. Maintaining an adequate airway and oxygenation are vital, because head injuries can become worse if there is an inadequate supply of oxygen to the brain. Oxygen should be titrated so that the SpO₂ is maintained about 95%. If no pulse oximeter is available, apply a nonrebreather mask at 15 lpm.

Mental Status. A decreasing mental status is the most important sign in cases of suspected head injury. The mental status is initially assessed using the AVPU mnemonic. Keep in mind that the patient’s mental status may change. For example, the patient may be alert but deteriorate slowly, or he may respond to verbal stimuli and deteriorate to responding to painful stimuli only.

A patient who responds to pain may do so in two ways. The patient may try to move away from or remove the pain. This is a purposeful response. Or the patient may respond by inappropriately moving parts of his body, reacting to the pain but not trying to stop it. This is a nonpurposeful response.

A nonpurposeful response to pain indicates a deeper state of unresponsiveness. Patients who respond nonpurposefully will usually do one of two things. They will posture by flexing their arms across their chest and extending their legs (flexion posturing or decorticate posturing), which indicates an upper-level brainstem injury, or they will extend both arms down at their sides, extend their legs, and sometimes arch their backs (extension posturing or decerebrate posturing). Decerebrate posturing represents the lowest level of
complain of pain or other symptoms of trauma. Therefore, it is extremely important to perform a complete physical exam in the patient with a head injury in an attempt to identify signs of trauma and injury to other areas of the body. When performing the assessment, keep in mind that the patient may not respond even if the area is injured. As an example, the head-injured patient with an abdominal injury may not experience or respond to the pain when you palpate the abdomen. This may allow you to miss potentially serious injuries.

Following the physical exam, you will check vital signs and obtain a history. Be aware, however, that patients with a head injury may become disoriented or unresponsive. If a patient is alert and oriented, you or your partner might wish to gather the history while the other performs the physical exam.

Remember that any patient who loses consciousness, even briefly, must be evaluated at the hospital. A patient whose mental status worsens at any stage of the assessment or treatment process needs immediate transport, preferably to the highest-level trauma center, and continuous monitoring during transport.

Physical Exam. Perform a physical exam, paying particular attention to the following parts of the exam in cases of suspected head injury:

- The Head. Use extreme care in checking the patient’s head (Figure 31-10 ■). Palpate for deformities, depressions, lacerations, or impaled objects around the head and face (Figure 31-11 ■). Be careful not to jab or apply pressure to skull depressions or deformities.

- The Eyes.
  1. Check the patient’s pupils with a bright light (Figure 31-12 ■). Are they equal in size? Do they react equally? Both pupils should react the same when a light is shined in only one of the pupils. This reflex in the unstimulated eye is known as a consensual reflex. If one or both pupils are fixed and dilated, this may signal an increase in pressure in the brain.
2. Check eye movements. Do the eyes track (follow movement normally)? Is one eye positioned downward and outward?

3. Is there any discoloration? A purplish discoloration (bruising) of the soft tissues around one or both eyes—**raccoon sign**—may be an indication of intracranial injury. It is a delayed sign of skull fracture that usually does not appear for up to 4–6 hours after the injury.

**PATHOPHYSIOLOGY PEARLS**

A fixed and dilated pupil in a patient with a brain injury is usually the result of compression of the third cranial nerve in the lower area of the brain and indicates severe compression of brain tissue.

**ASSESSMENT TIPS**

In a brain injury, the affected pupil is usually on the same side as the injury.

---

**The Ears and Nose.**

1. Check both ears for leakage of blood or clear fluid; skull fracture or intracranial bleeding can cause both (Figure 31-13).

2. **Battle sign,** a purplish discoloration (bruising) of the mastoid area behind the ear, is another delayed and very late sign of a basilar skull fracture.

3. Check the nose for leakage of blood or clear fluid, which can indicate skull fracture or intracranial injury.

**ASSESSMENT TIPS**

To distinguish a clear fluid leaking from the ears or nose from tears or nasal secretions, check the fluid for glucose. Cerebrospinal fluid contains glucose; tears and nasal secretions do not. The glucose reading in cerebrospinal fluid will be about half of the blood glucose reading. Note, however, that ANY discharge from the ears or nose must be taken seriously.
**Motor/Sensory Assessment.** To examine motor and sensory function, if the patient is alert, check his ability to move his fingers and toes. Have him squeeze your fingers with both hands simultaneously to test for equal grip strength. Ask the patient to tell which finger or toe you are touching without watching what you are doing. Pinch each extremity and ask if he can identify the pain. Ask if the patient feels any weakness on one side of the body compared to the other (Figure 31-14).

If the patient is only responsive to verbal or painful stimuli, motor and sensory function cannot be assessed accurately, but watch for a response such as a grimace or withdrawal from a painful stimulus.

**Vital Signs.** Check and record vital signs every 5 minutes, staying alert to any changes. In cases of possible head injury, be alert to the following:

- **Blood Pressure.** If the systolic blood pressure is high or rising, suspect pressure inside the skull; if it is low or dropping, suspect blood loss that has led to shock. Low blood pressure very early in a patient with a head injury almost always is due to bleeding elsewhere in the body (there is not enough space in the brain to permit enough bleeding to reduce blood pressure). It should be a signal to check the rest of the body for bleeding. However, a low blood pressure may also be an ominous sign that the head injury is so severe that the brain can no longer maintain an adequate blood pressure because of brainstem failure. Hypotension needs prompt attention, as it worsens the brain injury.

- **Pulse.** If the pulse is fast or increasing, suspect hemorrhage elsewhere in the body or early onset of hypoxia. If it is slow or decreasing, suspect pressure inside the skull or severe hypoxia.

- **Respiration.** Assess the rate, depth, and pattern of respiration. The patient may display several different respiratory patterns if the brain is compressed from increased intracranial pressure resulting from swelling and/or bleeding inside the skull. The respirations may be extremely fast and shallow, completely irregular, or absent (apnea).

If definite signs of brain herniation exist (unequal pupils, posturing, fixed pupil, Cushing reflex, hemiplegia or hemiparesis, decrease in the Glasgow Coma Scale of two points or more), and if you have not already done so, begin positive pressure ventilation and consider controlled hyperventilation at a rate of 20 ventilations per minute with supplemental oxygen. (Hyperventilation at a rate >20 for a prolonged period may reduce cerebral blood flow and worsen the head injury.) A sign of severe head injury, increasing intracranial pressure, and possible herniation is the **Cushing reflex**, in which the systolic blood pressure increases and the heart rate decreases. The respiratory pattern may also change and become irregular.

**PATHOPHYSIOLOGY PEARLS**

In the Cushing reflex, the systolic blood pressure increases from an attempt to force blood flow into the brain to maintain perfusion of brain cells that are being compressed from the injury.

**ASSESSMENT TIPS**

There is very little room for bleeding into the brain. So in the patient with trauma to the head, if the blood pressure is decreasing, the pulse pressure is narrow, the heart rate is elevated, and the respiratory rate is increased (signs of hemorrhage), suspect shock, but look for evidence of bleeding in an area of the body other than the brain.

If positive pressure ventilation is needed but significant signs and symptoms of severe brain injury and herniation are not present, ventilate at a rate of 10–12/minute.

**History.** The history can provide vital information about the mechanism of injury. A patient with a head injury may experience a deteriorating mental status. If he is unable to answer questions appropriately, try to obtain information from others at the scene. The following questions are particularly relevant in cases of head injury:

- When did the incident occur?
- What is the patient's chief complaint? Did he feel pain, tingling, numbness, or paralysis? Where? How have symptoms changed since the accident?
- How did the accident occur?
- Did he lose consciousness at any time? This information is critically important in assessing a brain injury. How long was the period of unresponsiveness? When did it occur in relation to the injury? Did the patient suddenly lose consciousness and then gradually reawaken, or did he pass out immediately, suddenly wake up, then gradually lose consciousness again?
- Was the patient moved after the incident?
- Is there any history of a previous injury to the head? If so, when did it occur? Was the patient knocked unconscious? Sometimes an injury to the head days or weeks after an incident in which a patient was knocked unconscious can reinjure the brain.
Signs and Symptoms. Signs and symptoms of head injury include the following:

- Altered mental status—disorientation to unresponsiveness that doesn’t improve or that continues to deteriorate
- Decreasing mental status
- Irregular breathing pattern (severe)
- Increasing blood pressure and decreasing pulse (Cushing reflex, a late finding) (severe)
- Obvious signs of injury—contusions, lacerations, or hematomas to the scalp or deformity to the skull
- Visible damage to the skull (visible through laceration in the scalp)
- Pain, tenderness, or swelling at the site of injury
- Blood or cerebrospinal fluid from ears or nose
- Discoloration (bruising) around the eyes in the absence of trauma to the eyes (raccoon sign—very late)
- Discoloration (bruising) behind the ears, the mastoid process (Battle sign—very late)
- Absent motor or sensory function (severe or poor response)
- Nausea and/or vomiting; vomiting may be forceful or repeated
- Unequal pupil size with altered mental status (severe) (Figure 31-15 ■)
- Diplopia—double vision
- Possible seizures
- Nonpurposeful response to painful stimuli (severe) (Figure 31-16 ■)
- Retrograde amnesia—the patient is unable to remember circumstances leading up to the incident
- Anterograde amnesia—the patient is unable to remember circumstances after the incident

Emergency Medical Care

To treat a patient with a head injury:

1. Take Standard Precautions.
2. Establish manual in-line spinal stabilization.
   - Maintain neutral positioning of the head and neck manually, even after a cervical collar is applied, until the patient is completely immobilized to a backboard (Figure 31-17 ■).
3. Maintain a patent airway, adequate breathing, and oxygenation. Oxygen deficiency in the brain is the most frequent cause of death following head injury.
   - Use a jaw-thrust maneuver to open the airway.
   - Remove any foreign bodies from the mouth, and suction blood and mucus.
   - Protect against aspiration by having suction available at all times and by being prepared to roll the secured patient to clear the airway.
   - Administer oxygen to maintain an $\text{SpO}_2$ of 94% or greater if breathing is adequate, or positive pressure ventilation with supplemental oxygen at 10–12/minute if breathing is inadequate.
• Consider controlled hyperventilation at a rate of 20 breaths per minute if signs of severe head injury and brain herniation are present—such as unequal pupils, severely depressed mental status, increased systolic blood pressure, irregular or absent breathing (or Cushing reflex: increased systolic blood pressure with decreased heart rate and changed breathing pattern), absent motor or sensory function on one side of the body, weakness on one side of the body, seizures, abnormal posturing (nonpurposeful movement), or a decrease in the Glasgow Coma Scale of two points or more.

4. Monitor the airway, breathing, pulse, and mental status for deterioration. Any patient who deteriorates must be transported immediately.

5. Control bleeding. Face and scalp wounds may bleed heavily, but such bleeding is usually controlled easily.
   • Do not apply pressure to an open or depressed skull injury; doing so can drive pieces of fragmented bone into the brain tissue.
   • Dress and bandage open head wounds as indicated in the treatment of soft tissue injuries.

• Do not attempt to stop the flow of blood or cerebrospinal fluid flowing from the ears or nose. Instead, cover loosely with a completely sterile gauze dressing to absorb, but not stop, the flow.

• For other wounds, use gentle, continuous direct pressure with sterile gauze only as needed to control bleeding.

• Never try to remove a penetrating object. Instead, immobilize it in place and dress the wound.

6. Be prepared to provide emergency care for seizures.

7. Transport immediately.

**Reassessment**

Provide a reassessment during transport, paying close attention to the airway and mental status of the patient. Repeat the reassessment every 5 minutes.

**Summary: Assessment and Care**

To review possible assessment findings and emergency care for injuries to the head, see Figures 31-18 and 31-19.

---

**HEAD INJURY**

The following are findings that may be associated with a head injury.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Ejection from a vehicle
- High-speed collision
- Sports injury
- Fall
- Crushing force
- Gunshot wounds

Evidence of other trauma:
- Impact mark on windshield
- Deformed helmet
- Obvious scalp and skull injuries

**Primary Assessment**

**General Impression**
- Altered mental status
- Open fracture sites to skull
- Obvious deformity to skull

**Mental Status**
- Alert to unresponsive based on type and degree of head injury
- Unresponsiveness or decreasing mental status associated with trauma to the head (a hallmark sign of head injury)
- Decorticate or decerebrate (nonpurposefull) posturing to painful stimuli
- Garbled or slurred speech

**Airway**
- Assume airway is closed if patient has an altered mental status
- May be occluded by bleeding associated with facial fractures
- Be prepared to manage vomiting

**Breathing**
- May be absent, inadequate, or normal
- Abnormal breathing patterns may occur

**Circulation**
- Pulse may be normal or decreased
- Skin is normal

**Status:** Priority patient if patient never regains consciousness or has a decreasing mental status

---

Secondary Assessment

Physical Exam

Head:
- Open or closed wounds to the head or face
- Leakage of blood or cerebrospinal fluid from ears, nose, or mouth
- Discoloration around eyes (raccoon sign) or behind ears (Battle sign) (late signs)
- Unequal pupils or fixed and dilated pupil

Extremities:
- No response to pain or light touch
- Inability to move extremities

Blood glucose level:
- Normal

Baseline Vital Signs
- BP: normal, may have a significantly increased systolic BP (Cushing reflex)
- HR: normal or bradycardia (Cushing reflex); tachycardia may be associated with shock associated with bleeding from other injuries
- RR: normal, irregular, decreased, or absent (Cushing reflex)

Skin: normal or may be pale, cool, and clammy if other injuries are present with bleeding and shock

Pupils: may be equal or unequal, reactive or unreactive; may be fixed and dilated

SpO₂: normal—may be <95% if respirations are abnormal or decreased

History

Signs and symptoms of an open or closed skull fracture:
- Pain, deformity, swelling
- Open wound associated with suspected fracture site
- Exposed bone ends
- Facial trauma
- Penetrating injuries or impaled objects in the head
- Cushing reflex (triad): increased systolic blood pressure, decreased heart rate, abnormal respiratory pattern
- Nausea and vomiting
- Abnormal motor/sensory response
- Patient loses responsiveness after impact to the head
- Loss of responsiveness, followed by a lucid interval, then a gradual loss of responsiveness

Emergency Care Protocol

HEAD INJURY

2. Establish and maintain an open airway. Insert an oropharyngeal airway if patient is unresponsive and has no gag or cough reflex. (A nasopharyngeal airway is not recommended, especially if there is cerebrospinal fluid leakage from the nose or injury to the face.)
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 20 ventilations/minute for an infant or child. Consider controlled hyperventilation at 20 ventilations/minute if signs of brain herniation are present and the patient is not hypotensive. Follow local protocol.
5. If breathing is adequate, administer oxygen to maintain an SpO₂ of 95% or greater.
6. Control any major bleeding. Be careful not to apply excessive pressure to open or depressed skull fractures.
7. Immobilize patient to backboard.
8. Transport.
9. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable. Be prepared for vomiting and seizures.
Emergency Care Algorithm  

**HEAD INJURY**

Manual in-line stabilization

Any major bleeding?

- **Yes**
  - Control bleeding
  - Assess mental status
  - Alert and able to obey commands
    - Consider oxygen administration
    - Assess circulation
    - Secondary assessment
    - Airway open?
      - **Yes**
        - Suction if necessary
        - Jaw-thrust maneuver
        - Oropharyngeal airway
      - **No**
        - Consider hyperventilation at 20 ventilations/min if signs of herniation*
        - Assess breathing
          - **Adequate**
            - Administer oxygen
          - **Inadequate**
            - PPV with \( \text{O}_2 \)

- **No**
  - Assess mental status
    - Altered
      - Airway open?
        - **Yes**
          - Suction if necessary
          - Jaw-thrust maneuver
          - Oropharyngeal airway
        - **No**
          - Consider hyperventilation at 20 ventilations/min if signs of herniation*
          - Assess breathing
            - **Adequate**
              - Administer oxygen
            - **Inadequate**
              - PPV with \( \text{O}_2 \)

*Signs of herniation:
  - Abnormal posturing
  - Fixed pupil with altered mental status
  - Dilated pupil with altered mental status

PPV = positive pressure ventilation  
Cream = assessment  
Green = key decision points  
Blue = interventions

**FIGURE 31-19** Emergency care algorithm: head injury.
SUMMARY

A head injury is a devastating injury that could lead to death or permanent disability. The rigid skull encapsulates the brain and provides significant protection. The same protective rigid skull does not provide any flexibility, and this can lead to severe increases in pressure within the skull, leading to compression and death of brain cells.

Head injuries are classified as scalp injuries, skull injuries, and brain injuries. The hallmark sign of a brain injury is an altered mental status that does not improve or that deteriorates. Emergency care focuses on protecting the spine and on establishing and maintaining an airway, effective ventilation, adequate oxygenation, and circulation to prevent or limit secondary brain injury.

Case Study Follow-up

Scene Size-up
You have been dispatched to an 18-year-old unresponsive male, Mike Ryan. As you arrive, his mother reports that he experienced a bump on the head that seemed minor. As you enter the young man’s room, you find him supine on his bed. His breathing is deep and fast with snoring respirations.

Primary Assessment
You immediately establish in-line spinal stabilization and open Mike’s airway using a jaw-thrust maneuver. The snoring sounds disappear, but he continues to breathe rapidly and deeply. While holding his airway open, your partner pinches his shoulder muscle and holds it. His arms flex across his chest, he arches his back, and his legs stiffen. Your partner inserts an oral airway. It is accepted without any gag reflex. You then provide positive pressure ventilation with supplemental oxygen at 20 breaths per minute because you suspect severe head injury with evidence of flexion posturing.

Secondary Assessment
Your partner performs a physical exam and takes vital signs. Mike’s left pupil is dilated and nonreactive to light. Vital signs are BP 190/72 mmHg, pulse is 62 bpm, and respirations are assisted at 20 per minute because you suspect severe head injury. SpO₂ is 99% after positive pressure ventilation has been initiated.

You obtain a history from the family. It reveals that Mike was knocked unconscious for about 3 minutes 2 weeks ago after a rollerblading accident. He said he was fine and never sought medical care. This morning he was playing basketball and, according to his brother Sean, was hit in the head with an elbow. After that, the two brothers walked home. Sean states he noticed that Mike was walking oddly and complained of being tired. Once home, Mike went up to his room to lie down.

When the exam and history findings are recorded, you and your partner prepare the patient for transport. You apply a cervical collar and move him onto a backboard. When immobilization is complete, Mike is taken to the ambulance.

Reassessment
En route to the hospital, you monitor Mike’s airway, breathing, circulation, and level of responsiveness. You continue with controlled hyperventilation.

During transport, you note no change in Mike’s condition. At the emergency department, he is transferred to the staff. You and your partner complete a prehospital care report and prepare the ambulance for another call.

A couple of months later, as you are passing the high school on the way to another call, you are happy to spot Mike and Sean walking toward the school. Mike seems to be fine.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.
IN REVIEW

1. Name the two parts of the central nervous system.
2. Define the meninges and name the three layers of the meninges.
3. Name the three anatomical components of the brain.
4. Describe an open and a closed head injury.
5. Name other types of injury that may be present and related to a head injury.
6. Name some of the major types of brain injury.
7. Explain why determining a baseline level of responsiveness is important in cases of head injury.
8. Explain why a history is important in cases of head injury.
9. List the signs and symptoms of head injury.
10. Outline the steps of emergency medical treatment in cases of head injury.
11. List signs of brain herniation.

CRITICAL THINKING

You arrive on the scene and find a 33-year-old male patient who startled an intruder when arriving home. The intruder stabbed the patient in the head with a screwdriver. The screwdriver is impaled in the skull. The police are on the scene. The patient responds to painful stimulus by flexing his arms, arching his back, and contracting his legs. He has blood in his mouth, and you hear gurgling sounds. His respirations are irregular at a rate of approximately 22 per minute with minimal chest rise and fall. Your partner indicates the radial pulse is strong and the HR is 42 bpm.

1. What immediate emergency care would you provide for the patient?
2. What do the vital signs indicate?
3. Would you hyperventilate the patient or not? Based on what criteria would you make the decision?
4. How would you manage the impaled screwdriver?
Spinal Column and Spinal Cord Trauma

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • Trauma (Content Area: Head, Facial, Neck, and Spine Trauma)

COMPETENCY • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

OBJECTIVES • After reading this chapter, you should be able to:

32-1. Define key terms introduced in this chapter.
32-2. Describe the structure and function of the spinal column, spinal cord, and tracts within the spinal column.
32-3. Recognize common mechanisms of spinal injury and describe the incidence of neurological deficits in patients with spinal column trauma.
32-4. Give examples of forces that would produce each of the following mechanisms of spinal injury:
   a. Compression
   b. Flexion
   c. Extension
   d. Rotation
   e. Lateral bending
   f. Distraction
   g. Penetration
32-5. Differentiate spinal column injury and spinal cord injury.
32-6. Describe the concept of complete spinal cord injury and differentiate between the concepts of spinal shock and neurogenic hypotension.
32-7. Describe the concept of incomplete spinal cord injury and syndromes that may result from incomplete spinal cord injury.
32-8. Use scene size-up, patient assessment, and patient history to develop an index of suspicion for spinal injuries.
32-9. Given a series of scenarios, demonstrate the assessment-based management of patients suspected of having an injury to the spine.
32-10. Demonstrate the assessment of pulse, motor function, and sensory function in the extremities of a patient who is suspected of having an injury to the spine.
32-11. Recognize signs and symptoms of injury to the spinal column and spinal cord.
32-12. Explain how complications of spinal injury may result in inadequate breathing, paralysis, and inadequate circulation.
32-14. Describe correct immobilization techniques for the following:
   a. Supine or prone patient
   b. Standing patient
   c. Seated patient
32-15. Describe the indications for rapid extrication and the correct procedures for rapid extrication.
32-16. Explain special handling and immobilization considerations when spinal injury is suspected for the following:
   a. Helmet removal
   b. Football injuries, including removal of face mask and immobilization
   c. Infants and children, including extrication from a car seat

KEY TERMS • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Spine injuries are among the most formidable and traumatic you will manage as an EMT. Yet you may face the probability of such injuries on almost a daily basis. Automobile crashes, shallow-water diving accidents, motorcycle crashes, and falls are common causes of spine injury. Likewise, accidents during skiing, sledding, football, and gymnastics can result in spine injury. It is your job as an EMT to recognize injuries that could damage the spinal column or spinal cord and provide appropriate emergency care. You must be aware that improper movement and handling of patients in such situations can lead to permanent disability or even death.

ANATOMY AND PHYSIOLOGY OF SPINE INJURY

To appreciate the potential severity of spine injuries, you should begin by understanding the relationship between the nervous system and the parts of the skeletal system most closely related to it, the skull and the spinal column, also referred to as the vertebral column. Before continuing, you may want to review the information about the skeletal and nervous systems that was presented in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” Chapter 30, “Musculoskeletal Trauma and Nontraumatic Fractures,” and Chapter 31, “Head Trauma.”

The Nervous System

Injuries to the spine have the potential for severity because within the spinal column is the spinal cord. This structure carries nerve impulses from most of the body to the brain and back to the body. A single spinal cord injury can affect several organs and body functions.

Parts of the Nervous System

The nervous system has two major functions: communication and control. It enables the individual to be aware of and react to his environment. It also coordinates the responses of the body to changes in the environment and keeps body systems working together.

The nervous system consists of nerve centers and nerves that branch off from the centers and lead to tissues and organs. Most nerve centers are in the brain and spinal cord.

The structural divisions of the nervous system (Figure 32-1) are:

- The central nervous system (CNS), which consists of the brain and the spinal cord.
- The peripheral nervous system, which consists of nerves located outside of the brain and spinal cord.

The functional divisions of the nervous system are:

- The voluntary nervous system, which influences the activity of voluntary (skeletal) muscles and movements throughout the body.
- The autonomic nervous system, which is automatic and influences the activities of involuntary muscles and glands; the autonomic system is partly independent of the rest of the nervous system. The sympathetic nervous system and parasympathetic nervous system are included in the autonomic nervous system.

The Skeletal System

The skeletal system gives the body its framework, supports and protects vital organs, and permits motion. The bony framework of the body is held together by ligaments—tough, fibrous connective tissue. The
Flexible column, the vertebrae are bound firmly together by strong ligaments. Between each two vertebrae is a fluid-filled pad of tough elastic cartilage called a disk that acts as a shock absorber. The spinal column, which surrounds and protects the spinal cord, is divided into five parts (Figure 32-2):

- The **cervical spine**—The first seven vertebrae that form the neck. The cervical vertebrae are the most mobile and delicate; injury to the cervical spine is the most common cause of spinal cord injury.
- The **thoracic spine**—The 12 vertebrae directly below the cervical vertebrae that compose the upper back.
- The **lumbar spine**—The next five vertebrae that form the lower back.
- The **sacral spine** (sacrum)—The next five vertebrae that are fused together and form the rigid posterior portion of the pelvis.
- The **coccyx** (tailbone)—The four fused vertebrae that form the lower end of the spine.

The **spinal cord**, composed of nervous tissue, exits the brain through an opening at the base of the skull. The cord is surrounded by a sheath of protective
membranes (meninges) and a cushioning layer of cerebrospinal fluid. The cord narrows as it goes, filling 95 percent of the spinal column “canal” in the cervical vertebrae (neck) but only 60 percent in the lumbar area (lower back). All nerves to the trunk and extremities originate from the spinal cord. The spinal cord carries messages from the brain to the various parts of the body through nerve bundles.

There are three main types of tracts within the spinal cord that are tested in the assessment to determine if spinal cord injuries exist. The motor tracts carry impulses down the spinal cord and out to muscles. As their name implies, motor tracts are tested by having the patient move. The motor tracts on the right side of the spinal cord carry the impulses that allow the patient to move on the right side of the body; the motor tracts on the left side allow movement on the left side of the body.

The pain tracts carry impulses from pain receptors up the spinal cord to the brain. The pain tracts are tested by applying pain to the patient. Upon entering the spinal cord, a pain tract crosses over and carries the impulse up the opposite side of the cord. Thus, pain applied to the right side of the body is actually carried up the left side of the spinal cord. To test the right pain tract in the spinal cord, you must apply pain to the left side of the body; to test the left pain tract, apply pain to the right side of the body.

The last set of tracts carry light touch impulses from sensory receptors up the spinal cord to the brain. The light touch tracts are tested by applying light touch to the patient. The light touch sensation is carried up the same side of the spinal cord as the side where the touch is applied. If you apply light touch to the right side of the body, the light touch is carried up the right side of the spinal cord; light touch applied to the left side of the body is carried up the left side of the cord.

Since light touch and pain are carried by different tracts, it is possible for the patient to be unable to feel light touch but able to feel the pain of a pinch. This finding may be present if the spinal cord is partially but not completely injured.

Studying the spinal cord tracts to understand where they are located and what impulses are carried by them will help you better understand assessment findings associated with incomplete spinal cord injuries, which will be discussed later in the chapter. Also, knowing that various tracts within the spinal cord carry different impulses will reinforce and help you better understand the steps in the neurological assessment.

### Pathophysiology Pearls

Motor and light touch tracts carry the impulse on the same side of the spinal cord as the extremity that is being tested, whereas pain is carried up the opposite side of the spinal cord from the extremity the pain is applied to. This may create what appear to be conflicting assessment findings in the incomplete spinal cord injury.

### Assessment Tips

You cannot assume that just because a patient cannot feel light touch he will also not be able to feel pain, since light touch and pain sensations are carried by different spinal tracts.

### Common Mechanisms of Spine Injury

The most common cause of spinal injuries is automobile crashes. These make up close to half (48 percent) of all spinal injuries. The next most common cause is falls (21 percent). Gunshot wounds and recreational activities such as diving and football are the next most frequent causes of spinal injuries. Any patient with a gunshot wound to the neck; the anterior, lateral, or posterior chest; the abdomen; or the pelvis must be assessed for spinal injury.

It is important to note that only 14 to 15 percent of patients who have spinal column fractures or dislocations will have a spinal cord injury that results in neurological deficits (motor or sensory dysfunction). This means that 85 to 86 percent of the patients who actually have a spinal fracture or dislocation will not present with a neurological deficit. When you arrive on the scene and find the patient walking, it does not mean the patient did not suffer a spinal injury. The patient could have suffered a spinal column injury with no spinal cord involvement. Improper management of this patient, however, can convert a spinal column injury into a spinal cord injury. The result, which may be permanent paralysis, is catastrophic. Conversely, it is important to note that a patient can have a spinal cord injury without any spinal (vertebral) column damage. This specific condition is referred to as spinal cord injury without radiologic abnormality or SCIWORA. Do not become complacent in the management of any patient with a significant mechanism of injury for spinal trauma or one who displays any signs or symptoms of spinal column or cord injury.

Elderly patients may suffer fractures much more easily with less force applied to the spine. C1 and C2 dislocations may be more common in elderly patients who suffer from rheumatoid arthritis, and may be more common in Down syndrome patients because of abnormal development of the odontoid (second cervical vertebra).

The spine is quite strong and flexible, but it is particularly susceptible to injury from the following mechanisms (Figure 32-3):  

- **Compression.** When the weight of the body is driven against the head. This is common in falls, diving accidents, motor vehicle crashes, or other accidents where a person impacts an object head first.
- **Flexion.** When there is severe forward movement of the head in which the chin meets the chest, or when the torso is excessively curved forward.

- **Extension.** When there is severe backward movement of the head in which the neck is stretched, or when the torso is severely arched backward.
MECHANISMS OF SPINAL INJURIES

FLEXION INJURY

COMPRESSION INJURY

HYPEREXTENSION INJURY

DISTRACTION INJURY

FLEXION-ROTATION INJURY

PENETRATION INJURY

FIGURE 32-3 Mechanisms of spine injury.
• **Rotation.** When there is lateral movement of the head or spine beyond its normal rotation.

• **Lateral Bending.** When the body or neck is bent severely from the side.

• **Distraction.** When the vertebrae and spinal cord are stretched and pulled apart. This is common in hangings.

• **Penetration.** When there is injury from gunshots, stabblings, or other types of penetrating trauma that involve the cranium or spinal column.

You must suspect spine injury in any case that may involve one or more of these mechanisms, even if the patient appears to be able to move normally. Injured vertebrae that are still aligned, but unstable, can become unstable at any moment and damage or sever the spinal cord. Conduct a thorough assessment to determine if spine injury is suspected and the need for complete spinal immobilization.

### Spinal Column Injury Versus Spinal Cord Injury

A **spinal column injury** is an injury to one or more vertebrae, that is, the portion of the spine composed of bone. Whether it is a fracture or a dislocation, a spinal column injury is a bone injury. One thing we know about fractures and dislocations is that they hurt! If a patient has an injury to the spinal (vertebral) column, which is the bony portion of the spine, it will produce a complaint of pain or tenderness somewhere along the spine. Remember, pain is what the patient complains of, and tenderness is pain elicited on palpation. You must gently palpate the length of the spine, feeling for any gross abnormalities, while also checking for tenderness. If at any point the patient complains of pain or tenderness along the length of the spinal column, it is an indication of potential injury. The patient must receive complete spinal immobilization, which is described later in the chapter.

A **spinal cord injury** involves damage to the nervous tissue that is enclosed inside the hollow center of the bony spinal column: the spinal cord. As discussed previously, the spinal cord contains motor tracts that transmit impulses from the brain that cause muscle movement, and sensory tracts that transmit impulses of light touch, pain, and pressure to the brain. If the spinal cord is injured, a disruption in one or more of the motor or sensory tracts is likely. Thus, the patient with a spinal cord injury would experience a loss of motor or sensory function or both.

Although a patient complaining of pain to the spinal column likely has a vertebral (spinal column) fracture or injury, pain does not indicate a spinal cord injury. Conversely, a loss of motor or sensory function indicates a spinal cord injury; however, it does not imply a vertebral fracture or injury. This is because a spinal column injury can occur without a spinal cord injury, and a spinal cord injury can occur without a spinal column injury. So a patient may experience a loss of motor or sensory function but have no pain. Or the patient may complain of pain but have no loss of motor or sensory function. In either case—pain/tenderness along the spinal column or loss of motor/sensory function—the patient would be considered to have a spinal injury and must be completely immobilized.

### Complete Spinal Cord Injury

A **complete spinal cord injury** results when an area of the spinal cord has been completely transected (cut crossways) either physically or physiologically. The injury, having severed the motor and sensory tracts, prevents any motor impulses from passing down from brain to body or sensory impulses from passing up from body to brain through the injured area of the cord. Therefore, there is a total loss of motor and sensory function below the level of injury. The patient presents with the inability to move or feel sensations of pain, light touch, and crude pressure below the level of injury. The patient will also likely present with a loss of bowel and bladder control because autonomic function is blocked.

When a patient presents with complete loss of motor and sensory function distal to the cord injury, however, it may not always indicate complete spinal cord injury. The patient may, instead, be experiencing spinal shock.

### Spinal Shock

**Spinal shock** is a temporary concussion-like insult to the spinal cord that causes effect below the level of the injury. Such an injury usually occurs high in the cervical region. Below the level of injury there is a loss of muscle tone (flaccid muscles), the patient is unable to feel sensations of light touch or pinch (anesthetic effect), and the patient is unable to move the extremities or any voluntary muscles (paralysis). The patient will typically lose control of the bladder and bowel. A male patient may have an involuntary erection of the penis called **priapism**. The vessels below the site of injury may dilate, leading to a decreased blood pressure (neurogenic hypotension, explained in the next section). Temperature regulation is also disrupted by the loss of vessel tone.

Spinal shock usually resolves within 24 hours after the incident but may last for several days. This patient should be managed as one with a spine injury, even if the dysfunction begins to resolve while you are managing the patient.

### Assessment Tips

A patient in spinal shock may present with complete paralysis that may resolve within 24 hours to several days after the injury.
**Neurogenic Hypotension from Spinal Shock.**

**Neurogenic hypotension** from spinal shock, also called *spinal-vascular shock* or *neurogenic shock*, results from an injury to the spinal cord that interrupts nerve impulses to the arteries. When the arteries lose nervous impulses from the brain and spinal cord, they relax and dilate (enlarge). This vasodilation causes a relative hypovolemia within the circulatory system. That is, there is more space than there is blood to fill the arteries. Because of this, the patient becomes hypotensive (has lowered blood pressure).

With spinal shock, sympathetic nerve impulses to the adrenal glands are lost, which prevents the release of epinephrine and norepinephrine. This causes vessel dilation (red skin) and a lack of sweat gland stimulation (causing the skin to remain dry). With the blood pooling in the periphery and the lack of circulating hormones (epinephrine and norepinephrine), the patient’s physical signs are different from those of classic hypovolemic shock (shock from fluid loss). Instead of pale, moist skin as would develop with hypovolemia, the spinal shock patient’s skin will be warm and dry and may appear slightly pink or red. In spinal shock, in which sympathetic impulses are impaired, the patient’s pulse is typically 60–80 beats per minute. This differs from the rapid rates that usually result from sympathetic nervous system stimulation in hypovolemia.

Treatment for spinal shock is much the same as for any other shock. Cervical spinal stabilization must be applied and the patient must be kept warm and completely immobilized.

**Incomplete Spinal Cord Injury**

**Incomplete spinal cord injury** occurs when the spinal cord is injured—but not completely through all of the three major tracts (motor, light touch, and pain tracts). That means that some of the tracts are spared and retain function. Because some tracts are injured and some are not, the patient may present with conflicting or confusing signs of spinal cord injury. Some of the spinal cord is not injured; therefore, some function is retained. The patient may be able to move some areas of the body and not move other areas of the body, or the patient may retain the sensation of pain to some areas of the body but not to others. Unlike a complete spinal cord injury, which causes complete loss of motor and sensory function below the level of injury, the incomplete spinal cord injury produces only loss of some function in some areas of the body.

The three most common types of incomplete spinal cord injury result in distinctive patterns of signs and symptoms (syndromes). They are central cord syndrome, anterior cord syndrome, and Brown-Séquard syndrome.

**Central Cord Syndrome.** If the central portion of the spinal cord is injured (Figure 32-4a ■), the patient may present with weakness or paralysis and loss of pain sensation to the upper extremities while the lower extremities have good function. This is opposite to what is expected in a patient with a complete spinal cord injury, which is loss of function below the site of injury. The reason for the loss of function in the upper extremities and not the lower is that the medial (inner) aspects of the motor and pain tracts control the upper extremities, whereas the lateral (outer) portions of the tracts control the lower extremities. In central cord syndrome, the medial or middle portion of the spinal cord is injured, causing a dysfunction in the inner tracts that control upper extremity motor and sensory function. Central cord syndrome is more commonly seen in elderly patients.

**ASSESSMENT TIPS**

In central cord syndrome, the patient presents with a loss of motor function or weakness and loss of pain sensation to the upper extremities while motor and sensory function remain normal in the lower extremities. ■

**Anterior Cord Syndrome.** Anterior cord syndrome results from injury of the sensory and motor tracts located in the anterior portion of the cord (Figure 32-4b ■). The posterior portion of the cord, where the tracts for light touch are located, is not injured. The patient will present with the loss of sensation to pain and
loss of motor function below the site of cord injury; however, the patient will retain the ability to feel light touch.

**ASSESSMENT TIPS**

In anterior cord syndrome, the patient loses the ability to feel pain and crude touch below the site of injury and also likely experiences the loss of motor function below the injury site. However, the patient retains the ability to feel light touch both above and below the site of injury.

**Brown-Séquard Syndrome.** An injury to a hemisection—the right or left half—of the spinal cord (Figure 32-4c) disrupts the spinal tracts on only one side of the cord. The patient experiences motor and sensory losses below the injury site, but the distinctive feature of Brown-Séquard syndrome is that the effects differ on the two sides of the body. The patient loses motor function and light touch sensation on one side but loses pain sensation on the opposite side. As an example, on the right the patient may be unable to move and unable to feel light touch but is able to feel pain. On the left he is able to move and feel light touch but does not feel pain. As you will recall from earlier in the chapter, the pain tracts cross over upon entering the spinal cord and carry the impulse up the opposite side of the cord, but the motor and light touch tracts carry the impulse up the same side as where they entered the cord. This explains the different assessment findings on opposite sides of the body.

**ASSESSMENT TIPS**

In Brown-Séquard syndrome, the patient loses motor function and light touch sensation on one side of the body while retaining pain sensation on that same side. On the opposite side of the body, the patient retains motor function and light touch sensation while losing pain sensation.

A complete spinal cord injury will result in the classic findings: total paralysis and loss of sensation below the level of injury. Any time you get abnormal motor function or sensation results from your assessment, findings that conflict with the classic findings, suspect incomplete cord injury. In either case, however, your emergency care must remain the same. The patient who has suffered any spinal cord injury—whether complete or incomplete—requires complete immobilization!

**EMERGENCY CARE FOR SUSPECTED SPINE INJURY**

**Assessment-Based Approach:**

**Spine Injury**

**Scene Size-up**

Because suspicion of spine injury is most often based on mechanism of injury, the scene size-up is an extremely important phase of patient assessment.

**Likely Mechanisms of Spinal Injury.** Be especially alert to the possibility of spine injury when called to any of the following scenes, since all of them are likely to produce the mechanisms that may result in spinal injury:

- Motorcycle crashes
- Motor vehicle crashes
- Pedestrian–vehicle collisions
- Falls
- Blunt trauma
- Penetrating trauma to the head, neck, or torso
- Sporting injuries
- Hangings
- Diving or other water-related accidents
- Gunshot wounds to the head, neck, chest, abdomen, back, or pelvis
- Unresponsive trauma patient
- Electrical injuries

Gunshot wounds to the head, neck, chest, abdomen, back, or pelvis should always cause suspicion of injury to the vertebrae or spinal cord. Even if entrance and exit wounds are closely aligned and appear to indicate a clean, straight-through wound, the bullet could have ricocheted and caused an injury to the vertebrae or spinal cord. Also, exploding fragments from other bones could have injured the spine. With any gunshot wound to the body, immediately establish manual in-line spinal stabilization and take the necessary spinal precautions during your emergency care until a more thorough assessment can be conducted.

Also suspect spine injury with any serious blunt injury to the head, neck, chest, abdomen, back, or pelvis—and even to the legs or arms. The energy of the impact can travel up the extremity to the spinal column.

**Clues to Mechanism of Injury.** Upon arrival, scan the scene closely for evidence of a mechanism of injury that could cause damage to the vertebrae or spinal cord. Look up, down, and around the patient for signs that an injury has occurred. If an unresponsive patient is lying on the ground near a tree, assume that the patient fell out of the tree until proven otherwise.

Even though there may be no overt signs of trauma to the patient, a spine injury may nevertheless exist. In such a situation, opening the airway using a head-tilt, chin-lift maneuver (which requires extension of the head and neck) or failing to provide proper manual in-line spinal stabilization may produce catastrophic permanent injury or even be lethal to the patient. These dire results can be avoided if you perform a thorough assessment of the patient.

You must deduce the mechanism of injury from the evidence at the scene and determine if such a mechanism could have injured the spine. For example, on arrival at the scene of an automobile collision, you may note damage to the front of the car. As you quickly scan the car, you note an impact mark on the front windshield on the driver’s side, apparently made by the
driver’s head (Figure 32-5 ■). You also note that the patient is not wearing his lap or shoulder restraint.

This evidence should create a high index of suspicion that the patient was propelled forward in the crash and struck his head on the windshield. This would likely have caused the head and neck to bend (flex) forward during the forward movement and bend backward (hyperextend) during the rearward movement. Both motions are significant mechanisms of injury that might not be suspected if the damage to the vehicle was not observed.

You may arrive at a collision scene and find the patient walking around or sitting in the back of a police car. This does not rule out the possibility of spine injury, especially an incomplete spinal cord injury or a vertebral injury. Many times, a patient with a stable spine injury does not exhibit signs and symptoms consistent with injury to the spine. Improper movement by either the patient or the EMT can easily cause the stable injury to become unstable, resulting in permanent neurological damage or even death. You must maintain proper in-line spinal stabilization, even if the patient has moved prior to your arrival.

Suspicion of injury to the spine or spinal cord is based primarily on the assessment findings and sets the standard for subsequent emergency care for the patient. All assessment and care must be conducted with extreme caution to avoid excessive movement and manipulation of the body. In-line spinal stabilization must be maintained throughout the entire patient contact.

**Primary Assessment**

When performing the primary assessment, the general impression may not lead you to suspect a spine injury, since the signs and symptoms may not be apparent. Regardless of the lack of obvious trauma or patient complaints, you must adopt a high index of suspicion and initiate immediate manual in-line spinal stabilization if the scene size-up has suggested a mechanism of injury that could cause spine injury. Manual stabilization must not be released until the patient is securely strapped to a backboard with his head and neck immobilized or until a thorough assessment is conducted and the findings do not indicate spinal injury. You must follow your local protocols regarding spinal immobilization.

An important factor to consider in the patient with a possible spine injury is the mental status. If the mental status is altered, it may be an indication of a head injury, alcohol intoxication, drug influence, shock, hypoxia, or other causes. An altered mental status does not allow the patient to respond adequately to questions or physical assessment or to provide complaints of pain, numbness, tingling, weakness, paralysis, or other signs of neurological dysfunction. In the case of an altered mental status, the patient is considered unreliable and you should always assume a spinal cord injury and completely immobilize that patient.

If the patient has other injuries, especially extremity fractures, the pain associated with these injuries may distract from any pain or tenderness the patient is experiencing to the spinal column. Thus, the patient does not complain of pain to the spinal column, allowing the EMT who is not prudent to miss the possible spinal injury. Be careful not to be drawn away from spinal assessment by other injuries, known as “distracting injuries.” Any patient with injuries above the clavicles (head, face, neck) should be assumed to have cervical spine injury.

Furthermore, if a patient has trouble communicating with you because of a language barrier, deafness, or other reasons, he may not be able to complain of symptoms or respond appropriately to your assessment.

Whenever spine injury is suspected, you must open the airway using the jaw-thrust maneuver instead of the head-tilt, chin-lift maneuver. Do not turn the patient’s head to the side to facilitate drainage of fluids from the airway. Instead, suction any secretions, blood, or vomitus from the patient’s mouth.

Spinal cord damage from a cervical spine injury can block nerve impulses traveling from the brain to the diaphragm and intercostal muscles, which are necessary for adequate respiration. Inadequate or absent breathing may result. There may be very little or no movement of the chest and only slight movement of the abdominal muscles, or you may note excessive abdominal muscle movement. Be prepared to provide positive pressure ventilation with supplemental oxygen.

**PATHOPHYSIOLOGY PEARLS**

An injury to the cervical spine in the area of the third (C3) to fifth (C5) cervical vertebrae may injure the phrenic nerve that controls the function of the diaphragm. Since the diaphragm provides more than 60 percent of the effort to breathe, the patient will develop respiratory failure and will require ventilation. An injury to the spinal cord at this level will also eliminate impulses to the intercostal muscles, because the nerves that control these muscles exit at the seventh cervical (C7) to first thoracic (T1) vertebrae.
The patient’s pulse and skin color, temperature, and condition may appear normal in spite of injury to the vertebrae. However, an injury to the spinal cord can interrupt the transmission of impulses from the brain to the heart and the blood vessels that control blood pressure. You may find the radial pulse weak or absent because of a reduced blood pressure. The skin may be warm and dry below the site of spinal cord injury and cool, pale, and moist above the site of injury. This is relatively rare.

**PATHOPHYSIOLOGY PEARSLS**
The warm and flushed skin is due to massive vasodilation below the site of injury and the loss of sympathetic tone provided to those vessels, allowing the blood to pool in the vessels in the skin and extremities.

**ASSESSMENT TIPS**
The skin may initially appear flushed and warm in the patient with a spine injury; however, as the pooled blood begins to de-oxygenate and cool, the skin will become mottled and cool.

The mental status of a patient with a spine injury may range from completely alert and oriented to unresponsive.

Based on the assessment findings, categorize the patient as either high or low priority for emergency care or transport. If the patient is unresponsive, is responsive but unable to obey your commands, or displays an abnormal respiratory pattern or obvious signs of spine injury such as numbness or paralysis, you must consider the patient a high priority for emergency care and prompt transportation to the highest level trauma center based on your destination proposals.

**Secondary Assessment**
Conduct the secondary assessment. Continue manual in-line spinal stabilization and reassess the patient’s mental status. Conduct a physical exam, then assess vital signs and gather a history.

**Physical Exam.** Instruct the patient to be still and not attempt to move. Do not attempt to unbutton or unzip clothing to expose the patient. Instead, reduce unnecessary movement by cutting clothing away. Conduct a physical exam. Inspect and palpate the head, neck, chest, abdomen, pelvis, extremities, and posterior body for evidence of trauma.

When spine injury is suspected, pay particular attention to the following during the exam:

- **Injuries Associated with Spine Injury.** Watch for evidence of trauma to the head, posterior cervical region, anterior neck, chest, abdomen, back, and pelvis. Injuries to these areas also frequently cause spine injury.
- **Cervical Spine Immobilization Collar.** Following your assessment of the neck, apply the cervical spine immobilization collar (CSIC). The cervical collar is only an adjunct to full spinal immobilization; it does not provide complete immobilization by itself. Do not release manual in-line spinal stabilization until the patient is fully immobilized on a backboard. This will be done after the secondary assessment.
- **Assessing Pulses and Motor and Sensory Function.** In the responsive patient, assess the pulses and motor and sensory function (EMT Skills 32-1) of each extremity. While assessment of pulses and motor and sensory function is being performed, maintain manual spinal stabilization.

To assess the pulses, do the following:

**Pulse Assessment**
- Check for the presence and strength of the radial pulses for the upper extremities, the pedal pulses for the lower extremities.

To assess for motor function, ask the patient to do the following:

**Motor Function Assessment: Upper Extremities**
- “Flex your arms (bend the arms at the elbows) across your chest” (tests motor function at C6).
- “Extend your arms (straighten the arms to the side of the body)” (tests motor function at C7).
- “Spread your fingers out on both hands and don’t let me squeeze them together” (tests motor function at T1).
- “Hold out both arms and don’t let me push your hand down” (done while you support the hand under the wrist) (tests motor function at C7).

**Motor Function Assessment: Lower Extremities**
- “Push down against my hands with your feet” (place your hands under the feet) (tests motor function at S1 and S2).
- “Pull up against my hands with your feet” (place your hands on the tops of the feet) (tests motor function at the level of L5).

A wooden Q-tip can be used for checking both pain and light touch. Break the stick in half. Use the jagged broken end to test for pain and the soft cotton tip to assess for light touch. If you don’t have a Q-tip, you can pinch the skin for pain and lightly touch the skin for light touch.

**Test for Pain Perception**
- Have the patient close his eyes. With the sharp end of the wooden Q-tip stick, poke one of the hands. When the patient grinaces, moans, or responds in some other way, ask “Where does it hurt?” Repeat the test on the other hand and then on each foot.

**Test for Light Touch Perception**
- Have the patient again close his eyes. Lightly touch the patient’s fingers on one hand, then the other. As you perform this test for light touch to the fingers, ask:
  - Can you feel me touching your finger?”
  - “Can you tell me what hand and which finger I’m touching?”
You would repeat the test on one of the toes on each foot. As you test for light touch on the toes, ask:

• “Can you feel me touching your toe?”
• “Can you tell me which foot and what toe I’m touching?”

If the patient is unresponsive, pinch the foot and hand to determine a sensory response. Compare the sensory function and strength in the upper and lower extremities. It is more common for spine injuries to cause paralysis to all four extremities (quadriplegia) or to the lower half of the body only (paraplegia). Loss of function confined to the right or left side of the body (hemiplegia) is more typical of a brain injury or stroke. Conflicting or partial loss of motor or sensory function may be an indication of an incomplete spinal cord injury.

**PATHOPHYSIOLOGY PEARLS**

Pain applied to an extremity may travel through a nerve tract, enter the spinal cord, and be immediately turned around and sent back out through a motor tract, causing the patient to move even though the impulse never reached the brain. Thus, the motor response to this does not tell you about the integrity of the brain and the nerve tracts, which is what it is intended to do.

**Posterior Exam.** Carefully log roll the patient with in-line spinal stabilization to assess the posterior body. Palpate the area of the spine very gently. Evidence of deformity, tenderness, contusions, lacerations, punctures, or swelling to the spine or around the spine should heighten your suspicion that a spinal column injury exists. Muscle spasms along the spinal column are a protective reflex and a common indication that a spine injury has occurred.

**Baseline Vital Signs.** Obtain and record a set of baseline vital signs. If the brain or spinal cord is damaged, baseline vital signs may reflect neurogenic hypotension. The blood pressure will be low and the heart rate normal or bradycardic. The hypotension associated with spinal shock is not usually severe but mild, with a systolic blood pressure usually no lower than 80 mmHg. As noted earlier in the chapter, in spinal shock the skin is warm and dry and the patient will present with motor and/or sensory deficit. Closely reassess the patient for deterioration and report these findings to the emergency department. If the hypotension is severe and the patient has tachycardia, suspect bleeding as the cause of shock and treat accordingly. Hypovolemia and spinal cord injury can both be present in the same patient; therefore, be cautious in your assessment, since spinal cord injury may prevent the typical signs of hypovolemic shock from occurring.

**PATHOPHYSIOLOGY PEARLS**

The hypotension in spinal shock is due to massive vasodilation and pooling of blood in peripheral vessels. No blood or fluid is lost from the vessels; however, the increase in the vessel size reduces the vessel resistance, the blood pressure, and perfusion. This produces a distributive type of shock.

**ASSESSMENT TIPS**

Neurogenic hypotension resulting from vasodilation in a spinal injury rarely produces a systolic blood pressure of less than 80 mmHg.

**History.** Obtain a history from the responsive patient. Because of the seriousness of a spine injury, try to take this history as the physical exam is being conducted. Questions that might be asked in cases of suspected spine injury include the following:

• Does your neck or back hurt?
• Where does it hurt?
• Can you move your hands and feet?
• Do you have any pain or muscle spasms along your back or to the back of your neck?
• Do you have any numbness or tingling sensations in either of your arms or legs?
• Was the onset of pain associated with a fall or other injury?
• Did you move or did someone move you before our arrival?
• Were you up walking around before our arrival?

Assess for allergies, medications, past medical history, and the last intake of food or drink. Remember to ask about events prior to the onset of signs or symptoms, because they may provide evidence of or clarify the mechanism of injury.

If the patient is unresponsive, obtain the history from the bystanders at the scene. Try to determine the patient’s mental status before your arrival, if the patient was moving any extremities, or if the patient was moved prior to your arrival.

**Signs and Symptoms.** In some EMS protocols, spinal immobilization is based on physical assessment findings and not solely on mechanism of injury. It is imperitive for you to recognize that a patient’s lack of pain in the spinal column or his ability to walk, to move his extremities, and to feel sensations does not rule out the possibility of spinal column (vertebral) or incomplete spinal cord injury.

The following are signs and symptoms of spine injury (Figure 32-6):

• Tenderness in the area of injury, specifically along the spinal column.
• Pain associated with movement from spine injury that may be localized. Ask the patient to pinpoint the location (by telling you where it is, not by trying to point to it). Do not ask the patient to move to try to elicit a pain response. Do not move the patient to test for pain.
• Pain independent of movement or palpation along the spinal column or in the lower legs. Such pain is generally intermittent instead of constant and may occur anywhere along the spinal column from the base of the head to the extreme lower back. If the lower spinal column is injured, the patient may complain of pain to the legs.
Indications for Spinal Immobilization Based on Assessment Findings. The following are indications for spinal immobilization in blunt and penetrating trauma based on a thorough assessment.

- Glasgow Coma Scale of <15
- Any suspected traumatic brain injury
- Any condition in which the patient has an altered mental status
- Signs of acute stress reaction (ASR) that may mask any pain the patient is experiencing
- Any pain or tenderness along the vertebral column
- Any paralysis (partial or complete), weakness, numbness, or tingling, prickling sensation
- Priapism
- Deformity along the vertebral column
- Incontinence of bowel or bladder
- A patient who has sustained a significant mechanism of injury and is under the influence of alcohol or drugs, cannot communicate effectively or understand, or has a painful distracting injury

If any of the above indications are found during the assessment, you must provide complete spinal immobilization. This is true even if the mechanism of injury doesn’t seem severe enough to produce a spinal injury.
Complications of Spine Injury. Spine injury may produce catastrophic permanent damage. Three major complications of spine injury are these:

- **Inadequate Breathing Effort.** Paralysis of the respiratory muscles may occur with injury to the cervical spine. Rapid deterioration of the patient's condition and death may result without quick intervention by the EMT. The diaphragm may continue to function even if the chest wall muscles are paralyzed. The patient will display shallow, inadequate breathing with little movement of the chest or abdomen. Continuous positive pressure ventilation is necessary.

- **Paralysis.** Paralysis may occur below the site of spinal cord damage. If the damage is to the spinal cord below the cervical region, paralysis is isolated to the lower half of the body (paraplegia). Damage to the cervical spinal cord can produce complete paralysis of the entire body (quadriplegia or tetraplegia). Paralysis and complete loss of sensation to only one side of the body (hemiplegia) is more common in head injuries and stroke; however, an incomplete spinal cord injury may cause loss of motor and sensory function in different areas of the body.

- **Inadequate Circulation.** Blood pressure and perfusion may be poor in the patient with spine injury as a result of spinal shock. If the spinal cord nerve fibers traveling from the medulla in the brain to the blood vessels are damaged, the blood pressure control center (vasomotor center) can no longer maintain the muscle tone in the blood vessels. Below the point of spinal cord injury, the blood vessels dilate (increase in size) and lower their resistance. Subsequently, blood begins to pool in the dilated vessels, the blood pressure drops, and the perfusion of other tissues of the body is reduced. Because of the blood vessel dilation, the skin is usually warm and dry, even though the tissue perfusion is poor. The heart rate typically remains normal or decreases slightly. In this case, be sure to look for other reasons for the low blood pressure.

**ASSESSMENT TIPS**

Pain or tenderness along the vertebral column is a significant sign of possible spinal column (vertebral) fracture.

**Emergency Medical Care**

In cases of suspected spine injury, it is not the role of the EMT to diagnose the condition or the site of the injury. The EMT must instead ensure that life-threatening conditions are cared for, that the possibility of further injury is reduced by careful handling of the patient, and that the patient is properly immobilized to a backboard and expeditiously transported to a medical facility.

*When in doubt, immobilize the patient.*

It is safer to err on the side of caution and completely immobilize a patient if spine injury is suspected. Immobilization devices can always be removed at the emergency department once the physician or radiographic studies determine that no spine injury exists. Paralysis resulting from failure to immobilize a patient because he did not display signs and symptoms of spine injury cannot be so easily undone.

The general guidelines for emergency care of a patient with a suspected spine injury are these:

1. **Take necessary Standard Precautions.**
2. **Establish manual in-line spinal stabilization immediately upon making contact with the patient** (EMT Skills 32-2). Ensure that the head is in a neutral, in-line position. That means bringing the head into a position in which the nose is in line with the navel (belly button) and the head is neither flexed forward nor extended backward. This manual stabilization must be maintained until the patient is completely secured and immobilized to the backboard.

   If the patient complains of severe pain to the neck or cervical spine, or the head does not easily move, stabilize and maintain the head in the position found.

   If an Emergency Medical Responder is holding manual in-line spinal stabilization upon your arrival, instruct him not to let go. If he can continue with the stabilization, evaluate the position of the patient's head and make any necessary readjustments. If the Emergency Medical Responder needs to be relieved, you should take over the in-line stabilization in a controlled manner. Replace the Emergency Medical Responder's hands on the patient's head with yours one at a time so that stabilization is never lost or uncontrolled.

3. **When performing the primary assessment, open and maintain the airway with the jaw-thrust maneuver.** Insert an oropharyngeal or nasopharyngeal airway, if necessary. Suction secretions without turning the patient's head. Provide positive pressure ventilation or supplemental oxygen to maintain an SpO2 of 94% or greater while manual in-line stabilization is maintained.

4. **Assess the pulse, motor function, and sensation (both pain and light touch) in all extremities.** Record these and document any differences or changes in the neurological status during your contact with the patient.

5. **Assess the cervical region and the neck before applying the cervical spine immobilization collar.** Gently palpate the cervical region for any deformities or tenderness.

6. **Apply a cervical spine immobilization collar.** Be sure that you are familiar with the type of cervical collar you are using. Refer to the manufacturer's instructions on proper sizing since each device is different. An improperly sized collar can cause more harm to the patient, compromise the airway, and further aggravate a potential spine injury. Information about sizing and applying the cervical spine immobilization collar is given on the following pages.
Because a spine injury is rarely an isolated injury, look for signs of shock (hypoperfusion): The skin becomes pale, cool, and moist; the blood pressure falls; the heart rate increases; and the patient’s mental status decreases. Remember that a decreasing level of responsiveness is an early sign of head injury, while a rising systolic blood pressure and decreasing heart rate are late signs of head injury.

If the patient has any further complaints, repeat those necessary parts of the physical exam. Be aware of complaints of tingling, numbness, loss of sensation, or paralysis anywhere in the body. Reevaluate any airway adjuncts, positive pressure ventilation devices, mask seal, oxygen therapy, splints, and immobilization devices. Record your findings in the prehospital care report and communicate them to the emergency department.
Abdomen:
- Blunt or penetrating trauma to abdomen

Pelvis:
- Blunt or penetrating trauma to pelvic area

Extremities:
- No response to pain or light touch
- Inability to move extremities
- Numbness or tingling sensation in extremities

Posterior body:
- Deformity to spinal column
- Evidence of trauma
- Swelling around spinal column
- Tenderness on palpation of spinal column
- Muscle spasms along spinal column
- Blunt or penetrating trauma to back

Baseline Vital Signs
BP: normal, or may be low
HR: normal, or bradycardia
RR: normal, irregular, decreased, or absent
Skin: normal, or may be pale, cool, and clammy above site of injury and flushed, warm, and dry below site of injury

SpO₂: 95% or greater unless poor perfusion status or breathing status is affected by cord injury
Pupils: equal and reactive, may be sluggish to respond to light

Note: If the blood pressure is low, heart rate is elevated, and skin is pale, cool, and clammy, suspect hypovolemic shock. Look for other trauma and treat for shock.

History
- Tenderness in area of injury
- Pain
- Deformity to the spine
- Soft tissue injuries to posterior body, neck, or cervical region
- Numbness, tingling, weakness, or paralysis in arms and/or legs
- Loss of bowel and bladder control
- Priapism (persistent erection of penis)
- Inadequate breathing or abnormal breathing patterns

Emergency Care Protocol

**SPINE INJURY**

1. Establish manual in-line stabilization. Do not release it until the patient is immobilized onto the backboard.
2. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen if the SpO₂ is less than 95% or any signs of respiratory distress or hypoxia are present.
6. Control any major bleeding.
7. Apply a cervical spine immobilization collar.
8. Place the patient on the backboard, pad any voids, and apply a minimum of three straps, at chest, hips, and above knees. Once the torso is secured, secure the head in a head immobilization device.
   - Standing patient: Immobilize using standing immobilization technique.
   - Seated patient with critical injuries: Perform rapid extrication and immobilize to a backboard.
   - Seated patient with no critical injuries: Apply a vest-type immobilization device. Extricate and immobilize to a backboard.
   - Supine or prone patient: Log roll the patient onto a backboard and immobilize.
9. If blood pressure and heart rate are low and skin is flushed below the level of injury, suspect spinal shock with neurogenic hypotension. Treat for shock.
10. If blood pressure is low, heart rate is elevated, and skin is pale, cool, and clammy, suspect hypovolemic shock. Look for other injuries and treat for shock.
11. Transport.
12. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable. Be prepared for vomiting and seizures.

Emergency Care Algorithm

SPINE INJURY

Emergency care algorithm: spine injury.
GUIDELINES FOR IMMobilization

As an EMT, you will encounter patients with spine injury or suspected spine injury in a variety of different circumstances. Some may be lying unresponsive on the ground. Others might be responsive, but seated in wrecked automobiles. Still others might be walking about. No matter what the circumstances, your task when you encounter a patient with suspected spine injury is to immobilize that patient safely and swiftly and transport him to a receiving facility. Mastering a variety of tools and techniques will help you carry out this task successfully.

Tools

The basic tools you will use in immobilizing patients are cervical spine immobilization collars, long backboards, and both rigid and vest-type short backboards.

Cervical Spine Immobilization Collars

A cervical spine immobilization collar should be used any time you suspect injury to the spine. There are several types of cervical collars (EMT Skills 32-3). Never use a soft collar; it permits too much movement.

The collar by itself does not immobilize the patient. The purpose of the collar is not to prevent the head from moving, but rather to prevent the head from moving in relation to the spine and to reduce the compression of the cervical spine during movement and transport of the patient. Even if you believe that the injury is only to the cervical (neck) area, the cervical collar is not enough. The entire spine must be stabilized and then immobilized. After a collar is applied, in-line manual stabilization must be maintained until the patient is fully secured to a backboard.

Sizing of the collar to the patient is based on the design of the device (EMT Skills 32-4). Be sure to use a collar of the proper size for the patient. Using a collar that is too small will not restrain the patient’s head adequately. Using a collar that is too large may cause extension of the patient’s neck and aggravate the spine injury.

Cervical spine immobilization collars should be applied by two rescuers: One stabilizes the neck manually in the neutral position while the other applies the collar. Placement of the cervical collar should never obstruct the patient’s airway. See EMT Skills 32-5, EMT Skills 32-6, EMT Skills 32-7, and EMT Skills 32-8 for detailed descriptions of how to apply a cervical spine immobilization collar.

Full Body Spinal Immobilization Devices

Several different types of long board immobilization devices exist to provide stabilization and immobilization of the head, neck, torso, pelvis, and extremities (EMT Skills 32-9A and 32-9B). Generally, long backboards are used to immobilize patients who are found in a lying or standing position. They may also be used in conjunction with short backboards. For proper immobilization of a patient, padding, straps, and cravats are also used with the long board.

Short Spinal Immobilization Devices

The most common short spine device is the commercially made vest-type device with supplied straps for the head, chest, and legs. A device now less commonly used than in the past is the rigid short spine board. This device requires the addition of backboard straps, padding, tape, or cravats to secure the patient. Both vest-type and rigid devices provide stabilization and immobilization to the head, neck, and torso. They require a significant amount of time to apply and are most commonly used to immobilize non-critical sitting patients with suspected spine injuries, not critical patients who require rapid transport.

It is very important to be completely familiar with the proper use of these devices to avoid further injury to the patient. For vest-type devices, follow all of the manufacturer’s instructions regarding application and use of the device.

Both vest-type and rigid short boards should be used only to immobilize the patient while moving him from a sitting position, then immediately to a long board. Short devices cannot adequately immobilize a patient because they can’t immobilize the surrounding joints of the head, torso, and legs.

Other Immobilization Equipment

Whenever a patient is placed onto a backboard, he must be secured to the board with backboard straps and some type of head immobilizer. Techniques for using this equipment to immobilize a patient to a long backboard are discussed in the next section.

Straps or cravats should be placed to keep the patient from sliding up and down or laterally on the board. Place straps across the chest and under the armpits in a manner that does not interfere with the patient’s breathing. Place straps across the pelvis and above the patient’s knees.

Deceleration straps are another important adjunct to immobilization. These straps are fastened across the patient’s shoulders. They help prevent the patient’s torso from sliding up the backboard and compressing the cervical spine when the ambulance slows or stops during transport.

Immobilization Techniques

You will encounter patients with suspected spine injuries in a variety of circumstances. The guidelines that follow tell you how to use the tools we have just described to immobilize patients in the most common situations.
**Immobilizing a Supine or Prone Patient**

When you encounter a supine or prone patient with a suspected spine injury, first ensure that all life-threatening situations have been managed, establish and maintain in-line manual spinal stabilization, and apply a cervical spine immobilization collar. Then you must immobilize the patient to a long backboard. A brief description of the four-rescuer log roll and immobilization procedures are provided in EMT Skills 32-10 and EMT Skills 32-11.

1. **Move the patient onto the spine board by log rolling the patient.** This move is ideally performed by at least four rescuers. One rescuer at the patient's head directs the movement and maintains in-line stabilization of the patient. One to three other rescuers actually move the patient onto the backboard. As the patient is rolled onto his side, his posterior body should be carefully assessed if this has not been done during the primary assessment.

2. **Position the long spine board under the patient by sliding the board under the patient during the log roll.** Then place the patient on the board at the command of the rescuer who is maintaining in-line stabilization. Use a slide, proper lift, log roll, or scoop stretcher to position the patient on the backboard so that movement is as limited as possible. (The method used will depend on the situation, the scene, and available resources.)

3. **Place padding in the spaces between the patient and the board.** In an adult, pad under the head and torso, taking care to avoid extra movement. In an infant or child up to approximately age 8 years, pad under the shoulders (because the child's relatively larger head will otherwise cause the neck to flex forward) and anywhere along the length of the body as necessary to maintain a neutral position.

4. **Immobilize the patient's torso to the board with straps.** The strap across the chest should be tight enough to prevent shifting of the torso but not so tight that it inhibits movement of the chest muscles and impairs breathing.

5. **Immobilize the patient's head to the board with a commercial head/cervical immobilization device or through the use of blanket rolls and tape.** Never place padding behind the neck itself. If the patient vomits, your strapping technique should be good enough to enable you to roll the patient onto his left side several times without any change in body position on the board.

6. **Secure the patient's legs to the board with straps.**

7. **Proceed with care as described earlier under “Emergency Medical Care.”**

If only two or three rescuers are available, the log roll can be done using the techniques shown in EMT Skills 32-12 and EMT Skills 32-13.

**Immobilizing a Standing Patient**

It is not uncommon to find patients with suspected spine injuries standing or walking around at the scene of an accident. Never permit such patients to sit down or to walk to the cot and lie down on a backboard. In such cases, you should instead use a standing long board technique to assist the patient from a standing to a supine position while keeping his spine aligned. This technique is outlined here and also illustrated in EMT Skills 32-14.

1. **One EMT should immediately take normal manual in-line spinal stabilization measures while another EMT applies a cervical collar.**

2. **Position the long board behind the patient.** Examine the back carefully.

3. **Two EMTs should stand on either side of the patient to support him.** Each should place one arm under the patient's armpit and grasp the highest reachable handhold on the long board. The EMTs' other hands should be holding the patient's elbows to steady and support him. The third EMT maintains in-line manual stabilization.

4. **The EMTs at the sides of the patient should each place a leg behind the board.** They should then slowly tip the board backward and begin lowering it to the ground while the third EMT maintains stabilization. Be sure to inform the patient what you are going to do before you tip the board backward.

5. **Once the board is lying level on the ground, one EMT maintains manual stabilization while the others perform the necessary assessment and care.** The patient is then immobilized on the backboard following the guidelines for prone and supine patients given earlier.

6. **Proceed with care as described earlier under “Emergency Medical Care.”**

This technique can also be adapted for use by two EMTs, as illustrated in EMT Skills 32-15.

**Immobilizing a Seated Patient**

If the patient with a suspected spine injury is found in a seated position, a short spinal immobilization device will be used. This will minimize movement and aggravation of potential spine injury while the patient is being transferred to a long board for complete immobilization.

The following are general steps to follow. The steps involved in using a vest-type device are illustrated in EMT Skills 32-16.

1. **Use manual in-line spinal stabilization and apply a cervical collar.** Assess pulses and motor and sensory function in all four extremities.

2. **Position the short spinal device behind the patient.** Examine the back carefully. Be careful that the EMT who is holding in-line spinal stabilization does
not move excessively or move the patient as the device is positioned. You should slide the board behind the patient and as far into the seat as you can. The top of the board should be level with the top of the patient’s head, and the bottom of the board should not extend past the coccyx. The body flaps should fit snugly under the patient’s armpits.

3. Secure the device to the patient’s torso. Make sure the straps are tight enough to prevent movement of the device laterally or vertically. If the device has straps that circle the legs, apply and tighten these after the chest straps are applied.

4. Pad behind the patient’s head to ensure neutral alignment of the head and neck with the remainder of the spine. Excessive padding will cause the head and neck to flex forward, whereas lack of padding will allow the head and neck to be extended.

5. Secure the patient’s head to the device. Make the head and neck stationary. This prevents the head and neck from flexing or extending. The alignment of the head and neck with the remainder of the spine must be maintained. The head and neck must be protected from accidental movement of the cervical spine.

6. Position a long backboard under or next to the patient’s buttocks and rotate him until his back is in line with the backboard. Lower the patient onto the backboard while maintaining manual in-line spinal stabilization. If it is not possible to get a long backboard next to the patient, lift the patient under his arms and legs and lower him onto the long board.

7. Follow the guidelines for immobilizing a patient to a long backboard. Release manual in-line spinal stabilization only when the patient is completely secured to the backboard. Assess pulses and motor and sensory function and record your findings on the prehospital care report.

8. Proceed with care as described earlier under “Emergency Medical Care.”

Rapid Extrication

There are several special considerations to be aware of when using a short spinal device:

- Always tighten the torso and leg straps before securing the patient’s head to the device. This prevents accidental movement of the patient’s head.
- Never allow buckles to be placed midsternum where they would interfere with proper hand placement if CPR becomes necessary.
- Never pad between the cervical collar and the board; doing so creates a pivot point that may cause hyperextension of the cervical spine.
- Assess pulses and motor and sensory function before and after applying the device.

- Never place a chin cup or chin strap on the patient. They will prevent the patient from opening his mouth to vomit.
- When applying the first strap to the torso, take care not to apply the strap too tightly, which could cause abdominal injury or impair breathing.

Rapid Extrication

There are times when you will have to move a patient with a suspected spine injury before immobilizing him to a long backboard or even to a short spinal device. The three situations in which such movement is permissible are as follows:

- The scene is not safe (because of the threat of fire or explosion, chemical spills, or gunfire, for example).
- The patient’s condition is so unstable that you need to move and transport him immediately.
- The patient blocks your access to a second, more seriously injured patient.

In these circumstances—when the time saved by immediate extrication will make the difference between life and death—a rapid extrication is performed. Rapid extrication eliminates the delay inherent in the use of spinal immobilization devices. Time is critical in the situations just described; therefore, the benefit of rapid transport outweighs the risk of movement during extrication.

Rapid extrication requires constant cervical spine stabilization and good communication among the EMTs moving the patient. The patient’s entanglement with seat belts, wreckage, or other objects can complicate rapid extrication procedures, so all rescuers need to be aware of the patient’s position as well as any potential problems as the extrication is proceeding.

In rapid extrication, the patient is brought into alignment with manual in-line spinal stabilization and a cervical spine immobilization collar is applied. A long backboard is positioned next to him. The patient is quickly transferred to the long backboard while manual in-line spinal stabilization is maintained. The rapid extrication procedure is described in more detail in EMT Skills 32-17A to 32-17D.

The rapid extrication technique requires EMTs to improvise at the scene based on the type of car, location of the roof support posts, console between the seats, and size of the patient. If time, resources, and patient condition permit, removal of the roof will allow for much better access to the patient and for easier removal using the rapid extrication technique, as illustrated in EMT Skills 32-17E and 32-17F.
SPECIAL CONSIDERATIONS

Handling and immobilization of patients with suspected spine injuries can be complicated by a variety of factors. Two of the more common situations you will encounter involve suspected spine injury in people wearing helmets and suspected spine injury in infants and children.

Helmets

Activities such as bicycle riding, motorcycle riding, and playing football can easily lead to accidents that can produce spine injury. People taking part in such activities often wear helmets, and you may arrive at an accident scene to encounter a patient still wearing a helmet. Thorough assessment of a patient is difficult under any circumstances; the presence of a helmet makes the task still more difficult. But removal of a helmet should not be an automatic step. Such removal could risk aggravating the spine injury, if one exists. You should first assess the patient wearing the helmet in the following areas:

• Assess the patient’s airway and breathing.
• Assess the fit of the helmet and the likelihood of movement of the patient’s head within the helmet.
• Determine your ability to gain access to the patient’s airway if intervention should be necessary to assist his breathing.

You should leave the helmet in place if your assessment reveals the following:

• The helmet fits well, and there is little or no movement of the patient’s head inside the helmet.
• There are no impending airway or breathing problems.
• Removal of the helmet would cause further injury to the patient.
• You can properly immobilize the spine with the helmet in place.
• The helmet doesn’t interfere with your ability to assess and reassess airway and breathing.

You should remove the helmet if your assessment reveals the following:

• The helmet interferes with your ability to assess or reassess airway and breathing.
• The helmet interferes with your ability to adequately manage the airway or breathing.
• The helmet does not fit well and allows excessive movement of the head inside the helmet.
• The helmet interferes with proper spinal immobilization.
• The patient is in cardiac arrest.

Helmet Removal

There are two basic types of helmets: sports helmets (such as those worn for football) and motorcycle helmets. Typically, sports helmets have an opening in the front and allow much easier access to the airway. Face masks on football helmets can be removed either by cutting the plastic clips that hold the mask to the helmet or by unsnapping the face mask retainers. Motorcycle helmets, on the other hand, generally cover the full face and have a shield that prevents access to the airway.

The techniques for the removal of motorcycle and sports helmets are illustrated in EMT Skills 32-18 and EMT Skills 32-19. The general steps for removal of a helmet are these:

1. Take the patient’s eyeglasses off before you attempt to remove the helmet.
2. One rescuer should stabilize the helmet by placing hands on each side of the helmet with fingers on the mandible (lower jaw) to prevent movement.
3. A second rescuer should loosen the chin strap.
4. The second rescuer should place one hand anteriorly on the mandible at the angle of the jaw and the other hand at the back of the head.
5. The rescuer holding the helmet should pull the sides of the helmet apart (to provide clearance for the ears), gently slip the helmet halfway off the patient’s head, then stop.
6. The rescuer who is maintaining stabilization of the neck should reposition, sliding his hand under the patient’s head to keep the head from falling back after the helmet is completely removed.
7. The first rescuer should remove the helmet completely.
8. The patient should then be immobilized as described earlier.

Football Injuries

When dealing with football injuries, the EMT has to take into consideration the equipment football players wear. In most cases, an injured player is wearing not only a helmet but also shoulder pads. Usually the shoulder pads and the helmet elevate the player’s head, neck, and shoulders off the ground, almost in a neutral position. Because of this, you should leave the helmet on the player unless it is absolutely necessary to remove it. Removing the helmet while leaving the shoulder pads on will cause the head to drop and hyperextend the neck. Removal of the shoulder pads is difficult because the player is usually on his back and the attempt may cause unnecessary movement, risking aggravation of his injury.

According to the Inter-Association Task Force for Appropriate Care of Spine-Injured Athletes, the face mask of the helmet should be removed at the earliest possible point, but before transportation. The face mask should be removed any time a spinal injury is suspected, regardless of the mental status and airway or respiratory status of the patient. As already noted, the helmet should only be removed in specific situations.
**Removal of the Face Mask.** If you are expected to respond to or on stand by at football events, it is important that you have the proper tools to remove the face mask of the helmet in the quickest way with the least amount of movement (EMT Skills 32-20). Several different types of tools, such as the FM extractor, Trainer’s Angel, knives, pruning shears, and PVC pipe cutters, can be used to remove the face mask. Even though the plastic clips holding the face mask are typically screwed in place, a screwdriver is *not* recommended to take off the face mask. Unscrewing the clips causes excessive movement of the head, especially if the screws have been in place for some time and are rusted. DuraShears, EMT shears, and a seat belt cutter are also not recommended because these tools take too much time to cut the plastic clips. A simple pruning tool used for gardening often is the best device to use.

The face mask of the helmet is usually secured by four plastic loop-clips or loop-straps that are screwed into the helmet. By cutting these plastic straps or clips, the face mask can be completely removed. This allows the EMT complete access to the airway for assessment and intervention. A common practice has been to cut the side clips or straps and lift or “peel” the face mask upward. By this method, the face mask is said to be “retracted” or “swung away.” This is no longer recommended, since it causes excessive movement of the head and neck during the process. It is now recommended that all four clips or straps be cut and the face mask completely lifted off the helmet.

**Immobilization of the Player.** One EMT or trainer will maintain in-line spinal stabilization by grasping the helmet and holding the head and neck in a neutral in-line position. The helmet, chin straps, and pads should be left in place. A second EMT will remove the face mask. Once the face mask has been removed, the patient assessed, and emergency care provided, the patient must be completely immobilized to a backboard.

Every attempt must be made to apply a cervical spine immobilization collar. However, it may be impossible to apply a cervical collar with the football equipment in place. Do not remove the helmet or shoulder pads to apply a cervical collar. Instead, if the collar cannot be applied with the helmet and pads in place, pad with towels, blanket rolls, or other such material to reduce movement.

A six-person lift is recommended to move the patient onto the backboard. Once on the backboard, straps must be applied to secure the chest, pelvis, and lower extremities above the knees. Acceleration/deceleration straps should be used to reduce movement during braking and acceleration of the ambulance. The helmet should be taped to the backboard to prevent movement. Keep the chin strap in place the entire time, even after the patient is completely immobilized. Any gaps between the patient and the backboard should be filled in with towels, pillowcases, or other items.

There are only two circumstances in which the helmet should be removed: (1) if it does not adequately secure the head because it is too large for the patient, or (2) if you cannot gain access to the airway. If the helmet is removed, padding must be added behind the head to ensure that the head and shoulder pads are kept in a neutral in-line position. Except in the noted circumstances, it is not recommended to remove the helmet.

**Infants and Children**

When treating infants or children, use a rigid board appropriate for the child’s size, following the guidelines outlined earlier for general immobilization. However, the following special considerations should apply when immobilizing infants or children:

- Pad from the shoulders to the heels of an infant or a child, if necessary, to maintain neutral in-line immobilization. The larger head of the infant or young child usually up until 8 years of age causes the head and neck to flex when supine. Use padding behind the shoulders and upper back to eliminate flexion and maintain neutral alignment of the head, neck, and spine.

- Make sure the cervical collar fits properly before applying it to an infant or child. If you don’t have a collar that fits, immobilize the neck with a rolled towel, tape the towel to the backboard, and manually support the patient’s head in a neutral in-line position. An improperly fitted collar will do more harm than good.

**Extrication from a Car Seat.** If you are at an automobile collision involving a child in a car seat, you cannot use that car seat to stabilize the child for transport. Car seats involved in crashes may have lost the integrity of the structure and may not provide protection to the child if another crash were to occur. Transfer the child to a backboard. If a child needs to be extricated from a car seat for treatment, follow the steps shown in EMT Skills 32-21.
Assessing Neurological, Motor, and Sensory Function

- **32-1A** Assess flexion.
- **32-1B** Assess extension.
- **32-1C** Assess finger abduction.
- **32-1D** Assess finger adduction.
- **32-1E** Assess the wrist and hand.
- **32-1F** Assess plantar flexion.
32-1G Assess dorsiflexion.

32-1I Assess pain response in the foot.

32-1K Assess light touch response in the foot.

32-1H Assess pain response in the hand.

32-1J Assess light touch response in the hand.

32-1L Assess flexion of the great toe on the same foot.
EMT SKILLS 32-2
Establish Manual In-Line Stabilization

**32-2A** Properly position your hands.

**32-2B** Keep the head in a neutral position and the nose in line with the patient’s navel.

**EMT SKILLS 32-4**

Sizing a Cervical Spine Immobilization Collar

■ **32-4A** To size a cervical spine immobilization collar, first draw an imaginary line across the top of the shoulders and the bottom of the chin. Use your fingers to measure the distance from the shoulder to the chin.

■ **32-4B** Check the collar you select. The distance between the sizing post (black fastener) and lower edge of the rigid plastic should match that of the number of stacked fingers previously measured against the patient’s neck.

■ **32-4C** Assemble and preform the collar.

**EMT SKILLS 32-5**

Applying a Cervical Spine Immobilization Collar to a Seated Patient

■ **32-5A** After selecting the proper size, slide the cervical spine immobilization collar up the chest wall. The chin must cover the central fastener in the chin piece.

■ **32-5B** Bring the collar around the neck and secure the Velcro. Recheck the position of the patient’s head and collar for proper alignment. Make sure the patient’s chin covers the central fastener of the chin piece.

continued
If the chin is not covering the fastener of the chin piece, readjust the collar by tightening the Velcro until a proper sizing is obtained. If further tightening will cause hyperextension of the patient’s head, then select the next smaller size.

EMT SKILLS 32-6

Applying a Cervical Spine Immobilization Collar to a Supine Patient

- **32-6A** Slide the back portion of the cervical spine immobilization collar behind the patient’s neck. Fold the loop Velcro inward on the foam padding.

- **32-6B** Position the collar so that the chin fits properly. Secure the collar by attaching the Velcro.

- **32-6C** Hold the collar in place by grasping the trachea hole. Attach the loop Velcro so it mates with (and is parallel to) the hook Velcro.
EMT SKILLS 32-7

Applying an Adjustable Collar to a Seated Patient

■ 32-7A Stabilize the head and neck from the rear.

■ 32-7B Properly angle the collar for placement.

■ 32-7C Position the collar bottom.

■ 32-7D Set the collar in place around the neck.

■ 32-7E Secure the collar.

■ 32-7F Maintain manual stabilization of the head and neck.
**EMT SKILLS 32-8**

**Applying an Adjustable Collar to a Supine Patient**

- **32-8A** Kneel at the patient’s head and stabilize the head and neck.
- **32-8B** Set the collar in place.
- **32-8C** Secure the collar.
- **32-8D** Continue to manually stabilize the head and neck.

**EMT SKILLS 32-9**

**Examples of Immobilization Devices**

Always follow local protocol in purchasing and using immobilization devices.

- **32-9A** Full body vacuum splint. (© Ferno Corporation)
- **32-9B** KED (Kendrick Extrication Device). (© Ferno Corporation)
EMT SKILLS
32-10

Four-Rescuer Log Roll and Long Spine Board Immobilization

■ 32-10A  Establish and maintain in-line stabilization. Apply a rigid cervical spine immobilization collar.

■ 32-10B  Place a long spine board parallel to the patient. If possible, pad the voids under the head and torso.

■ 32-10C  Three rescuers kneel at the patient’s side opposite the board, leaving space to roll the patient toward them.

■ 32-10D  The EMT at the head directs the others to roll the patient as a unit onto his side. Assess the patient’s posterior side.

■ 32-10E  The EMT at the waist reaches over, grasps the spine board, and pulls it into position against the patient. (This can also be done by a fifth rescuer.) The EMT at the head instructs the rescuers to roll the patient onto the spine board.

■ 32-10F  Secure the patient to the board with straps. Loosely tie the wrists together.

continued
Immobilizing a Patient to a Long Board

- **32-10G** Using a head/cervical immobilizer, secure the patient’s head to the spine board.
- **32-10H** Transfer the patient and the spine board as a unit. Secure the patient and the spine board to the cot.

**EMT SKILLS 32-11**

- **32-11A** Apply straps to secure the patient to the backboard. Place one strap at the level of the chest, one at the hip, one above the knee, and another below the knee. Pad between the legs.
- **32-11B** An "X" strap method secures the torso to the backboard. Also apply one strap at the hip, one above the knee, and one below the knee.
- **32-11C** A “spider” strap method with Velcro straps.
- **32-11D** Secure the patient’s head to the backboard with a head immobilization device (cardboard disposable device shown).
Three-Rescuer Log Roll

■ 32-11E Disposable head immobilization device (Styrofoam disposable device shown).

■ 32-11F Blanket rolls and tape can be used.

■ 32-12A Maintain in-line spinal stabilization while preparing for the log roll.

■ 32-12B Roll the patient onto the side at command of the EMT maintaining stabilization. Inspect the back.

■ 32-12C Move the spine board into place.

■ 32-12D Lower the patient onto the spine board at command of the EMT maintaining in-line stabilization. Center the patient on the board.
EMT SKILLS 32-13

**Two-Rescuer Log Roll**

- **32-13A** Maintain an open airway and in-line spinal stabilization while applying a cervical spine immobilization collar.
- **32-13B** Maintain in-line support while moving the patient onto the side.
- **32-13C** Pull the board against the patient.
- **32-13D** Roll the patient gently onto the board and secure.

EMT SKILLS 32-14

**Immobilizing a Standing Patient—Three EMTs**

- **32-14A** Apply a cervical spine immobilization collar while in-line stabilization is being held.
- **32-14B** Position the backboard behind the patient and align it properly. Check the position of the board from the front of the patient.
The EMTs at the sides of the patient place their hands under each arm and grasp the next highest handhold. Their other hands grasp the elbows of the patient to provide additional stabilization on the board.

Lower the patient to the ground. Continue holding in-line stabilization until the patient is completely immobilized to the backboard with a head/cervical immobilization device and straps.

Apply a cervical spine immobilization collar and position the long board behind the patient.

The EMTs on each side of the patient hold the long board in place and hold the patient’s head in a neutral in-line position.
■ 32-16A The Ferno Kendrick Extrication Device (K.E.D.).

■ 32-15C Each EMT then places the leg closest to the board behind it and lowers the board to the ground.

■ 32-16B After a cervical spine immobilization collar has been applied, slip the K.E.D. behind the patient and center it.

■ 32-15D Once the patient is horizontal on the ground, one EMT takes over in-line stabilization until the patient is completely immobilized.

■ 32-16C Immobilizing a Seated Patient with a Ferno K.E.D. Extrication Device
■ **32-16C** Properly align the device. Then wrap the vest around the patient’s torso.

■ **32-16D** When the device is tucked well up into the armpits, secure the chest straps.

■ **32-16E** Secure the leg straps.

■ **32-16F** Secure the patient’s head with the Velcro head straps.

■ **32-16G** Tie the hands together.

■ **32-16H** Pivot the patient onto the backboard while maintaining in-line stabilization.
Rapid Extrication

- **32-17A** Bring the patient’s head into a neutral in-line position. This is best achieved from behind or to the side of the patient. Perform a primary assessment and a rapid physical exam. Then apply a cervical spine immobilization collar.

- **32-17B** Support the patient’s thorax. Rotate the patient until her back is facing the open car door. Bring the patient’s legs and feet up onto the car seat.

- **32-17C** Bring the board in line with the patient and against the buttocks. Stabilize the cot under the board. Begin to lower the patient onto the board.

- **32-17D** Lower the patient onto the board. Depending on the structure of the car, it may be necessary to change positions to maintain in-line stabilization while lowering the patient onto the board.

- **32-17E** If the structural features of the vehicle, time, resources, and the patient’s condition permit, it may be worthwhile to remove the roof before performing a rapid extrication.

- **32-17F** Depending on variables such as the vehicle’s structure and the patient’s condition, a rapid extrication may be performed more easily and safely if the roof has been removed.
Helmet Removal

- **32-18A** One rescuer applies stabilization by placing hands on each side of the helmet with fingers on the patient’s mandible to prevent movement.

- **32-18B** A second rescuer places one hand on the mandible at the angle of the jaw.

- **32-18C** With the other hand, the second rescuer holds the occipital region. This maneuver transfers the stabilization responsibility to the second rescuer.

- **32-18D** The rescuer at the top begins to remove the helmet, pulling the sides apart to clear the ears and allowing the second rescuer to readjust his hand position around the mandible and under the occipital region.

- **32-18E** Throughout the removal process, the second rescuer maintains in-line stabilization from below to prevent head tilt.

- **32-18F** After the helmet has been removed, the rescuer at the top replaces his hands on either side of the patient’s head with palms over the ears, taking over stabilization.

**continued**
Helmet Removal—Alternative Method

**EMT SKILLS 32-19**

- **32-18G** Stabilization is maintained from above until a cervical spine immobilization collar is applied to the patient and complete immobilization to the backboard is achieved.

- **32-19A** Apply steady stabilization with the neck in neutral position.

- **32-19B** Remove the chin strap.

- **32-19C** Remove the helmet by pulling out laterally on each side.

- **32-19D** Apply a suitable cervical spine immobilization collar and secure the patient to a long board.
EMT SKILLS 32-20

Immobilizing a Patient with a Football Helmet

32-20A  Take manual in-line stabilization and remove the mouthpiece.

32-20B  Cut the clips that secure the face mask.

32-20C  Remove the face mask by lifting it straight off the helmet.

32-20D  Immobilize the patient with straps and tape the helmet to the board last.

32-20E  Transport the patient with the football equipment still in place.

■ 32-20A  Take manual in-line stabilization and remove the mouthpiece.

■ 32-20B  Cut the clips that secure the face mask.

■ 32-20C  Remove the face mask by lifting it straight off the helmet.

■ 32-20D  Immobilize the patient with straps and tape the helmet to the board last.

■ 32-20E  Transport the patient with the football equipment still in place.
Extrication from a Child Safety Seat

**32-21A** EMT #1 stabilizes the car seat in an upright position and applies manual stabilization to the child’s head and neck. EMT #2 prepares equipment, then loosens or cuts the seat straps and raises the front guard.

**32-21B** A cervical collar is applied to the child as EMT #1 maintains manual stabilization of the head and neck.

**32-21C** As EMT #1 maintains manual stabilization, EMT #2 places the child safety seat on the center of a backboard and slowly tilts it into supine position. The EMTs are careful not to let the child slide out of the safety seat. For a child with a large head, place a towel under the area where the shoulders will eventually be placed on the board to prevent the child’s head from tilting forward.

**32-21D** EMT #1 maintains manual stabilization and calls for a coordinated long axis move onto the backboard.
EMT #1 maintains manual stabilization as the move onto the board is completed with the child’s shoulders over the folded towel.

EMT #1 maintains manual stabilization as EMT #2 places rolled towels or blankets on both sides of the child.

EMT #1 maintains manual stabilization as EMT #2 places rolled towels or blankets on both sides of the head, then tapes the head securely in place across the forehead and cervical collar. DO NOT TAPE ACROSS THE CHIN TO AVOID PRESSURE ON THE NECK.

EMT #1 maintains manual stabilization as EMT #2 straps or tapes the child to the board at the level of the upper chest, pelvis, and lower legs. DO NOT STRAP ACROSS THE ABDOMEN.

SUMMARY

Spine injuries could lead to permanent damage to the spinal cord that results in paralysis and loss of sensation below the level of injury. Thus, it is imperative to assess for and manage the patient appropriately to reduce any risk of further injuring the spine or spinal cord. A patient may have a spinal column (vertebral) injury with no spinal cord involvement. Improper management by EMS could convert the spinal column injury into a spinal cord injury. If you have any indication that the patient has suffered a spinal injury, whether it is to the cord or to the column, take the necessary precautions and provide efficient and effective spinal immobilization.

A multitude of signs and symptoms may occur from a spine injury. An injury to the vertebrae will typically produce pain or tenderness along the spinal (vertebral) column. An injury to the spinal cord will usually produce motor or sensory deficits. Complications of spinal injury may include inadequate breathing effort, paralysis, and poor perfusion. Beware of confusing assessment findings, which may be an indication of an incomplete spinal cord injury.

Use the proper techniques and equipment to protect the spine and spinal cord from further injury. Complete spinal immobilization should be done on any patient suspected of having a spinal column or spinal cord injury.
Scene Size-up

You are dispatched to a gymnastics meet for a 12-year-old girl who has fallen during the competition. As you arrive on the scene, you are directed into the gymnasium by an assistant. The lights are bright and the music is loud. You and your partner make your way around various pieces of gymnastics equipment to the far side of the gym, where a small group of girls, some in tears, are crowded around a young girl supine on the mat. Immediately above her are a set of uneven parallel bars at approximate heights of 10 and 6 feet. A woman, who identifies herself as the coach, is kneeling next to the girl and holding her head and body still. The coach says, “She missed a maneuver off the top bar. She fell and hit the bottom bar with the middle of her back, then landed head first on the floor.”

Primary Assessment

Recognizing the mechanism of injury, your partner immediately brings the patient’s head and neck into a neutral position and establishes manual in-line spinal stabilization. You and your partner introduce yourselves and instruct the patient not to move. The young girl cries out, “My legs are numb and tingly! Am I going to be paralyzed?” You ask, “Can you tell me your name?” She says, “Carrie.” “Well, Carrie,” you say, “we’re going to take good care of you and get you to the hospital where the doctors can figure out what’s wrong and treat it.” Carrie’s airway is patent and her breathing is rapid but adequate at a rate of approximately 28 per minute. Her radial pulse is strong and estimated at a rapid 125 per minute. Her skin is slightly cool to touch, slightly pale, and dry. You note, however, that the gymnasium temperature is relatively cool. You apply a pulse oximeter and obtain a reading of 98% on room air; therefore, you determine the oxygenation status to be adequate and do not apply oxygen.

Secondary Assessment

You ask the coach if she actually saw the accident. You also ask if the patient attempted to get up or if she moved or was moved after the fall. The coach explains that she was standing next to Carrie when she fell. Because of how she landed, the coach immediately went to her side and instructed her to keep extremely still.

You proceed with a physical exam. Very gently, you assess the head and find a contusion along the scalp region at about the level of the sixth vertebra. You apply her neck, Carrie complains of tenderness to the cervical area. You then inspect and carefully palpate the lower extremities for any signs of injury. The pedal pulses are present bilaterally. You instruct her to wave her foot very gently. She is able to move both feet. You touch the big toe on the right foot and ask, “Can you tell me which foot and toe I am touching?” She cries, “No!” Stabilizing the leg to avoid unsuspected and exaggerated movement, you pinch the top of the left foot. Carrie states, “I can feel that on my left foot.” You repeat the same on the right foot and get a response to the pinch.

You enlist the help of the coach, who is familiar with log rolling, and instruct her to position herself at Carrie’s feet. You position the backboard next to the patient. At the direction of your partner holding in-line stabilization at Carrie’s head, you log roll her up and quickly assess her back, finding no deformities but some tenderness in the lumbar region. The backboard is positioned under her and she is rolled back onto it. A void behind the lumbar region is padded and straps are applied to the torso and legs and secured. A head/cervical immobilization device is applied and secured. Your partner releases manual in-line spinal stabilization and moves to the side to take the baseline vital signs. The blood pressure is 104/76 mmHg, the heart rate is 118 bpm, and the skin is slightly cool to touch, slightly pale, and dry. You obtain a history from the patient.

Carrie’s parents have been notified by the gym staff. You and your partner meanwhile transfer Carrie to the ambulance and begin transport.

Reassessment

During the reassessment, you reevaluate the spinal immobilization. All straps are secure and all pads properly positioned. Carrie complains of some discomfort to her back but says it is from the hard backboard. You reassess her pulses and motor and sensory function in all the extremities and find no change. You reassess and record the vital signs.

Upon arrival at the emergency department, you help the hospital staff gently transfer the backboard to the emergency department bed. You provide an oral report regarding your findings. You briefly reassure Carrie then proceed to the EMS room to complete your prehospital care report as your partner restocks the ambulance. You finally notify dispatch that you are prepared for another call.
Later that day, on another call to the same hospital, you find time to check on Carrie’s condition. The emergency medicine physician states that she suffered a spinal concussion and will completely recover. He praises the coach’s work in keeping Carrie still until EMS arrived. He thanks you and your partner for the very detailed information provided both orally and in the prehospital care report regarding the scene characteristics and mechanism of injury. He also states, “Very nice immobilization job.”

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

Case Study Follow-up continued

---

IN REVIEW

1. Describe the relationship between the spinal column and the spinal cord.
2. Name the most common mechanisms of spine injury.
3. List the signs and symptoms of potential spine injury.
4. Explain the types of stabilization and immobilization that must be applied in cases of suspected spine injury.
5. Describe how the airway is managed in a patient with suspected spine injury.
6. Explain the purpose and use of the cervical spine immobilization collar.
7. Explain how to assess motor and sensory function in a patient with suspected spine injury.
8. Explain the use of long and short spinal immobilization devices for seated patients with suspected spine injuries.
9. Under what circumstances is rapid extrication appropriate?
10. Under what circumstances should you leave a helmet in place in a patient with suspected spine injury?
11. Describe the patient presentation in a complete spinal cord injury.
12. Describe the patient presentation in an incomplete spinal cord injury.

CRITICAL THINKING

You arrive on the scene and find an elderly patient who is complaining of severe weakness to her upper extremities. She is alert and responding appropriately to your questions. Her respirations are 22 per minute with a good tidal volume. Her radial pulse is present at a rate of 92 bpm. Her skin is warm and dry. Her SpO₂ reading is 95% on room air. The patient states that she fell while coming down the stairs and struck her face on the floor. You note a contusion to the bottom of her chin. She is also complaining of pain to her neck and cervical region of the spine. She has a history of arthritis and atrial fibrillation. She takes Coumadin for the atrial fibrillation.

The patient’s pupils are equal and reactive to light. Her anterior and posterior neck areas are tender. No deformities are noted. Her breath sounds are equal and clear bilaterally. Her abdomen is soft and nontender. Her pelvis is stable. Her radial pulses are present. She has severe weakness in the upper extremities, but she is moving her lower extremities with no problem. Her BP is 168/88 mmHg, HR 92 and irregular, R 22.

1. What initial emergency care would you provide to the patient?
2. What would you assess in your neurological exam on the patient?
3. Based on the presentation, what type of spinal cord injury do you suspect?
4. What other assessment findings would confirm the type of spinal injury suspected?
5. How would you manage the spinal injury?
Eye, Face, and Neck Trauma

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Trauma (Content Area: Head, Facial, Neck, and Spine Trauma)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

33-1. Define key terms introduced in this chapter.
33-2. Describe the anatomy and function of the eye, face, and structures of the neck.
33-3. Discuss special considerations in the assessment and management of patients with injuries to the eye, face, and neck, including:
   a. Airway compromise
   b. Profuse bleeding
   c. Potential that injuries may be self-inflicted or due to violence
   d. Patient fears associated with these injuries
33-4. Discuss the assessment-based management of patients with injuries to the eye, face, and neck.
33-5. Demonstrate the assessment and management of specific injuries of the eye, including:
   a. Foreign body in the eye
   b. Injury of the orbit
   c. Injury to the eyelid
   d. Injuries to the globe of the eye
   e. Chemical burns to the eye
   f. Impaled objects in the eye
   g. Extruded eyeball
33-6. Explain the indications and procedure for removing contact lenses from an injured eye.
33-7. Demonstrate the assessment and management of specific injuries of the face, including:
   a. Facial fracture
   b. Avulsed tooth
   c. Impaled object in the cheek
   d. Injury to the nose
   e. Injury to the ear
33-8. Demonstrate the assessment and management of specific injuries of the neck, including:
   a. Penetrating injury to the neck
   b. Blunt injury to the neck

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- anterior chamber p. 930
- conjunctiva p. 928
- cornea p. 929
- diplopia p. 930
- eyelids p. 928
- globe p. 929
- iris p. 932
- mandible p. 934
- maxilla p. 934
- orbits p. 928
- pupil p. 928
- sclera p. 933
Case Study

**The Dispatch**
EMS Unit 201—respond to 400 Mill Street—you have a 22-year-old male patient complaining of blindness and severe eye pain. Time out is 1345 hours.

**Upon Arrival**
As you pull into the patient’s driveway, a neighbor greets you: “He’s in the house!” Crossing the patient’s driveway, you see battery jumper cables linking two cars together. Beneath the hood of one of the cars, you see powdery white battery acid sprayed across the engine. Once inside the patient’s home, you hear someone screaming, “My eyes! My eyes! I can’t see!”

**How would you proceed to assess and care for this patient?**

During this chapter, you will learn special considerations of assessment and emergency care for a patient suffering eye, face, and neck injuries. Later, we will return to the case and apply the procedures learned.

---

**INTRODUCTION**

If you have ever experienced a serious eye, face, or neck injury, you can appreciate a patient’s fear and panic associated with one of these emergencies. Aside from the pain, injuries to the eye cause emotional distress as the patient thinks about the possible loss of vision, and the patient who suffers a facial injury may fear permanent scarring or disfigurement. Neck injuries may lead to major bleeding, airway compromise, or permanent nerve damage.

As an EMT, you must remain aware that injuries to the eyes, face, or neck have a high probability of causing airway compromise, severe bleeding, and shock. Additionally, injury to the face and neck is likely to be associated with spinal injury. While caring for these sometimes dramatic or horrific injuries, you must always maintain a high index of suspicion for spinal injury and give first priority to care for life-threatening compromise of the airway and circulation.

---

**ANATOMY OF THE EYE, FACE, AND NECK**

**The Eye**

The globe of the eye, or eyeball (Figure 33-1 ■), is a sphere approximately 1 inch in diameter. It is covered with a tough outer coat called the sclera (the exposed portion of the sclera is “the white of the eye”). The clear front portion of the eye, the cornea, covers the dark center, the pupil, and the colored portion, the iris. The cornea is the window through which light enters the eye. It is extremely sensitive and susceptible to injury. A superficial scratch or the smallest foreign object can cause extreme pain with redness and a flow of tears.

The pupil is the opening that expands or contracts to allow more or less light into the eye through the lens, just behind the pupil. The lens focuses light on the retina, or back of the eye. The inner surface of the...
eyelids and the exposed portion of the sclera are lined with a paper-thin covering called the conjunctiva. The conjunctiva does not cover the cornea.

The interior of the eye contains the anterior chamber (front chamber), which is anterior to the iris and is filled with a watery fluid called the aqueous humor. Behind the lens is the large vitreous body, which is filled with a clear jelly called the vitreous humor. The bony structures of the skull that surround the eyes are called the orbits, or eye sockets.

All of the structures of the eyes, the muscles that hold the eyes in position, and the orbits of the eyes are susceptible to trauma ranging from minor abrasion and irritation, to impaled objects that invade the interior of the eye, to extrusions in which an eye is pulled out of its socket.

The Face

The bones of the skull and face were introduced in Chapter 7, “Anatomy, Physiology, and Medical Terminology.” Collectively the skull is made up of 22 bones, 8 of which form the cranium and 14 that comprise the facial bones. Thirteen of these facial bones—the orbits of the eyes, the nasal bones, the zygomatic bones (cheekbones), and the maxillae (fused upper jawbones)—are immovable. One bone, the mandible (lower jaw), moves on hinged joints.

The face is extremely vascular (contains many blood vessels). Facial injuries, even otherwise minor ones, may bleed profusely. Blood and pieces of broken bone, teeth, and other tissues may cause airway compromise when the face is injured.

The facial bones are part of the skull. They provide minimal protection for the airway and allow points of attachment for the muscles that control facial expressions and the manipulation of food. Compromise of the facial structures (Figure 33-2 ■) can cause a closed or an open brain injury with possible leakage of cerebrospinal fluid from the nose or ears. A mechanism of injury that causes trauma to the face may cause injury to the spine or spinal cord.

**PATHOPHYSIOLOGY PEARLS**

The facial structures are very vascular (contain many blood vessels) and are often injured with blunt and penetrating trauma to the anterior body. For this reason, the EMT should suspect and continuously assess the blunt anterior trauma patient for airway compromise.

The Neck

The major blood vessels and structures of the neck were introduced in Chapter 7, “Anatomy, Physiology, and Medical Terminology.” The anatomy of the neck is of special concern to the EMT because it contains numerous vital structures in a very small space. Body systems represented within the neck include the cardiovascular, musculoskeletal, central nervous, respiratory, digestive, and endocrine. More specifically, the neck contains the major arteries (carotid) and veins (jugular) that carry blood to and from the head. It also contains major structures of the airway, including the trachea and the larynx. Injuries to the neck (Figure 33-3 ■) can cause life-threatening bleeding and airway compromise that can be difficult to control. Damage to structures of the airway is a serious life threat. The posterior neck contains the cervical spine, which houses and protects the proximal spinal cord. Any injury to the neck should automatically be assumed to have caused spinal injury.

---

**FIGURE 33-2** Facial fractures.
The eyes, face, and neck may be subject to a wide variety of injuries. However, these injuries may present you with some challenges in common:

- **Eye, face, and neck injuries can hemorrhage profusely.** You will need to take the necessary Standard Precautions, to include gloves and protective eyewear.
- **Many injuries to the eyes, face, and neck are the result of assault.** In addition, injuries to the neck may be caused by accidental or intentional hanging.
- **You may need to treat emotional trauma as well as physical trauma.** The responsive patient who has suffered an eye injury fears blindness. A face injury arouses fear of permanent facial disfigurement or scarring. A neck injury may cause fear of immediate lethal bleeding or breathing difficulty. These patients, and their friends and family at the scene, may be emotionally distraught or panicked. You will need to display a calm and reassuring manner to gain the patient’s confidence so you can begin care and treatment of the physical trauma.

**Assessment-Based Approach: Eye, Face, and Neck Injuries**

The assessment procedures and considerations described here will apply, overall, to the specific eye, face, and neck injuries described in the rest of this chapter.

**Scene Size-Up**

Because mechanism of injury will guide your treatment, you will want to think about the forces behind the injury as soon as you get the dispatcher’s call. Soft tissue injury to the face and neck is common in trauma. Over half of the cases of facial trauma that present to the emergency department result from motor vehicle crashes, with assaults and sports-related injuries making up the majority of remaining cases.

During the scene size-up it may be difficult to gather information from the patient, because he is likely to be in a state of extreme pain and emotionally distraught. Try to determine the mechanism of injury or nature of the problem from bystanders, friends, or family. Make sure to protect your own safety and call for police backup if the mechanism of injury involves an assault.

**Primary Assessment**

While conducting your primary assessment, keep in mind that severe trauma to the face and neck can cause altered mental status, airway compromise, severe bleeding, and spinal injury. Establish manual in-line stabilization of the head and neck on first contact with the patient. Control major bleeding with direct pressure. Open the airway with a jaw-thrust maneuver and suction vomitus and other substances as needed. Consider advanced life support (ALS) backup, if available, since advanced airway procedures may be required. If necessary, administer supplemental oxygen to maintain an SpO₂ at 94% if breathing is adequate; provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations per minute if breathing is inadequate.

In making a priority decision, consider any patient with chemical burns to the eye, an impaled object in the eye, an extruded eyeball, respiratory distress, severe injuries to the face or neck, major bleeding, suspected spinal column or cord injury, or airway compromise to be a high priority for immediate transport with assessment and care continuing en route.
Secondary Assessment

Conduct a secondary assessment. Inspect and gently palpate for any sign of injury to the eye sockets or bones of the cheek, nose, or jaw. If the patient has suffered an eye injury, use a small penlight to examine the eyes. Never push directly on the eyes.

Record the vital signs and, in patients with severe bleeding, be prepared to treat for shock. Obtain a history. Particularly in the case of eye injuries where time could mean the difference between sight and loss of vision, ask the patient or bystanders questions regarding the events leading up to the injury.

Signs and symptoms of eye, face, and neck injuries, as well as emergency care steps, are detailed throughout this chapter within the sections on the particular injuries you will encounter.

Reassessment

Conduct a reassessment and check interventions. Monitor especially for deterioration of mental status, airway, or breathing. Conduct the reassessment every 5 minutes if the patient is unstable or every 15 minutes if the patient is stable.

SPECIFIC INJURIES INVOLVING THE EYE, FACE, AND NECK

Injuries to the Eye

While usually not life threatening, an injury to the eye can take away the precious gift of sight. Time is a critical consideration in your treatment, particularly in cases such as chemical burns, impaled objects in the eye, or extruded eyeballs.

Assessment and Care Guidelines

When you conduct the physical exam on a patient with an eye injury, assess the eyes separately and together with a small penlight (Figure 33-4a) to evaluate:

- The orbits (eye sockets) for bruising, swelling, laceration, and tenderness
- The eyelids for bruising, swelling, and laceration
- The conjunctivae for redness, pus, and foreign bodies
- The globes for redness, abnormal coloring, and laceration
- The pupils for size, shape, equality, and reactivity to light

Additionally, ask the patient to follow your finger (Figure 33-4b) as you move it left and right, up and down, to evaluate:

- Eye movements in all directions for abnormal gaze, paralysis of gaze, or pain on movement
Consult medical direction or local protocol before irrigating. Some jurisdictions do not permit irrigating an injured eye, except in the case of a chemical burn.

Do not put salve or medicine in an injured eye.

Do not remove blood or blood clots from the eye. Sponge blood from the face to help keep the patient comfortable, but leave the eye alone.

Have the patient lie down and keep quiet. Never let a patient with an eye injury walk without help, especially up or down stairs. The patient should be transported with the head elevated unless other injuries preclude this from occurring.

Limit use of the uninjured eye. It is usually best to cover it along with the injured eye. Eyes move together, and if the patient is using the uninjured eye, chances are the injured eye is moving, too.

Give the patient nothing by mouth in case general anesthesia is required at the hospital.

Every patient with an eye injury must be transported for evaluation by a physician.

Never apply direct pressure to an injured eye.

If possible, bring the liquid or material to which the eye was exposed with the patient. If it is too dangerous or not possible to do so, clearly note the substance and ensure that the information is left with the receiving medical facility personnel.

**Foreign Object in the Eye.** Foreign objects—such as particles of dirt, sand, cinders, coal dust, or fine pieces of metal—can be blown or driven into the eye and lodged there (Figure 33-5 a). A flow of tears often washes out these substances before any harm is done. A patient with a foreign object in the eye will complain of feeling the object, and the globe will appear red. Determine if the patient or others made any attempt to remove the object, possibly causing abrasions to the cornea.

Generally, it is safer to transport the patient for further medical evaluation than to attempt to remove foreign particles from the eye in the field. You should attempt removal only of objects in the conjunctiva, not of those on the cornea or lodged in the globe.

If you need to remove a foreign particle from the conjunctiva, use the following techniques if permitted by medical direction or local protocol: If possible, flush the eye with clean water, holding the eyelids apart (Figure 33-6). **Remember that some EMS systems do not recommend flushing the eye except in cases of chemical burns.**

If you cannot flush the eye, the removal technique depends on where the object is located. To remove an object from the white of the eye, pull down the lower lid while the patient looks up or pull up the upper lid while the patient looks down. Then remove the object with a piece of sterile gauze or a swab (Figure 33-7).

If the object is under the upper lid, draw the upper lid down over the lower lid. As the upper lid returns to its normal position, the undersurfaces will be drawn...
over the lower lashes, possibly removing the object. If the object remains, grasp the lashes of the upper lid and turn the lid upward over a cotton swab or similar object. Carefully remove the object with the corner of a piece of sterile gauze or a swab (EMT Skills 33-1). If the object is under the lower lid, pull down the lid and remove the object with sterile gauze or a swab.

If a foreign object becomes lodged in the eyeball, do not attempt to disturb it. Place a bandage over both eyes and transport the patient as soon as possible.

**Injury to the Orbits.** Trauma to the face may result in the fracture of one or several of the bones that form the orbits of the eyes. If fracture of the orbits is suspected, establish and maintain spinal stabilization. Injuries serious enough to cause orbital fractures may also cause cervical spine trauma.

The signs and symptoms of orbital fracture include the following: dioplopia (double vision); a marked decrease in vision; loss of sensation above the eyebrow, over the cheek, or in the upper lip; nasal discharge; tenderness to palpation; a bony “step-off” (defect in smooth contour of bone); or paralysis of upward gaze in the involved eye (the patient’s eye will not be able to follow your finger upward).

Orbital fractures may require hospitalization and possible surgery. If the signs and symptoms lead you to suspect a possible orbital fracture, take the following emergency care steps: If the eyeball has not been injured, place cold packs over the injured eye to reduce swelling and transport the patient in a sitting position. If you suspect injury to the eyeball, avoid using cold packs and transport the patient in a supine position.

**Lid Injury.** Lid injuries include bruising (black eyes), burns, and lacerations (Figure 33-8 ■). Because the eyelid is richly supplied with blood vessels, lacerations can cause profuse bleeding. Anything that lacerates the lid can also cause damage to the tear drainage system or eyeball, so assess the injury carefully. Inspect the area around the lid for evidence of injury.

To treat a lid injury: Control bleeding with light pressure from a dressing; use no pressure at all if the eyeball itself may be injured. Cover the lid with sterile gauze soaked in saline to keep the wound from drying. Preserve any avulsed skin and transport it with the patient for possible grafting. If eyeball injury is not suspected, cover the injured lid with cold compresses to reduce swelling. Cover the uninjured eye with a bandage to decrease movement, and transport.

**Injury to the Globe.** Injuries to the globe of the eye (Figure 33-9 ■) include bruising, lacerations, foreign objects, and abrasions. Overuse of contact lenses (even extended-wear lenses) can cause corneal abrasions, inflammation of the conjunctiva, and corneal ulcers. Deep lacerations and penetrating injuries can cut the cornea, causing the contents of the eyeball to spill out.

Some injuries to the globe—such as lacerations or embedded objects—are immediately apparent. Other signs and symptoms of injury to the globe may include a pear- or irregular-shaped eyeball and blood in the anterior chamber of the eye (a condition called hyphema). A high-speed activity such as grinding can lead to penetration of the globe with minimal external signs. Globe injuries should be treated with great caution.

Injuries to the globe are best treated at the hospital. In the field: Apply patches lightly to both eyes. Do not use a patch or any kind of pressure if you suspect a ruptured eyeball, since pressure can force the eye contents to leak out. Avoid the use of cold packs over the globe. If you apply an eye shield to the injured eye, be sure that it puts no pressure on the injury. Keep the patient supine, and transport.

**Chemical Burn to the Eye.** A chemical burn to the eye (Figure 33-10 ■) represents a dire emergency. Permanent damage can occur within seconds, and the first 10 minutes of intervention following injury often determine the final outcome. Burning and tissue damage...
will continue to occur as long as any substance is left in the eye, even if that substance is diluted. If, during your scene size-up and primary assessment, you determine the mechanism of injury is a chemical to the eye, you must begin treatment immediately!

The signs and symptoms of chemical burns to the eye include a history consistent with exposure; irritated, swollen eyelids; redness of the eye or red streaks across the surface of the eye; blurred or diminished vision; excruciating pain in the eyes; or irritated, burned skin around the eyes.

In all chemical burns of the eye, immediately begin irrigation with water or saline (Figure 33-11 ■). It need not be sterile, but it should be clean. Hold the eyelids open so all chemicals can be washed out from behind the lids. Continuously irrigate the eye for at least 20 minutes—or if the injury involves alkali, for at least an hour—or until arrival at the hospital. Use running water or continually pour the water or saline from the inside corner, across the eyeball to the outside edge, taking care not to contaminate the uninjured eye. You may have to force the lids open, since the patient may be unable to do so because of pain. If available at the site, have the patient irrigate the eye(s) with an eye wash system. Do not use any irrigants other than sterile saline available on the ambulance or clean tap water. Never irrigate the eye with any chemical antidote, including diluted vinegar, sodium bicarbonate, or alcohol—despite what any well-intentioned bystanders or family may want you to do.

Contact lenses must be removed or flushed out. If left in, they will trap chemicals between the contact lens and the cornea (see the section on contact lens removal later). Remove any solid particles from the surface of the eye with a moistened cotton swab. Place the patient on his side on the stretcher, with a basin or towels under his head, and continue irrigation throughout transport.

Following irrigation, avoid contaminating your own eyes by washing your hands thoroughly and using a nail brush to clean under your fingernails. Bring any bottles in with the patient for further identification.

**Impaled Object in the Eye or Extruded Eyeball.** Impaled or embedded objects in the eye should not be removed. Field care consists of stabilizing the object to prevent accidental movement or removal until the patient receives further medical attention.

During a serious injury, the eyeball may be forced or extruded out of the socket (Figure 33-12 ■). Never attempt to replace the eye in the socket. An impaled object in the eye or an extruded eyeball is a true emergency.

Although an impaled object in the eye or extruded eyeball should be treated with great urgency, you should not manipulate the eye during treatment. Treatment for both is the same (EMT Skills 33-2): Place the patient supine and immobilize the head and spine. Encircle the eye and the impaled object or extruded eyeball with a gauze dressing or other suitable material, such as soft, sterile cloth. Do not apply pressure. You can cut a hole in a single bulky dressing to accommodate an impaled
object. Place a metal shield, crushed paper cup, or cone over the impaled object or extruded eyeball. Do not use a Styrofoam cup, since it can crumble. The impaled object or eyeball should not touch the top or sides of the cup.

Hold the cup and dressing in place with a self-adhering bandage or roller bandage that covers both eyes. Do not wrap the bandage over the cup, which can push the cup down onto the impaled object or extruded eyeball. Make sure you bandage both eyes to prevent eye movement. If the patient is unresponsive or has no gag or cough reflex, consider immobilizing the patient on a backboard.

Give the patient nothing by mouth. Never leave the patient alone, and constantly provide verbal reassurance, because he might panic with both eyes covered. Transport immediately.

Summary: Emergency Care—Eye Injuries

To review possible emergency care for eye injuries, see Figure 33-13.

Removing Contact Lenses

Eye injuries are often further complicated by the presence of contact lenses. To detect lenses, shine a penlight into the eye at a slight angle. A soft lens will show up as a shadow on the outer portion of the eye, while a hard lens will show up as a shadow over the iris. Some patients wear a contact lens in only one eye, so do not dismiss the possibility of contact lenses after examining only one eye. Some patients, especially the elderly, wear both contact lenses and eyeglasses, so you also

Emergency Care Protocol

</tbody>
</table>

If not successful and the object is under the upper lid, draw the upper lid down over the lower lid. |
If the object remains, lift the lid with a cotton swab or similar object and remove with a corner of the sterile gauze or swab.

If the eyeball has not been injured, place ice packs over the injured eye.

If the eyeball is injured, do not use cold packs. (Refer to the following information on management of a globe injury.)

If eyeball injury is not suspected, cover the lid with a cold compress.

Patch both eyes.

Injury to the Globe:

Apply patches to both eyes.

Do not apply any type of pressure.

Apply an eye shield to the injured eye.

Keep the patient supine.

Chemical Burn to Eye:

Begin irrigation with water or saline immediately and for at least 20 minutes or until arrival at the hospital.

Do not contaminate the uninjured eye.

Force the lids open if necessary to flush.

Remove contact lenses.

Remove solid particles from the eye surface with a moistened cotton swab.

Continue to irrigate en route to the medical facility.

Immovilize the patient to a backboard if you suspect spine injury.

Transport.

Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.
can’t dismiss the possibility of contact lenses just because the patient is wearing eyeglasses.

When determining whether to remove contact lenses, seek medical direction and follow local protocol. Generally, you should remove contact lenses if:

- There has been a chemical burn to the eye.
- The patient is unresponsive and is wearing hard contact lenses, and transport time will be lengthy or delayed.

Generally, you should not remove contact lenses if:

- The eyeball is injured (other than a chemical burn).
- Transport time is short enough to allow emergency department personnel to remove the lenses.

Removing Soft Contact Lenses. Even though they are designed for extended wear, soft contact lenses can cause damage if left in for a long time. Over time, they can gradually dehydrate and shrink, adhering to the cornea and making removal difficult.

Soft lenses are slightly larger than a dime and cover all of the cornea and some of the sclera. One way to remove them is to place several drops of saline on the lens, then gently lift the lens off the eye by pinching the lens between your thumb and index finger.

You can also remove soft lenses with the following method (Figure 33-14 ■):

1. With your middle fingertip on the lower lid, pull the lid down.
2. Place your index fingertip on the lower edge of the lens, then slide the lens down to the sclera, or white of the eye.
3. Compress the lens gently between your thumb and index finger, allowing air to get underneath it, and remove it from the eye.
4. If the lens has dehydrated on the eye, run sterile saline across the eye surface, slide the lens off the cornea, and pinch it up to remove it.
5. Store the removed soft contact lens in water or a saline solution.

Removing Hard Contact Lenses. Even though soft contact lenses are much more popular, hard contact lenses are still in use. About the size of a shirt button, they fit over the cornea. To remove (Figure 33-15 ■):

1. Separate the eyelids.
2. Position the visible lens over the cornea by manipulating the eyelids.
3. Place your thumbs gently on the top and bottom eyelids, and open the eyelids wide.
4. Gently press the eyelids down and forward to the edges of the lens.
5. Press the lower eyelid slightly harder and move it under the bottom edge of the lens.
6. Moving the eyelids toward each other, slide the lens out between them.

You can also use a contact lens removal kit, which is commonly available on the ambulance. This is a kit that typically includes a small suction cup, affixed to a handle, which the EMT moistens with saline and uses to remove hard contact lenses. The kit also contains a portable lens case that you can put each contact lens in for safe transporting to the hospital (Figure 33-16 ■).
Injuries to the Face

The specialized structures of the face, prone to injury because of their location, can be permanently and irreversibly damaged (EMT Skills 33-3 and EMT Skills 33-4). Injuries to the face are quite common. Approximately 75 percent of all those involved in motor vehicle accidents sustain at least minor facial trauma. While some injuries to the face are minor, many such injuries are life threatening because they compromise the upper airway. In addition, many injuries of the face stem from impacts strong enough to cause cervical spine damage or skull fracture.

Assessment and Care Guidelines

There are some special assessment considerations you should heed for injuries to the face, mouth, or jaw. During your scene size-up, it is important to consider the mechanism of facial injury. For example, during a head-on collision, did the patient’s head strike the windshield? If so, what was the estimated speed of travel? In patients with trauma to the face, mouth, or jaw, you should suspect possible spinal cord injuries. Patients who sustain significant trauma to the face may also have fractures of the jaw and damage to or loss of teeth.

In any case of severe facial trauma, suspect cervical spine injury. Establish manual in-line stabilization of the spine on first contact with the patient and maintain it until the patient can be completely immobilized to a long backboard. An added benefit of cervical spine stabilization and immobilization is the stabilization of facial bones. During your primary assessment, immediately manage airway, breathing, oxygenation, and circulation problems. Be prepared to suction the immobilized patient. Severe trauma to the face may cause an altered mental status from possible head injury or hypoxia from airway compromise.

In patients with a significant mechanism of injury, conduct a secondary assessment. Inspect and palpate for evidence of trauma. When the mandible (lower jaw) is fractured, it is generally broken in at least two places and will be unstable. Bruising and swelling may be obvious. Fracture of the maxilla (upper jaw) is often accompanied by a black eye. The face may appear elongated, and the patient’s bite will no longer be even. Again, swelling may be noticeable.

In the field, you do not need to diagnose whether a fracture has actually occurred. If the patient has any pain, swelling, deformity, crepitation, discoloration, or instability to the face, maxilla, or mandible—provide emergency care as follows:

1. Establish and maintain in-line spinal stabilization.
2. In establishing and maintaining a patent airway, do the following:
   - Inspect the mouth for small fragments of teeth or broken dentures, bits of bone, pieces of flesh, or foreign objects (such as pieces of broken glass). Pick them from the mouth or remove them with finger sweeps as thoroughly as possible.
   - If dentures are in the mouth and are secure and unbroken, leave them in place; they can help support the structures of the mouth. If dentures are broken or loose, remove them. Transport any dentures or pieces of dentures with the patient so the surgeon can use them to establish proper alignment when wiring the jaw.
   - In facial injury, the tongue may lose its support structure and may fall back, occluding the airway. Open the airway using a jaw-thrust maneuver and, if necessary, grasp the tongue to pull it forward. If possible, insert an oropharyngeal airway.
   - Suction any blood, vomitus, secretions, or small debris from the mouth and oropharynx throughout treatment and transport.
   - Request ALS backup, if needed and available, to provide advanced airway management.

3. If necessary, administer supplemental oxygen to maintain an SpO₂ of 94% or greater or, if breathing is inadequate, begin positive pressure ventilation with supplemental oxygen at a rate of 10–12 per minute in the adult and 12–20 per minute in an infant or child. It may be difficult to get a good mask seal with facial injuries.

4. Control severe bleeding. Several major arteries run through the face, and they can bleed profusely and rapidly enough to cause death if left unmanaged. Use direct pressure and pressure dressings. Apply pressure gently if you suspect fractured or shattered bones under the wound as pressure may further obstruct an already endangered airway.

5. If nerves, tendons, or blood vessels have been exposed, cover them with a moist, sterile dressing.

Pathophysiology Pearls

Facial injuries may need aggressive maneuvers to establish and maintain an airway. Since there is a high likelihood of head injury with facial trauma, hypoxia from an occluded airway could lead to severe secondary brain injury.
Avulsed Tooth. If a tooth has been lost, try to find it. The tooth may be reimplanted. To treat for an avulsed tooth:

- Rinse the tooth with saline to gently remove any debris; never scrub the tooth. Transport the tooth in a cup of saline or wrapped in gauze soaked in sterile saline. Seek medical direction. Follow local protocol. Never wrap the tooth in dry gauze. Guard against the tooth drying out.
- Never handle the tooth by the root; there may still be ligament fibers attached that could enable successful reimplantation.
- If you cannot find teeth that have been knocked out, assume that the patient has swallowed or aspirated them.
- Control bleeding from the tooth socket with a gauze pad.

Injury to the Midface, Upper Jaw, or Lower Jaw. Midface and jaw injuries (Figure 33-17) may be simple, such as undisplaced nasal fractures, or extensive, involving severe lacerations, bony fractures, and nerve damage. Such injuries can result from a blunt instrument, a blow from the fist, an automobile accident, or a gunshot.

The following are signs and symptoms of fracture or other severe trauma to the midface, upper jaw, and lower jaw:

- Numbness or pain
- Distortion of facial features
- Crepitation
- Irregularities in the facial bones that can be felt before swelling occurs
- Severe bruising and swelling; black eyes
- Distance between the eyes too wide or eyes not level
- Bleeding from the nose and mouth
- Diplopia (when the orbit is fractured)
- Limited jaw motion
- Palpable movement to the maxilla
- Teeth not meeting normally (malocclusion)
- Hematoma (collection of blood) under the tongue
- Limited jaw motion
- Mouth open or patient unable to open the mouth
- Saliva mixed with blood flowing from the mouth
- Drooling (pain prevents the patient from swallowing)
- Painful or difficult speech

- Missing, loosened, or uneven teeth (even if teeth are not missing, the patient may complain that teeth do not “fit together right”)
- Pain around the ears
- Elevation of the tongue

As emphasized earlier, you do not need to diagnose whether a facial fracture has actually occurred. If there is a significant mechanism of injury and any of the signs and symptoms just listed, treat as if a fracture has occurred. Your first priorities are establishing and maintaining spinal stabilization and a patent airway, supporting breathing as necessary, maintaining adequate oxygenation, and controlling life-threatening bleeding. Request ALS backup if needed and available, because patients with severe facial trauma may be difficult to ventilate and require advanced airway procedures. Assess for spine injury, skull and/or brain injury, eye injury, and facial burns, which are commonly associated with facial injury.

Object Impaled in the Cheek. If the patient has a foreign object impaled in the cheek, stabilize it with bulky dressings and transport the patient. If the object has penetrated all the way through the cheek and is loose—such that it may fall into the mouth, obstructing the airway—you need to remove it as follows:

1. Pull or push the object out of the cheek in the opposite direction to which it entered the cheek.
2. Pack dressing material between the patient’s teeth and the wound. Leave some of the dressing outside the mouth and tape it there to prevent the patient from swallowing the dressing. Monitor closely to make sure the dressing doesn’t become loose and compromise the airway.
3. Dress and bandage the outside of the wound to control bleeding.
4. Suction the mouth and throat frequently throughout transport.

Injury to the Nose. Soft tissue injuries to the nose should be assessed and cared for as you would other soft tissue injuries (EMT Skills 33-5). Take special care to maintain an open airway, and position the patient so that blood does not drain into the oropharynx or pharynx. Nasal fractures are the most common type of facial fracture because of the delicate structure of the nose. If a nasal fracture involves only the cartilaginous septum, it usually results in deformity, swelling, pain, and minor hemorrhage. If, however, the trauma is severe enough to break the underlying nasal bones and deeper nasal structures, such as the ethmoid bones, significant hemorrhaging can occur—especially if the vascular supply of the nasal turbinates is involved. In such cases, airway obstruction is of great concern. For information on the emergency medical care of nosebleeds, see Chapter 28, “Bleeding and Soft Tissue Trauma.” Never pack the injured nose; clear or bloody fluids can indicate a skull fracture, and packing the nose can create dangerous pressure. Additional treatment includes the application of cold compresses to reduce swelling, and transport.
Foreign objects in the nose usually occur among small children. To treat, reassure and calm the child and parent, then transport the patient. Do not try to remove the object.

The most common signs and symptoms are swelling and deformity.

**Injury to the Ear.** Cuts and lacerations of the ear are common (EMT Skills 33-6). Occasionally, a section of the ear may be severed. The pinna—the visible, exposed portion of the ear—is frequently traumatized with injuries to the head. Because of the limited blood supply to this cartilaginous framework of the external ear, it does not bleed significantly when injured. Assess and treat as for other soft tissue injuries. Save any avulsed parts; wrap avulsed parts in saline-soaked gauze, and transport with the patient. When dressing an injured ear, place part of the dressing between the ear and the side of the head. As a general rule, don’t probe into the ear. Never pack the ear to stop bleeding from the ear canal. Clear or bloody fluid draining from the ear can indicate a skull fracture. Place a loose, clean dressing across the opening of the ear to absorb blood and fluids, but do not exert pressure to stop the bleeding.

Foreign objects in the external ear are a common problem among children. Do not attempt to remove the object. Instead, reassure the child and parent and transport the patient to the hospital.

**Summary: Emergency Care—Facial Injuries**

To review possible emergency care for facial injuries, see Figure 33-18. 

---

**Emergency Care Protocol**

**FACIAL INJURY**

1. Establish manual in-line stabilization. Do not release it until the patient is immobilized onto the backboard if spinal injury is suspected.
2. Establish and maintain an open airway. Avoid using a nasopharyngeal airway if there is midface or nasal trauma.
3. Suction blood and secretions as necessary. Remove any broken teeth or loose bone fragments from the mouth.
4. If dentures are in the mouth and secure, leave them in place. If the dentures are loose, remove them.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 95% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary if the injury is isolated to the soft tissue of the face. If massive facial injury, severe blood loss, head injury, spine injury, or multiple injuries are present, or signs of hypoxia or respiratory distress are present, or the SpO2 reading is less than 95%, administer O2 to maintain an SpO2 of 95% or greater.
7. Control any major bleeding.
8. Apply a moist sterile dressing to any exposed nerves, tendons, or blood vessels.
9. Treat specific injuries as follows:
   - **Avulsed Tooth:** Rinse with saline; do not scrub or handle the tooth by the root.
   - Place in a cup with sterile saline or wrap in gauze soaked in sterile saline.
   - Do not wrap in dry gauze.

---

Control the bleeding from the tooth socket with a gauze pad. Make sure that the pad does not work loose and become an airway obstruction.

**Foreign Object in Cheek:**
- If the object did not penetrate completely through the cheek or is not loose, use bulky dressings to stabilize the object in place.
- If the object penetrated through to other side of the cheek and is loose, do the following:
  - Push or pull the object out of the cheek in the same direction it entered.
  - Pack with dressings between the teeth and wound; make sure dressings do not work loose and become an airway obstruction.
  - Dress and bandage outside of wound.
  - Suction blood as necessary.

**Injury to Nose:**
- Manage as a soft tissue injury.
- Position the patient to allow blood to drain.
- Do not pack the nose.
- Transport if a foreign body is in the nose.
- Suction blood as necessary.
- Apply cold compresses if a nose fracture is suspected.

**Injury to Ear:**
- Manage as a soft tissue injury.
- Save avulsed parts; wrap in saline-soaked gauze and transport with patient.
- Place part of dressing between the ear and side of head.
- Do not probe into the ear.
- Do not pack the ear.
- Place a loose dressing over the ear to absorb blood and fluid; do not apply pressure.
- Do not attempt to remove foreign objects in the ear.

10. Immobilize the patient to a backboard if you suspect spine injury.
11. Transport.
12. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.
Injuries to the Neck

The neck can be injured by any blunt or penetrating trauma (EMT Skills 33-7). Common causes include hanging (accidental or intentional), impact with a steering wheel, knife wounds, gunshot wounds, or running or riding into a stretched wire or clothesline. In cases of accidental or intentional hanging, call law enforcement. If the neck is lacerated, bleeding from a major artery or vein can occur. Air may enter a lacerated vein. Other common consequences of neck injuries are a fractured larynx and a collapsed trachea. Do not overlook the possibility of a cervical spine injury.

Besides obvious lacerations or other wounds, signs and symptoms of an injured neck include the following:

- Obvious swelling, bruising, or hematoma formation
- Difficulty speaking
- Change in or loss of the voice
- Subcutaneous emphysema in the neck
- Airway obstruction that is not obviously due to other sources (such obstruction may be caused by swelling of the throat)
- Crepitation heard during speaking or breathing as air escapes from an injured larynx
- Displacement of the trachea to one side (also a sign of possible chest injury)

Maintaining an airway is extremely important in neck injuries, because—in addition to swelling or presence of damaged airway structures or debris such as bone fragments—blood will clot when it is exposed to air and can threaten the airway. Maintain a high index of suspicion for possible cervical spine injury.

To treat a neck injury, use proper Standard Precautions, establish and maintain in-line spinal stabilization, establish a patent airway, maintain adequate oxygenation with supplemental oxygen if necessary or provide positive pressure ventilation with supplemental oxygen if breathing is inadequate, control severe bleeding, treat for shock, and transport. Of special concern is a laceration of the jugular vein. Jugular vein laceration could permit development of an air embolism, because venous pressure drops below atmospheric pressure during deep inhalation if the patient is breathing spontaneously. In that circumstance, the negative pressure in the vein may suck in air. For this reason, quick application of an occlusive dressing for this type of injury is necessary. Consider requesting ALS backup if advanced airway management is needed, especially with laryngeal or tracheal injuries.

If one of the major blood vessels of the neck is severed, follow the guidelines for care that were outlined in Chapter 28, “Bleeding and Soft Tissue Trauma,” and summarized in EMT Skills 33-8. When treating bleeding wounds to the neck, never probe open wounds or use circumferential bandages, which can interfere with blood flow to the brain on the uninjured side of the neck and can also impair respiration.

Summary: Emergency Care—Neck Injuries

To review possible emergency care for neck injuries, see Figure 33-19.

---

**Emergency Care Protocol**

**NECK INJURY**

1. Establish manual in-line stabilization. Do not release it until the patient is immobilized onto a backboard if spinal injury is suspected.
2. Control any major bleeding from the neck by applying direct pressure.
3. Establish and maintain an open airway. Avoid using a nasopharyngeal airway if there is midface or nasal trauma.
4. Suction secretions as necessary.
5. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
6. If breathing is adequate, the SpO₂ reading is greater than 95%, and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary if the injury is isolated to the soft tissue of the neck and no major bleeding is present. If severe blood loss, head injury, spine injury, or multiple injuries are present, or signs of hypoxia or respiratory distress are present, or the SpO₂ reading is less than 95%, administer O₂ to maintain the SpO₂ at 95% or greater.
7. Apply a nonporous dressing taped on four sides.
8. Immobilize the patient to a backboard if you suspect spine injury.
10. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

**FIGURE 33-19** Emergency care protocol: neck injury.
**EMT SKILLS 33-1**

**Removal of Foreign Object—Upper Eyelid**

- **33-1A** Grasp eyelashes between the thumb and forefinger and tell the patient to look downward.

- **33-1B** Place an applicator swab along the center of the upper eyelid.

- **33-1C** Pull the eyelid forward and upward over the applicator swab.

- **33-1D** The undersurface of the eyelid is exposed and the foreign object can be gently removed with a sterile, moistened applicator swab.

**EMT SKILLS 33-2**

**Emergency Care—Impaled Object in the Eye**

- **33-2A** Impaled object in the eye.

- **33-2B** Place padding around the object.
33-2C Stabilize the impaled object with a cup.

33-2D Bandage the cup in place.

Once bleeding is controlled, apply a pressure dressing. A figure-eight bandage is wrapped over the dressing, across one shoulder, across the back, under the opposite armpit, and anchored at the shoulder.

If spinal injury is not suspected, position the patient on his left side, head tilted downward. If spinal injury is suspected and the patient is immobilized to a spine board, board and patient can be turned and tilted as a unit. Continue administration of oxygen. Care for shock, and transport.
SUMMARY

During a career in EMS, the EMT will encounter many patients with significant injuries. Few of these will rival the potentially gruesome and clinically challenging patient with severe facial or neck trauma. Understanding the anatomy, physiology, injury presentation patterns, and management principles will allow the EMT to provide optimum emergency care to these patients and keep morbidity and mortality to a minimum.

Even though most facial and neck trauma is not life threatening, there will be patients whose injuries require immediate intervention, because without it the likelihood of death or permanent disability is high. So long as the EMT follows a well-grounded assessment procedure and employs airway control, spinal immobilization, ventilatory support, and oxygenation as appropriate, along with soft tissue management—as described in this chapter—the patient will receive the best care possible.

Scene Size-up
You and your partner have been dispatched to a 22-year-old male patient complaining of blindness and severe eye pain. As you approach the patient’s driveway, you see no safety hazards. Walking past two vehicles with jumper cables, you begin to think the mechanism of injury might be an exploding car battery. The sight of white battery acid sprayed across the car hood and a brief talk with a neighbor confirm your suspicion. The neighbor tells you the patient was smoking a cigarette over the car battery when there was a big explosion.

Once inside the patient’s house, you find him running around the living room with a wet towel wrapped around his face. You try to calm him. He tells you his name is Hector Fernandez. He says he can’t see, and it hurts “really bad.”

Primary Assessment
Since he is talking to you and answers questions appropriately, you determine that Hector’s airway, breathing, and mental status are adequate. He denies breathing difficulty but tells you both eyes are extremely painful. Your general impression is that Hector seems alert and oriented, but he needs eye care immediately or he’ll be in danger of losing his sight.

Quickly you walk the patient into the kitchen. You ask if he is wearing contact lenses. He says “no.” You direct the patient to lean over the sink. Next you turn on the faucet and direct Hector to lean under it. You have him turn his head from side to side so that the water runs from the medial to the lateral side of each eye in turn.

Secondary Assessment
You are unable to conduct an exam of Hector’s eyes while he is irrigating them at the kitchen sink, but your partner is able to take Hector’s baseline vitals. He reports Hector’s pulse at 120 bpm; blood pressure is 140/80 mmHg. His skin is warm and dry. His respirations are regular at 24 per minute. Meanwhile, you are able to gather a history from Hector who replies to your questions while continuing to keep his eyes under the running water. He describes the pain to his eyes as “about 7 or 8” on a scale of 1 to 10. He reports no known allergies and is not taking any medications or seeing a doctor for any medical problems. His last oral intake was lunch about an hour ago. Events leading to the present problem were, as described by the neighbor, an explosion of battery acid while he was working on his car.

While you are busy treating Hector’s eyes, your partner conducts a secondary assessment to see if there were further injuries from the battery explosion. He does not find any further trauma. Medical direction instructs you to irrigate for a total of 20 minutes prior to transport and continue to irrigate en route.

After 20 minutes of irrigation with copious amounts of tap water, Hector’s pain decreases. He says, “I can see, now—some.” You place Hector on his side on the stretcher with a basin under his head. You continue irrigation with your ambulance’s bottled water and transport.

Reassessment
You perform a reassessment. Hector’s vital signs are stable, and you reassess his eyesight to find that it continues to improve. Once at the hospital, you transfer Hector to the care of emergency department personnel, provide an oral report, complete your prehospital care report, and prepare the ambulance for return to service.

Case Study Follow-up

CHAPTER 33 • Eye, Face, and Neck Trauma
IN REVIEW

1. Describe the emergency care that may need to be undertaken during primary assessment of eye, face, or neck injuries.
2. Explain why, during the primary assessment, you should consider requesting advanced life support backup for injuries to the eyes, face, or neck.
3. Describe how to conduct the physical exam of a patient with an eye injury.
4. List the basic rules of emergency care for eye injuries.
5. Describe the emergency care steps for a patient with a foreign object (a) located on the white of the eye, (b) located under the upper eyelid, and (c) lodged in the eyeball.
6. Describe the emergency care steps for a patient with a chemical burn to the eye.
7. List the reasons for removing, and the reasons for not removing, contact lenses from a patient with an eye injury.
8. List the general emergency medical care guidelines for injuries to the face, mouth, and jaw.
9. Describe the care for a foreign object in the nose or ear.
10. In addition to obvious lacerations or wounds, list the signs and symptoms of neck injury.

CRITICAL THINKING

You are called one night for domestic violence. While en route, dispatch advises that the police are also en route and that you are to stage in the area until confirmation is received from the responding patrol officers that the scene is safe to enter. While you are staging, your partner quickly scans through the trauma bag to ensure that all supplies are there and that the oxygen level in the tank is good, since you have been running calls all day long. After about a 5-minute wait, you get the signal from dispatch that the police have entered the scene and it is now secure and safe for your entry. The police report that you have one male patient, 17 years of age, who was in an altercation with his stepfather.

Upon repositioning your ambulance outside the address and donning your protective equipment, you and your partner cautiously enter the scene. You first see the police with a handcuffed male adult, who they tell you reportedly attacked his stepson for coming home “drunk.” The patient, a 17-year-old male, is found in the kitchen, where you see a moderate amount of blood splattered on the wall and countertop, and a bloodied handheld blender lying about 6 feet away. You stay away from the blender, as this is possible crime scene evidence that should not be disturbed.

During the primary assessment, you quickly discern that the patient is not alert or responding to verbal or painful stimuli and that there is an odor resembling alcohol about him. You also note extensive facial trauma, with his right eye almost completely extruded. The patient’s nose is markedly deformed and displaced to the right, there is a large laceration to his upper lip bleeding briskly, and you can hear audible gurgling as the patient tries to breathe. You quickly glance at your partner to tell him to call for ALS backup, but you see him already lifting the portable radio to do so.

1. What is the most important initial step the EMT should perform in the management of this patient?
2. Briefly describe three different reasons that may explain why this patient is unresponsive.
3. If attempts at clearing the airway with suctioning fail, how else may the EMT ensure the adequacy of this patient’s airway?
4. After treating all life threats, what would be the specific management for the eye injury?
5. What could be the advantage of calling ALS backup for this patient?
Chest Trauma

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Trauma** (Content Area: Chest Trauma)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

34-1. Define key terms introduced in this chapter.
34-2. List the major structures of the thoracic cavity.
34-3. Define and list specific types of open chest injury.
34-4. Define and list specific types of closed chest injury.
34-5. Explain the pathophysiology of each of the following injuries:
   a. Flail segment
   b. Pulmonary contusion
   c. Open pneumothorax, tension pneumothorax, hemothorax
   d. Traumatic asphyxia
   e. Cardiac contusion
   f. Pericardial tamponade
   g. Rib injury
   h. Commotio cordis

34-6. Discuss an assessment-based approach to manage patients with chest trauma.
34-7. Discuss the following aspects of chest trauma care:
   a. General emergency care for chest trauma
   b. Specific emergency care for an open chest wound
   c. Specific emergency care for a flail segment

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- cardiac contusion p. 952
- commotio cordis p. 953
- flail segment p. 948
- hemoptysis p. 957
- hemothorax p. 952
- open pneumothorax p. 951
- paradoxical movement p. 949
- pericardial tamponade p. 953
- pneumothorax p. 947
- pulmonary contusion p. 950
- sucking chest wound p. 948
- tension pneumothorax p. 948
- traumatic asphyxia p. 952
Case Study

The Dispatch
EMS Unit 106—respond to the corner of Mark et Street and Breaden Avenue—you have a man down with an unknown problem—be advised that this was called in by a person driving by. Time out is 2206 hours.

Upon Arrival
As you and your partner are turning the corner onto Market Street, you note what appears to be a man lying in a prone position on the sidewalk. You pull up to the scene and turn on the driver-side scene lights. You look for any other people or activity. It is a cold night and the patient is dressed in a heavy overcoat. You can hear him moaning as you step out of the ambulance. As you approach the patient, you say, “Sir, we are emergency medical technicians, and we are here to help you. Can you tell me if you are hurt or ill?” The patient responds with a moan.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency medical care for patients suffering from chest trauma. Later, we will return to the case study and put in context some of the information you learned.

INTRODUCTION

Most injuries to the chest are not characterized by large, gaping wounds. Unlike some injuries to the extremities, they rarely involve bones protruding through the skin. Injuries to the chest, in fact, are often not very dramatic in appearance and can be easily overlooked in the physical assessment. The patient may actually complain of much more pain from injuries to bones and joints or from surface lacerations and abrasions. Initially, the patient may not even realize that he has a serious injury to the chest.

It is important to understand, however, that the chest contains vital organs, and injuries to the chest may be lethal. Chest injuries can cause a disturbance in respiration, oxygen exchange, and circulation and may produce severe internal bleeding and shock. Rely on the mechanism of injury, a high index of suspicion, and careful physical examination to determine and then care for life-threatening injuries to the chest.

THE CHEST

Anatomy of the Chest

Before you read this section on chest injuries, it may be helpful to review Chapter 7, “Anatomy, Physiology, and Medical Terminology,” for descriptions of the structures and organs of the chest, as well as the anatomy and physiology of the circulatory and respiratory systems.

To recap briefly, the chest cavity is also known as the thoracic cavity (Figure 34-1). It is surrounded by the ribs, which form a bony cage around the organs of the respiratory and circulatory systems. The thoracic cavity is bordered inferiorly by the diaphragm, which separates it from the abdominal cavity. A hollow area, the mediastinum, is located in the middle of the thoracic cavity between the right and left lungs. The mediastinum houses the trachea (conduit to the lungs), the venae cavae (the two great veins that collect blood from the upper and lower body and return it to the heart), the aorta (the great artery carrying blood from the heart to the body), the esophagus (the tubelike structure that connects the pharynx with the stomach), and the heart.

With this collection of vital organs, it is easy to see why injury to the chest can be life threatening.

The pleural lining of the thorax plays a major role in some types of chest injuries. The pleura consists of the visceral pleura and the parietal pleura. The visceral pleura is the innermost layer and is in contact with the lung. The parietal pleura is the outermost layer and is in contact with the thoracic wall. The two pleural layers
are separated by serous fluid that provides lubrication to reduce the friction between them.

Between the pleural layers is a potential space. Because of the pull of the parietal pleura on the visceral pleura during inhalation, the pressure between the pleura is negative. It acts like a vacuum. As an example, a similar pull or vacuum would be created by placing a glass on a flat countertop surface with a film of water between the glass and the countertop and then pulling straight up on the glass. A vacuum is created between the glass and the countertop. The more forcefully you pull up on the glass and try to separate it from the countertop, the greater the negative pressure that is created. Thus, each time the chest wall expands, the negative pressure or vacuum between the pleura increases.

**PATHOPHYSIOLOGY PEARLS**

The constant pull or tug caused by the lung tissues’ natural tendency to recoil and collapse creates the constant negative pressure inside the pleural space.

If a puncture to the visceral pleura, the parietal pleura, or both pleura occurs, the seal is broken and air is sucked into the pleural space each time the chest wall expands. As the pleural space expands, it creates pressure on the lung and the lung collapses, leading to a pneumothorax (Figure 34-2). Since no gas exchange occurs outside of the alveoli, the air that flows into the pleural space is not contributing to gas exchange. As the lung continues to collapse, the gas exchange becomes more and more disturbed, and the patient becomes hypoxic.

This concept plays a major role in understanding chest injuries and open wounds to the chest. If an open wound to the chest is at least two-thirds the internal diameter of the trachea, a significant amount of air will be sucked into the open wound to the chest and into the pleural space, and not through the trachea and into the lungs. The normal adult trachea is about the size of a quarter. A hole about the size of a nickel would be a severe injury that would lead to a significant lung collapse.

**General Categories of Chest Injuries**

There are two general categories of chest injuries: open and closed. Closed injuries to the chest are the result of blunt trauma applied to the chest cavity, which can cause extensive damage to the ribs and internal organs. Blunt trauma is often associated with falls, automobile crashes, and blows to the chest.

**Open Chest Injury**

An open chest injury is the result of a penetrating chest wound caused by a knife, gunshot, or a wide variety of other objects such as ice picks, screwdrivers, letter openers, broken glass, nails, and car keys. A knife or similar object damages the tissues and organs along the path of penetration. A bullet, however, can make a tiny entrance wound to the chest in one area, ricochet around, and cause extensive internal damage throughout the chest cavity. It may create a second, or exit, wound, which is typically larger than the entrance wound if the bullet leaves the body (Figure 34-3). A bullet, because of its velocity, also causes cavitation—a hollowing-out of tissues along the path of the bullet that is much greater in diameter than the bullet itself.
The heart is a special type of contractile muscle. It can be injured by both penetrating and blunt trauma: a knife or bullet, a fractured rib that slices into the heart or lung, or even the simple transmission of kinetic energy from a blow to the chest or impact with a steering wheel. Injury to the heart can lead to ineffective pumping or to severe blood loss.

The major vessels in the chest carry large amounts of blood, some at very high pressures, and if injured can result in immediate death.

The organs and structures responsible for breathing are also contained in the chest. Inhalation occurs when the muscles between the ribs, the intercostal muscles, pull the ribs upward to increase the size of the rib cage. The diaphragm contracts and moves slightly downward and flares the bottom portion of the ribs outward. This expands the space in the thoracic cavity, thus generating negative pressure, or a vacuum, which causes the lungs to inflate and “pull in” air from the atmosphere. Any gas will flow from a higher pressure to a lower pressure area. When the thoracic cavity expands and the lungs inflate, the pressure inside the lungs is lower than in the atmosphere and, as a consequence, atmospheric air flows into the airway and lungs. The reverse happens during exhalation when the intercostal muscles and diaphragm relax, the thoracic cavity gets smaller, and the pressure in the lungs becomes higher than in the atmosphere, so that air flows out of the lungs.

The ability of the lungs to inflate is seriously impeded when there is an open chest wound—when the chest wall is penetrated and air flows into the thoracic cavity around the lungs. As noted earlier, air in the chest cavity is called a pneumothorax; from pneumo, meaning “air,” and thorax, meaning “chest.” Pneumothorax can be caused even when there is no open wound to the chest: For example, a fractured rib can penetrate a lung, causing air to flow from the lung into the surrounding chest cavity, collapsing the lung. (Also see the following discussion of pneumothorax under “Specific Chest Injuries.”)

An open chest wound can pull air into the thoracic cavity, sometimes with a noticeable sucking sound. This is referred to as a **sucking chest wound**. There are two problems in managing an open or sucking chest wound. One is preventing additional air from being sucked into the chest cavity, and the other is avoiding trapping the air that is already in the chest cavity.

Cover a sucking chest wound with your gloved hand on first identifying it, then apply a nonporous dressing and tape it on three sides. This will prevent both pulling in additional air and trapping air that is already in the cavity. (A **tension pneumothorax** that is caused by air leaking into the chest cavity from a damaged lung with no opening through the outer chest wall cannot be managed by EMTs in the prehospital setting. Early recognition and rapid transport is especially critical in this situation. See more about tension pneumothorax under “Specific Chest Injuries.”)

### Closed Chest Injury

A closed chest injury occurs when blunt trauma is applied to the chest but no open wound results. Injury to the lung, heart, great vessels (aorta and vena cava), respiratory tract, diaphragm, and esophagus can result from blunt trauma. A common life-threatening closed chest injury occurs when two or more adjacent ribs are broken in two or more places. This creates a segment of the chest that is unattached to the rest of the rib cage, an injury known as a **flail segment** (Figure 34-4). A flail segment may also result from more than one rib being fractured and separated from the cartilage along the edge of the rib cage.

A large, unstable flail segment is life threatening because it interferes with proper expansion of the chest.
cavity, causing intrathoracic pressure changes and severe respiratory distress or inadequate respiration and rapid patient deterioration. Also, it is commonly associated with underlying lung injury.

### Specific Chest Injuries

A variety of chest injuries can result from either penetrating or blunt trauma to the chest. Because these injuries can interfere with ventilation, oxygenation, or perfusion, they are considered to be, in most cases, life threatening.

#### Flail Segment

As already mentioned, a flail segment occurs when two or more consecutive ribs have been fractured in two or more places, producing a freely moving section of chest wall. During inhalation and exhalation, the flail segment displays **paradoxical movement**, that is, the flail segment moves in a direction opposite to the movement of the rest of the chest wall (Figure 34-5).

The effects of pressure during inhalation and exhalation explain why paradoxical movement happens. Inhalation takes place when the chest expands, making pressure inside the chest less than the pressure outside the chest, which causes air to push in from outside the lungs. The pressure that draws air into the expanded chest also moves the flail segment inward. Exhalation takes place when the pressure inside the chest becomes greater than the pressure outside the chest, pushing air out of the lungs and decreasing the size of the chest. The pressure that pushes air out of the contracting chest also pushes the flail segment outward. This is why a flail segment displays paradoxical movement, moving inward while the rest of the chest is moving outward, and moving outward when the rest of the chest is moving inward.

The flail segment requires immediate recognition and management, but the underlying contusion to the lung is a more serious injury, resulting from the blunt force applied to the chest. The flail segment will prevent the chest from generating the normal negative pressure necessary for inhalation. This may reduce the volume that can be breathed in, leading to hypoxia (oxygen deficiency) and poor oxygenation. With lung contusion, gas exchange between the alveoli and pulmonary capillaries is reduced, leading to hypoxemia.

Stabilization of the segment may reduce the paradoxical movement; however, it may also compromise other chest wall motion and lead to the collapse of more lung tissue and alveoli. Therefore, placing the patient on the injured side or stabilizing with sandbags or other devices that compromise chest wall motion are contraindicated. Because lung contusion and lung collapse are associated with a flail segment, continuous positive airway pressure (CPAP) or positive pressure ventilation with supplemental oxygen is the ideal treatment.
It expands the alveoli that are collapsed, greatly reducing the amount of hypoxia (oxygen deficiency) by forcing ventilation and increasing oxygenation. However, it should only be performed if the patient is demonstrating signs of respiratory distress or failure.

**ASSESSMENT TIPS**

Immediately after an injury, a flail segment may be stabilized by contraction of the intercostal muscles and may not initially produce dramatic paradoxical movement. However, as the muscles begin to fatigue, the stabilization provided will be reduced and obvious paradoxical movement may be seen.

**Pulmonary Contusion**

**Pulmonary contusion** (bleeding within the lung tissue) is often a serious consequence of a flail segment and can lead to death. Bleeding occurs in and around the alveoli and into the interstitial space that separates the alveoli and capillaries. This greatly reduces the exchange of oxygen and carbon dioxide, leading to severe hypoxia (oxygen deficiency) (Figure 34-7).

A patient who has suffered a direct blow or any other blunt trauma to the chest should be suspected of having a pulmonary contusion. Such injuries are often seen in association with a flail chest.

The amount of respiratory distress depends on the amount of damaged lung tissue. Other signs and symptoms include dyspnea (shortness of breath), cyanosis, and signs of blunt trauma to the chest. Emergency care is directed toward support of ventilation and administration of supplemental oxygen to maintain an SpO2 at 94% or greater. If supplemental oxygen alone is not able to improve or maintain adequate oxygenation in the alert and spontaneously breathing patient who is in respiratory distress, the use of continuous positive airway pressure (CPAP) may improve oxygenation. If the patient has inadequate breathing, positive pressure ventilation with supplemental oxygen must be initiated.

**Pneumothorax**

As noted earlier, a pneumothorax is the accumulation of air in the pleural cavity, causing collapse of a portion of the lung. It is usually due to either blunt or penetrating trauma. Blunt trauma may cause a fractured rib to penetrate the lung, leaving a hole that leaks air. The lung may rupture if, upon impact and chest compression, the patient’s epiglottis is closed over the trachea. This causes a “paper-bag effect” similar to an inflated paper
A bag that is sealed and ruptures when it is compressed between the hands. The resultant hole in the visceral pleura of the lung allows air to enter the thoracic cavity. Penetrating trauma is another way the lung can be punctured.

The accumulation of air in the thoracic cavity causes the lung on the injured side to collapse, either partially or fully. This results in decreased volume within the alveoli, which causes a reduction of oxygen delivered to the cells of the body. Signs and symptoms of a pneumothorax include chest pain that worsens with deep inspiration, dyspnea (shortness of breath), tachypnea (faster than normal rate of breathing), and decreased or absent breath sounds on the affected side. A patient may suffer a pneumothorax in the absence of blunt or penetrating trauma to the chest. This condition is called a spontaneous pneumothorax, because it occurs without an external cause. It usually is the result of a congenitally weak area on the surface of the lung (called a bleb), which ruptures and allows air to enter the thoracic cavity. Spontaneous pneumothorax is common among smokers and emphysema patients. A sudden onset of dyspnea (shortness of breath), respiratory distress, sharp chest pain, and absent breath sounds on one side are typical signs and symptoms.

### Open Pneumothorax

An open pneumothorax is a result of an open wound to the chest created by a penetrating object (Figure 34-8). Air may be heard escaping or entering through the chest wound, creating a bubbling or sucking sound. An open pneumothorax is referred to as a "sucking chest wound," as discussed earlier in this chapter. The signs and symptoms of an open pneumothorax are the same as for a closed pneumothorax, with the exception of an open wound to the chest. You must immediately occlude an open wound to the chest. Initially seal it with your gloved hand and then with an occlusive dressing.

### Tension Pneumothorax

A tension pneumothorax is an immediately life-threatening condition resulting from a pneumothorax that continues to trap air in the thoracic cavity with no relief or escape (Figure 34-9). With each breath, air accumulates in the thoracic cavity on the injured side. This completely collapses the injured lung and begins to compress and shift the mediastinum over to the uninjured side. The uninjured lung, heart, and large veins are compressed, leading to poor cardiac output and hypotension from a reduced preload, ineffective ventilation, inadequate oxygenation, and severe hypoxia. Death can occur rapidly.

Rapid deterioration, severe respiratory distress, signs of shock, and absent breath sounds on one side of the chest should alert you to a possible tension pneumothorax. Other signs and symptoms include cyanosis, unequal

---

**ASSESSMENT TIPS**

A pneumothorax is primarily identified by decreased or absent breath sounds to the side of the chest where the lung is partially or totally collapsed. If the patient with a pneumothorax is in a seated position, gravity will cause the air in the pleural space to move upward, and the decreased breath sounds will be heard in the apex (top) of the lung first.

---

**FIGURE 34-7** When the lung is bruised (pulmonary contusion), there is bleeding into and around the alveoli and the space between the alveoli and the capillaries, greatly reducing the exchange of oxygen and carbon dioxide in the affected area.

**FIGURE 34-8** Open pneumothorax is a possible complication of chest injury.
movement of the chest, distended neck veins, diminished breath sounds on the side opposite to the injury, and deviation of the trachea to the uninjured side. This condition may develop following the application of an occlusive dressing to an open chest wound. Alleviate the pressure by lifting the dressing and allowing air to escape during expiration, even if it is taped on only three sides. If you suspect a tension pneumothorax, rapid transport is critical.

**PATHOPHYSIOLOGY PEARLS**

In addition to collapsing the lung, a tension pneumothorax will shift the mediastinum and compress the vena cava, aorta, and heart, causing a decrease in the amount of blood being ejected from the left ventricle. The result is a decrease in blood pressure and perfusion.

**Hemothorax**

With a hemothorax, the thoracic cavity is filled with blood rather than air (*b emo* means “blood”) (Figure 34-10). As the blood continues to collect, the lung is compressed. A hemopneumothorax, which is the collection of both blood and air (*b emo*, “blood”; *p neumo*, “air”), also may occur.

A hemothorax may be the result of blunt or penetrating trauma to the chest and may be associated with open or closed injuries. The bleeding usually originates from lacerated blood vessels in the chest wall or chest cavity caused by penetrating objects or fractured ribs. The patient can lose a significant amount of blood in the chest, which results in severe shock. Early signs and symptoms of hemothorax are usually the same as for shock. Signs and symptoms of respiratory distress develop late. Bleeding in and around the lung will commonly produce a pink or red frothy sputum when the patient coughs. Care is the same as for pneumothorax and shock.

**Traumatic Asphyxia**

Traumatic asphyxia is brought about when severe and sudden compression of the thorax causes a rapid increase in the pressure in the chest (Figure 34-11). The heart and lungs are usually severely compressed by the sternum and ribs, causing a backflow of blood out of the right ventricle and into the veins of the head, shoulders, and upper chest. The patient often looks as if he has been strangled.

The signs and symptoms of traumatic asphyxia include bluish or purple discoloration of the face, head, neck, and shoulders; jugular vein distention; bloodshot eyes that are protruding from the socket; cyanotic and swollen tongue and lips; and bleeding of the conjunctiva (area found under the lower eyelid). Provide emergency care for any wounds to the chest and for shock.

**Cardiac Contusion**

Cardiac contusion is a common cardiac injury following severe blunt trauma to the chest. It occurs as the heart is violently compressed between the sternum and the spinal column (Figure 34-12). An actual bruise may occur to the heart wall. The heart wall could be ruptured or a disturbance in its electrical conduction system may occur. The right ventricle, directly beneath the sternum, is the most likely area of the heart to be injured.
Signs and symptoms of cardiac contusion may include chest pain or chest discomfort; signs of blunt trauma to the chest, including bruises, swelling, crepitation (grating sensation), and deformity; tachycardia (faster than normal heart rate); and an irregular pulse. Prompt transport is required.

**Commotio Cordis**

Sudden cardiac arrest from blunt force applied to the precordial area of the anterior chest (center of sternum) is a rare event. It is often seen in young males (mean age is 13 years) with no underlying cardiac disease during sporting events where a projectile such as a baseball strikes the patient in the center of the chest, causing ventricular fibrillation and cardiac arrest (sudden death). This condition is referred to as **commotio cordis**. It is believed that the blow to the chest occurs at a very vulnerable period in the cardiac cycle leading to a lethal dysrhythmia. Other experts theorize that the blow may induce vasospasm of the coronary arteries leading to the lethal dysrhythmia.

The patient will present in sudden cardiac arrest. The most common presenting rhythm is ventricular fibrillation; therefore, the applied AED will likely recommend defibrillation. A bruise may be noted to the center of the anterior chest wall.

Emergency care is focused on providing effective CPR and early defibrillation. Although in this case the patient is suffering cardiac arrest from trauma, he should be treated using the same protocol as for cardiac arrest from a myocardial infarction or acute coronary syndrome.

**Pericardial Tamponade**

Blunt or penetrating trauma may cause bleeding into the tough fibrous sac that surrounds the heart—the pericardial sac. Since this sac cannot expand outward very much with the filling blood, the result is inward compression of the heart (Figure 34-13 ■). The compression of the ventricles prevents adequate ventricular filling leading to a reduction in preload, stroke volume, and cardiac output. A reduction in cardiac output leads to hypotension. Because blood flow into the right side of the heart is flowing against greater resistance, the venous pressure increases, causing distention of the jugular veins and other peripheral veins. This condition is known as **pericardial tamponade**. It is a life-threatening condition that requires prompt recognition and transport.

The most common cause of a pericardial tamponade is a penetrating wound to the heart from a knife or similar object. Bullets may also cause tamponade, but more often a bullet wound directly to the heart causes immediate death.

The signs and symptoms of pericardial tamponade are similar to those of tension pneumothorax, except that breath sounds remain normal in pericardial tamponade because only the heart is involved and not the lungs. Signs and symptoms will progressively worsen as the pericardial sac fills with more blood. They include jugular vein distention; signs of shock (hypoperfusion); tachycardia, with a heart rate that is extremely high in severe cases; decreased blood pressure; narrow pulse pressure (less than 30 mmHg); and weak pulses, with radial pulses disappearing or diminishing during inhalation (pulsus paradoxus).

Emergency care focuses on early recognition and rapid transport while maintaining an adequate airway, ventilation, and oxygenation. Maintain an SpO₂ at 94% or greater.

**Rib Injury**

While a fractured rib is not life threatening, it can cause life-threatening damage to other structures and organs. The most commonly fractured ribs are the third through the eighth. The most common site of fracture is on the lateral aspect of the chest. The intercostal artery or vein may be lacerated as a result of the fracture and cause bleeding into the chest cavity.
Rib fractures in children are less common because of a more resilient cartilage that does not break easily. The mechanism of injury should heighten your suspicion that chest injury may have occurred.

The most common signs and symptoms of rib injury include (Figure 34-14 ■) pain, often excruciating, with movement and breathing; crepitation (grating sensation); tenderness upon palpation; deformity of the chest wall; inability to breathe deeply; coughing; and tachypnea (rapid breathing) that may be shallow.

If a simple rib fracture is suspected, the patient usually presents in the guarded position, holding his arm over the injured site. You can use the arm to splint the injury by placing it over the injury site and applying a sling and swathe to hold it in place (Figure 34-15 ■). The patient could also be given a pillow to hold firmly over the injury in order to manually splint it. Do not completely wrap the chest or apply the swathe snugly. This would impede normal ventilation.

A patient who has suffered a chest injury may appear relatively well at first but can deteriorate suddenly and rapidly. The patient may not complain about a chest injury. In fact, the patient’s chief complaint related to the chest may only be shortness of breath. It is your responsibility to suspect a potential chest injury based on mechanism of injury and a high index of suspicion, to adequately assess the patient, and to provide the necessary emergency medical care.

An open (sucking) chest wound and paradoxical movement (flail segment) are the two immediately life-threatening chest injuries that require management in the prehospital setting. Because they are life threatening, they must be managed immediately upon identification. Other injuries to the internal organs and structures of the chest cannot be directly treated in the field. Early recognition and rapid transport are critical.

**Assessment-Based Approach: Chest Trauma**

**Scene Size-up**

Conducting a scene size-up to ensure your safety and that of your partner is especially important when the chest injury was a result of violence with a knife or gun. When you arrive on the scene, a threat to your safety...
may still exist. Do not enter the scene of a shooting or stabbing until the police secure it and tell you it is safe to enter. Remember to take the necessary Standard Precautions. Since bleeding is often found with both blunt and penetrating injuries, it is necessary to be wearing gloves and eye protection before entering the scene.

While the scene is being cleared of safety hazards, concentrate on the mechanism of injury. Ask bystanders to tell you what happened. Scan the scene. Blunt trauma commonly occurs in sports accidents, falls, blows to the chest during fights, and, most commonly, automobile crashes. Penetrating trauma most often is associated with violence.

As you consider the mechanism of injury, look for and note the following:

- **Was the patient involved in a sports accident?** Did the patient take a direct blow to the chest? A direct blow to the anterior chest by a football helmet, a line-drive baseball, a hockey puck, an elbow during a rebound in basketball, or other similar mechanisms can produce serious injury, including heart rhythm disturbance and sudden cardiac arrest.

- **Did the patient fall?** How far did the patient fall? How did he land? What did he hit on the way down? In what position was he found? What caused him to fall? What did he land on?

- **Was there a fight?** Was the patient punched or kicked in the chest? Were any weapons involved in the fight, such as a knife, gun, club, rocks, or bottles? Is there a bloody object found at the scene that could have penetrated the chest? Did the patient feel a sting or hear a pop and suddenly become short of breath?

- **Is there any evidence that a shooting took place?** Were gunshots heard? Are there spent shell casings on the ground? Did dispatch indicate that this was a shooting?

- **Was the patient involved in an auto collision?** How fast was the car traveling? Where is the impact to the vehicle (and therefore to the patient)? Is the steering wheel bent, broken, or damaged? Is there damage to the dashboard on the passenger side? Is there an impact mark to the windshield indicating the patient was violently thrown forward? Was the patient wearing a seat belt? Were both the shoulder and lap belts worn properly? Did the air bag deploy? Is there any protruding metal or object in the vehicle that may have penetrated the chest?

- **Was the patient crushed between two objects?** Was the patient possibly run over by a heavy object?

- **Was an explosion involved?** Blast injuries can cause blunt injury from the blast wave and penetrating injury from flying debris.

### Primary Assessment

As soon as you have determined that the scene is safe, proceed with the primary assessment. If spine injury is suspected, establish and maintain in-line spinal stabilization. (A blow to the chest can be forceful enough to cause spine injury.) Form a general impression of the patient: Is the patient severely cyanotic? Does he appear to be in extreme respiratory distress? Is he breathing shallowly and rapidly? Is he holding his arms tightly against his chest to splint the movement? Does he appear to be in extreme pain? Are there any open wounds to the chest? Is the chest moving unevenly when he breathes?

Clothing can disguise a life-threatening sucking wound or flail segment. If the mechanism of injury indicates possible chest injury or the patient shows any signs of respiratory distress, quickly expose the chest and examine it. If you note an open wound to the anterior, lateral, or posterior chest, immediately place a gloved hand over the flail segment to splint it in an inward position. The ideal treatment for a flail segment is positive pressure ventilation.

Continue with the primary assessment and determine the patient’s mental status. An altered mental status or unresponsiveness may be an indication of severe hypoxia (oxygen deficiency) resulting from a significant chest injury. Visually inspect the airway in the patient with an altered mental status. Look for blood or other potential obstructions. Listen and feel for air movement. Because spinal injury should be suspected if the chest injury is due to blunt trauma, perform the jaw-thrust maneuver to open the airway, if necessary.

Note the patient’s speech pattern. Does the patient speak a few words and then gasp for a breath? This would indicate severe respiratory distress. Many chest injuries produce ineffective ventilation. In some cases where the chest wall is injured and the ribs fractured, the pain is so severe that the patient purposely will breathe with extremely shallow, fast breaths in an attempt to reduce the pain. This can easily lead to hypoxia from inadequate breathing.

Carefully assess the breathing status. If breathing is adequate, administer supplemental oxygen to maintain an SpO2 of 94% or greater. Continuous positive airway pressure (CPAP) can be considered in flail segment or pulmonary contusion if the patient meets the criteria for application and doesn’t have any of the contraindications. Do not apply CPAP to any patient suspected of having a pneumothorax. If breathing is inadequate, immediately initiate positive pressure ventilation with supplemental oxygen (Figure 34-16).

If a tension pneumothorax exists, it will be increasingly difficult to ventilate the patient. (Expanding pressure in the chest cavity makes it increasingly difficult to inflate the lungs.) The pulses may be weak and fast if the injury is associated with bleeding in the chest or compression of the heart. Cyanosis is an indicator of poor oxygenation and ventilation. Pale skin may indicate early onset of hypoxia, blood loss, or poor pumping function of the heart. The skin may be moist and cool to the touch.

---

**Chapter 34 • Chest Trauma**
If the pulse becomes weak or absent during inhalation, it may indicate either a tension pneumothorax or pericardial tamponade (compression of the heart from blood or fluid in the pericardial sac). If the cyanosis is severe or progressively gets worse, reevaluate the breathing status and consider positive pressure ventilation.

Note: If you suspect that the patient has been shot or stabbed, the patient complains of breathing difficulty, or the breathing rate or depth appears to be abnormal, it is vital that the patient is log rolled to assess the posterior body for another potentially life-threatening open (entrance or exit) wound.

Secondary Assessment

Perform a rapid secondary assessment. It is likely that other injuries exist, especially if the mechanism of injury suggests blunt trauma. Inspect and palpate for deformities, contusions, abrasions, punctures/penetrations, tenderness, lacerations, and instability.

Cyanosis to the face, inside the mouth, or under the tongue indicates poor oxygenation. If the cyanosis is severe or progressively gets worse, reevaluate the breathing status and consider positive pressure ventilation.

Assess the neck for subcutaneous emphysema, jugular vein distention, and tracheal deviation. Air tends to flow upward; therefore, with chest injury subcutaneous emphysema (air trapped under the skin giving it a bubbly, inflated appearance and a crackling feel when palpated) is usually present in the upper chest and neck. Jugular vein distention is an indication of possible cardiac injury or tension pneumothorax. In a tension pneumothorax, the trachea will move toward the side of the uninjured lung (tracheal deviation). When assessing for tracheal deviation, it is necessary to palpate the trachea immediately above the suprasternal notch (indentation immediately above the sternum). Inspection of the trachea will rarely reveal the deviation; however, palpation may allow you to feel the abnormal shift prior to being able to see it. The buildup of pressure in a tension pneumothorax will also cause the heart and large vessels to be compressed, causing decreased blood flow to the heart and ineffective pumping, which produce signs and symptoms of shock (hypoperfusion). Jugular vein distention and tracheal deviation are very late signs of a tension pneumothorax. Signs and symptoms of respiratory distress are better indicators.

Assessment Tips

Watch the jugular veins during inhalation. If they engorge during inhalation, it may be a sign of a tension pneumothorax or pericardial tamponade. This engorgement is a result of an increased venous pressure and is referred to as Kussmaul sign.

If a spinal injury is suspected, apply a cervical spine immobilization collar. Most immobilization collars have a large opening on the anterior side allowing for re-assessment of the jugular veins and trachea. Do not release manual in-line stabilization until the patient is completely immobilized to a backboard.

If you have not already done so, expose the chest by cutting the clothing. Inspect the chest carefully and thoroughly for any open wounds. If you suspect a penetrating injury, roll the patient and inspect the back for open wounds. Lift the arm and inspect the axillary (armpit) area. An open wound to the back or side of the chest is just as lethal as one to the anterior chest. If an open wound is found there, immediately seal it by placing a gloved hand over the wound.

Paradoxical movement of the chest indicates flail segment. One of the major complications associated with a flail segment is the inability of the patient to generate pressure changes in the chest necessary to adequately move air into the chest cavity. If the patient is exhibiting signs and symptoms of a flail segment with evidence of inadequate breathing, the ideal treatment is to provide positive pressure ventilation. When positive pressure ventilation is delivered to the patient, the air being forced into the lungs overrides the inadequate movement of the chest to create a negative pressure to draw air into the lungs. In a sense, you are eliminating the need for the chest to create a negative pressure because you are delivering a positive pressure. Thus, you can effectively manage a flail segment through positive pressure ventilation. The most significant problem then associated with the flail segment is the potential contusion to the lung underlying the fracture. This will interfere with gas exchange and lead to hypoxia.

Look for retractions of the muscles, contusions, lacerations, or any other signs that blunt force may have
been applied to the chest. Inspect the chest if the patient was a driver involved in an automobile crash. A bent or damaged steering wheel and positive markings on the patient's chest are indications of possible severe chest injury, especially if the driver was not wearing a seat belt. Air leaking from the respiratory tract or an injured lung may produce subcutaneous emphysema.

Palpate the chest, checking for symmetry (equal movement of both sides), paradoxical movement, swelling, and deformities. Fractures of the ribs may produce crepitation (a grating sound or sensation) and are usually accompanied by excruciating pain upon palpation. You will likely find that the patient with an injury to the chest wall or injury to the ribs will breathe shallowly and will place his arm over the injured area to guard and splint it during breathing (Figure 34-17).

Auscultate the breath sounds bilaterally. Determine if the breath sounds are clear and equal, decreased or absent on one side, or decreased or absent on both sides. Decreased or absent breath sounds may indicate a collapsed lung or air or blood in the thoracic cavity. The patient in severe pain from a chest wall injury may have decreased or absent breath sounds bilaterally, which may indicate that both lungs are collapsed. A tension pneumothorax usually produces absent breath sounds on the injured side and decreased breath sounds on the side of the uninjured lung. Closely reevaluate the breathing status and determine if positive pressure ventilation should be initiated.

Inspect the abdomen for excessive muscle movement during breathing. This may be an indication of severe respiratory distress associated with a chest injury.

Assess the baseline vital signs. The blood pressure may be low because of either bleeding or compression of the heart. The breathing rate can be significantly increased. Pain associated with chest injury may cause the patient’s breathing to be very fast and shallow. The pulse is usually rapid and may be weak. The skin may appear cyanotic or pale, cool, and moist. The pulse oximetry may be less than 94% as a result of hypoxia associated with a chest injury. An increasing heart rate and decreasing blood pressure associated with increasing respiratory distress is an ominous sign of severe chest injury. Immediate transport should be considered.

**ASSESSMENT TIPS**

A sudden drop in the systolic blood pressure by greater than 10 mmHg during inhalation may be another sign of a tension pneumothorax or pericardial tamponade. The drop in systolic blood pressure during inhalation is referred to as pulsus paradoxus.

Obtain a history from the responsive patient. If the patient is unresponsive or is unable to answer your questions, attempt to gather information from others at the scene.

**Signs and Symptoms.** Certain signs and symptoms may occur in major open or closed chest trauma, many simultaneously. The major indications of chest trauma are:

- Cyanosis to the fingernails or fingertips, lips, or face
- Dyspnea (shortness of breath)/difficulty in breathing
- Breathing rate that is faster (tachypnea) or slower (bradypnea) than normal and usually shallow
- Contusions, lacerations, punctures, swelling, or other obvious signs of trauma to the chest
- Hemoptysis (coughing up blood or blood-stained sputum)
- Signs of shock (decreasing blood pressure, narrowing pulse pressure, increasing heart rate, and pale, cool, and clammy skin)
- Tracheal deviation
- Paradoxical movement of a segment of the chest wall
- Open wound that may or may not produce a sucking sound
- Subcutaneous emphysema
- Jugular vein distention (JVD), especially during inhalation
- Absent or decreased breath sounds upon auscultation
- Pain at the injury site, especially pain that increases with inhalation and exhalation
- Failure of the chest to expand normally during inhalation
- Peripheral pulses that become extremely weak or become absent during inhalation
- A drop in systolic blood pressure of 10 mmHg or more during inhalation

Not all of these signs need to be present in order to suspect serious chest injury. Sometimes only subtle signs of pain or symptoms of slight breathing difficulty are present. Consideration of the mechanism of injury and signs of trauma to the chest cavity should heighten your suspicion that a serious chest injury has occurred. Remember that an altered mental status, alcohol intoxication, or head injury can decrease the patient’s ability to complain of symptoms that might indicate chest injury.
General Emergency Medical Care—
Chest Trauma

Chest injuries can be life threatening. Prompt recognition and emergency medical care is essential to the patient's survival. An open chest wound, a flail segment that produces paradoxical movement, and inadequate breathing are all conditions that must be managed immediately upon identification.

1. Maintain an open airway. Take in-line stabilization and open the airway, using a jaw-thrust maneuver if spinal injury is suspected. If the patient's condition continues to deteriorate, it may be necessary to insert a nasopharyngeal or oropharyngeal airway. Suction any secretions, blood, or vomitus. Remember that signs of inadequate breathing may occur from an occluded airway and not necessarily from a worsening chest injury. Continuously reassess the airway.

2. Maintain adequate oxygenation. Because most chest injuries produce disturbances in oxygen and carbon dioxide exchange in the lungs, the cells may not be receiving an adequate amount of oxygen. This leads to cellular hypoxia (oxygen deficiency). It is essential to maintain an SpO2 of 94% or greater.

3. Reevaluate breathing status. Chest injuries can cause sudden and rapid deterioration. You should carefully and continuously reassess the breathing status and circulation. If at any time signs of inadequate breathing appear, immediately begin positive pressure ventilation with supplemental oxygen. Ventilation should be administered at a maximum of 10 to 12 ventilations per minute in the adult and 12 to 20 ventilations per minute in the infant and child.

   Keep in mind that providing positive pressure ventilation may actually worsen a pneumothorax by forcing air out of the lung through the visceral pleura and into the pleural space. This will increase the air in the pleural space and cause the lung to collapse more. Even though this is a complication associated with ventilation of a patient with a chest injury, if the breathing is inadequate you have no choice but to provide positive pressure ventilation. Be vigilant and continuously assess for deterioration of the patient, worsening cyanosis, and increases in resistance noted by more difficulty when squeezing the bag of the bag-valve-mask device. Do not provide forceful ventilations. A pneumothorax can be converted into a tension pneumothorax by ventilating a patient. Consider ALS backup or immediate transport.

4. Stabilize an impaled object in place. If an impaled object is found, do not remove it. Stabilize the object with bulky gauze and bandages to prevent excessive movement.

5. Completely immobilize the patient if spinal injury is suspected. A cervical spine immobilization collar must be applied and the patient must be immobilized to a backboard with straps and a head immobilization device.

6. Treat the patient for shock (hypoperfusion) if signs and symptoms are present. Many chest injuries involve blood loss or cardiac compromise from compression of the heart.

Emergency Medical Care—
Open Chest Wound

The open chest wound is an immediately life-threatening emergency that can lead to rapid deterioration and death if not managed properly. Emergency medical care includes the general care we have just detailed, plus the following:

1. Immediately seal the open wound with your gloved hand. Do not delay in order to find a dressing.

2. Apply an occlusive dressing to seal the wound (not a regular porous dressing, which would allow air to enter easily). Plastic wrap from an oxygen mask, the wrap covering an intravenous fluid bag, or Vaseline gauze may be used. The occlusive dressing should be a few inches wider than the wound. Place it over the entire wound and tape it on three sides (Figure 34-18 ■). During inhalation, the dressing is sucked up against the wound, preventing air from entering. The side that is not taped allows for air that has built up in the thoracic cavity to escape during exhalation (Figure 34-19 ■). An alternative method is to tape the dressing on four sides and occasionally lift a corner during expiration to relieve any pressure. Paramedics and some Advanced EMTs are able to decompress the chest to relieve the trapped air using an over-the-catheter needle. A valve may be connected to prevent air from being drawn into the catheter.
Severely decreased or absent breath sounds on the injured side
• Cyanosis
• Tachycardia (heart rate faster than normal)
• Decreasing blood pressure with a narrowing pulse pressure
• Jugular vein distention (late sign)
• Tracheal deviation (late sign)
• Unequal movement of the chest wall (the injured side remains hyperinflated and will not move equally with the uninjured side)
• Extreme anxiety and apprehension
• Increased resistance to positive pressure ventilation

If these signs and symptoms develop after the occlusive dressing has been applied, you must lift a corner of the dressing for a few seconds to allow the air to escape during expiration. A rush of air may be heard or felt, and immediate relief of the signs and symptoms of severe compromise should occur. Reseal the wound with the occlusive dressing. It may be necessary to repeat this procedure several times.
Emergency Medical Care—Flail Segment

Paradoxical movement of a flail segment should not be splinted in any way that would reduce chest wall movement or compromise ventilation. It was once recommended that patients be placed on the injured side or that the chest wall be splinted to prevent outward movement. These emergency care procedures are no longer recommended because they will potentially impede chest wall movement and increase the amount of alveolar collapse, worsening hypoxia. The focus must be on providing adequate ventilation if needed and maintaining adequate oxygenation.

In the patient with adequate breathing, maintain an \( \text{SpO}_2 \) of 94% or greater by administering supplemental oxygen. If in respiratory distress and adequate oxygenation can’t be maintained with supplemental oxygen, apply CPAP to improve oxygenation if the patient meets the application criteria and no contraindications exist. If the patient is breathing inadequately, initiate positive pressure ventilation.

Reassessment

During the reassessment, evaluate the effectiveness of your treatment and assess for further deterioration of the patient’s condition. Signs and symptoms of increasing breathing difficulty, decreasing mental status, decreasing breath sounds, worsening cyanosis, and shock should prompt you to reevaluate your treatment and repeat the rapid secondary assessment, looking for signs of injury that might have been missed initially. It may be necessary to reconsider the need to provide positive pressure ventilation if it has not already been initiated. Look for signs of a developing tension pneumothorax. If an occlusive dressing is in place, lift it to relieve any pressure that has potentially built up.

Reassess and record the baseline vital signs. A decreasing blood pressure, increasing heart rate, increasing respiratory rate, and cyanotic, cool, moist skin may indicate a worsening chest injury or shock from blood loss.

Summary: Assessment and Care—Chest Trauma

To review possible assessment findings and emergency care for chest injuries, see Figures 34-21 and 34-22.

Assessment Summary

CHEST TRAUMA

The following findings may be associated with a chest injury.

Scene Size-up

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Automobile crash, bent steering wheel
- Sports accident, especially blow to chest as from football helmet, baseball
- Fall
- Gunshot wound
- Fight, especially with blow to chest
- Crush injury
- Explosion

Primary Assessment

General Impression
- Severe cyanosis
- Extreme respiratory distress
- Patient splinting chest with arm
- Obvious open wound to chest
- Uneven chest wall movement
- Speech pattern: gasping for breath between words

Physical Exam
- Head:
  - Cyanotic tongue, oral mucous membranes, and face
- Assess neck for subcutaneous emphysema

Mental Status
- Alert to unresponsive, based on type and degree of injury
- Unresponsiveness or decreasing mental status associated with hypoxia and hypoperfusion

Airway
- Assume airway is closed if patient has an altered mental status

Breathing
- May be absent, inadequate, or normal
- May be very shallow if ribs are injured
- May be labored

Circulation
- Pulse and skin color vary depending on injury
- Pulse may be normal
- Pulse is increased if hypoxia, blood loss, or tension pneumothorax
- Skin may be normal if minor chest injury
- Cyanosis if perfusion disturbance or hypoxia

Status: Priority patient if any chest injury
Jugular venous distention and tracheal deviation (late
signs of tension pneumothorax)
Neck veins that become engorged during inhalation—
Kussmaul sign indicating a tension pneumothorax
or pericardial tamponade

Chest:
Evidence of blunt trauma to chest: contusions, lacerations
Penetrating trauma to chest: knife, gunshot wounds
(look for exit wound)
Retractions of suprasternal notch, supraclavicular
spaces, lateral neck
Palpate for symmetry, deformities, crepitation, pain
Paradoxical movement indicates flail segment; minimal
paradoxical movement may be noted early in flail seg-
ment because of muscle splinting, but will become
more prominent as the intercostal muscles fatigue)
Breath sounds diminished or absent on one side or both

Abdomen:
Excessive movement during breathing (indicates se-
vere respiratory distress)

Extremities:
Weak peripheral pulses (may indicate a tension pne-
umotheorax or poor perfusion)
Pulse that weakens with inspiration (may indicate a
tension pneumothorax)

Posterior Body:
Inspect for entrance and exit wounds
Evidence of blunt trauma

Baseline Vital Signs
BP: normal; may be low if severe hypoxia, blood loss,
tension pneumothorax, or cardiac tamponade
HR: normal, or tachycardia from severe hypoxia, blood
loss, tension pneumothorax, or cardiac tamponade
Pulses may become weak or absent during inhalation
indicating a tension pneumothorax or pericardial
tamponade
RR: normal, irregular, decreased, absent, or labored
Skin: normal; may be pale, cool, clammy if severe hy-
poxia, blood loss, tension pneumothorax, or cardiac
tamponade
Pupils: equal and reactive, may be sluggish to respond
to light
SpO₂: <95% if gas exchange is affected

History
Dyspnea
Coughing up frothy blood
Pain at site of injury
Cyanosis
Obvious trauma to chest
Shock
Decreasing blood pressure with increasing pulse that
comes weaker
Tracheal deviation and distended neck veins
Paradoxical movement of chest
Absent or decreased chest sounds
Failure of chest to rise with inhalation

Emergency Care Protocol

CHEST TRAUMA

1. Establish manual in-line stabilization. Do not release
it until the patient is immobilized onto a backboard if
spinal injury is suspected.

2. If you find an obvious open wound to the chest dur-
ing the general impression, place a gloved hand over
the wound until it can be covered with a nonporous
dressing taped on three sides.

3. Establish and maintain an open airway. Insert a na-
sopharyngeal or oropharyngeal airway if the patient
is unresponsive and has no gag or cough reflex.

4. Suction secretions as necessary.

5. If breathing is inadequate, provide positive pres-
sure ventilation with supplemental oxygen at a rate of
10–12 ventilations/minute for an adult and 12–20
ventilations/minute for an infant or child.

6. If breathing is adequate, administer oxygen by non-
rebreather mask at 15 lpm for chest trauma, because of
the potential for gas exchange disturbances and
hypoxia.

7. Control any major bleeding.

8. Treat the specific condition or wound:
   Impaled Object:
   Stabilize the impaled object in place.
   Open Chest Wound:
   Place a gloved hand over the wound immediately.
   Apply an occlusive, or nonporous, dressing taped
   on three sides.
   Flail Segment (Paradoxical Chest Wall Movement):
   If inadequate breathing, begin positive pressure ven-
tilation, which will splint the segment internally.
   Place a gloved hand over the segment, then stabi-
   lize with a blanket, pillow, bulky dressing, or the
   patient’s own arm.

10. Immobilize to a backboard if you suspect spine
    injury.

12. Perform a reassessment every 5 minutes if unstable
    and every 15 minutes if stable.

13. If an open chest wound is occluded with a dress-
    ing and the patient suddenly begins to deteriorate,
    lift the dressing off the wound during exhalation to
    relieve trapped air, then reapply the dressing.
Suspected spine injury?

- Yes: Manual in-line stabilization
  - Yes: Occlude with gloved hand then with occlusive or nonporous dressing
    - Yes: Can patient tolerate positive pressure ventilation?
      - Yes: Stabilize with hand then pillow, blanket, bulky dressing
        - Yes: Any major bleeding?
          - Yes: Control bleeding
            - Alert and able to obey commands
              - Assess mental status
                - Altered
                  - Consider oxygen administration
                    - Assess circulation
                      - Secondary assessment
                        - Rapid secondary assessment
                          - Assess breathing
                            - Adequate
                              - Administer oxygen
                                - Assess circulation
                                  - PPV with \(O_2\)
                                    - Rapid secondary assessment
                                      - Impaled object in chest?
                                        - No: Stabilize object in place
                                          - Immobilize to backboard
                                            - Transport
                                              - Reassessment
                                                - Rapid deterioration of patient?
                                                  - No: BP decreasing, HR increasing, signs of poor perfusion, absent breath sounds, labored breathing?
                                                    - Yes: Look for other injuries
                                                      - Look for other injuries
                                                        - Lift off corner of dressing during expiration to relieve pressure
                                                          - Continue ongoing assessment every five minutes
                                                            - PPV = positive pressure ventilation
                                                              - Cream = assessment
                                                                - Green = key decision points
                                                                  - Blue = interventions

SUMMARY
Chest injuries may be life threatening. Chest injuries could lead to severe respiratory compromise and poor ventilation and oxygenation status. They also could be a source of serious bleeding. An open wound to the chest, tension pneumothorax; and flail segment must be recognized and managed during the primary assessment. All open wounds to the chest must be covered with an occlusive dressing taped on three sides.

Case Study Follow-up

Scene Size-up
You have been dispatched to a street corner for a man down. As you drive up to the scene, no bystanders appear to be present. It is dark outside, so you turn on the scene lights and carefully assess for hazards. None are observed so you and your partner exit the ambulance. However, you still have your guard up. As you approach the patient, you note that he is lying in a prone position on the sidewalk. He is dressed in a heavy overcoat, and he is moaning. No visible blood is noted. You and your partner tell the patient you are emergency medical technicians and are there to help. The patient responds with a moan.

Primary Assessment
Because you are unaware of the mechanism of injury or nature of the illness, you and your partner establish in-line spinal stabilization. You log roll the patient as a unit with spinal precautions being maintained. You ask, “Sir, are you hurt or ill?” The patient only responds with a moan. There still does not appear to be any visible injury or bleeding anywhere to the body. The airway is open and clear of any secretions or vomitus. The breathing is rapid and shallow at a rate of approximately 40 per minute. You prepare the bag-valve-mask device and instruct your partner to begin ventilating with supplemental oxygen. He kneels at the head of the patient, holding in-line stabilization with his upper legs. The radial pulse is weak and very rapid. The skin is cool, moist, and pale. You identify this patient as a high priority.

Secondary Assessment
In-line spinal stabilization is maintained by your partner as he continues to ventilate the patient with a bag-valve-mask device. The patient is still responding to verbal commands only with moans. There is no evidence of trauma to the head. The pupils are equal and reactive, but sluggishly respond. The jugular veins are flat and the trachea is midline. You quickly expose the chest and find what appears to be a small-caliber gunshot wound to the right anterior aspect of the chest at about the third intercostal space on the midclavicular line. A bubbly crackle is heard when the patient inhales spontaneously. You immediately place your gloved hand over the wound. You then apply the plastic wrap from the oxygen tubing over the wound and tape it on three sides.

You rapidly log roll the patient and closely inspect the back for an exit wound and find none. You also assess the axillary region for any other wounds to the chest. Auscultation of the lungs reveals significantly decreased breath sounds to the right and good breath sounds on the left. There is no evidence of any wounds or trauma to the abdomen or pelvis. Palpation of the abdomen does not elicit a moan or other pain response. The extremities are quickly inspected. Pedal pulses are absent and the radial pulses are extremely weak and fast. A pinch to the extremities causes the patient to moan.

The carotid pulse is 138 beats per minute. The spontaneous respiratory rate is 35 per minute and shallow. The blood pressure is 80/60 mmHg. The skin is cyanotic, pale, cool, and moist. The pulse oximeter will not provide a reading because of the poor perfusion status. A history is unobtainable.

You apply a cervical spine immobilization collar and immobilize the patient to a backboard with straps and a head immobilization device. You place the patient in the back of the ambulance and transport rapidly.

Reassessment
En route to the hospital, the mental status remains unchanged. You insert a nasopharyngeal airway and reassess ventilation. Positive pressure ventilation is continued with supplemental oxygen. The pulse rate has decreased slightly to 130 per minute. The cyanosis has subsided slightly. The skin remains pale, cool, and moist. You record the vital signs.

Suddenly you notice that it is becoming extremely difficult to ventilate the patient. The heart rate has increased to 148 per minute and the skin is becoming severely cyanotic. You immediately lift the corner of the occlusive dressing off the wound and note the sound of air escaping. Almost immediately the patient’s condition improves and you replace the dressing. You contact the hospital and give a report.

continued
Upon arrival at the hospital, you give an oral report to the physician who is waiting for you at the door. The patient is transferred to the hospital bed in the trauma room. While your partner cleans the ambulance and gathers the necessary supplies, you complete the prehospital care report. You check on the patient prior to leaving and are told by the physician that a chest tube was inserted and he is now in surgery. His prognosis is unknown. You clear the hospital and mark back in service.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

### Case Study: Follow-up continued

Upon arrival at the hospital, you give an oral report to the physician who is waiting for you at the door. The patient is transferred to the hospital bed in the trauma room. While your partner cleans the ambulance and gathers the necessary supplies, you complete the prehospital care report. You check on the patient prior to leaving and are told by the physician that a chest tube was inserted and he is now in surgery. His prognosis is unknown. You clear the hospital and mark back in service.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

### IN REVIEW

1. Identify and describe the two general categories of injuries to the chest.
2. List the signs and symptoms associated with major chest trauma.
3. Describe the general guidelines for emergency medical care of trauma to the chest.
4. Describe additional emergency medical care required for (a) an impaled object to the chest, (b) an open wound to the chest, and (c) a flail segment (paradoxical movement).
5. Describe the difference between pneumothorax, open pneumothorax, hemothorax, and tension pneumothorax.

### CRITICAL THINKING

You arrive on the scene and find the driver of a vehicle that was in a frontal collision with another vehicle. The patient was not wearing his seat belt. The air bag deployed during the crash. The patient is responding to verbal stimuli with moans. He is breathing at 34 times per minute with a shallow chest rise. His radial pulse is 124 bpm and is barely palpable. The skin is pale, cool, and clammy. During the rapid secondary assessment, you note a large contusion to his left upper chest. Upon inhalation, that portion of the left upper chest moves inward. He moans loudly when his chest is palpated. His pedal pulses are absent. His blood pressure is 72/64 mmHg, HR 124 bpm, R 34 with poor chest rise, and the SpO₂ is not obtainable because of a continuous error reading.

1. What emergency care would you provide in the primary assessment?
2. What signs and symptoms in this patient are indicators of shock?
3. What type of chest injury is the patient suffering from?
4. How would you manage the chest injury?
5. What overall emergency care would you provide?
Abdominal and Genitourinary Trauma

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Trauma** (Content Area: Abdominal and Genitourinary Trauma)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

35-1. Define key terms introduced in this chapter.
35-2. Describe the anatomy of the abdominal cavity and its contents.
35-4. Give examples of both blunt and penetrating mechanisms of abdominal trauma and discuss the potential for severe internal bleeding.
35-5. Discuss an assessment-based approach to management of the patient with open and closed abdominal injury, including evisceration and impaled objects.
35-6. Recognize signs and symptoms associated with injuries to the abdomen.
35-7. Explain the general emergency medical care for abdominal trauma.
35-8. Explain the emergency medical care for abdominal evisceration.
35-9. Explain the special considerations in management of trauma to the male and female genitalia.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- abdominal evisceration p. 967
- Kehr sign p. 967
- peritoneal space p. 966
- peritonitis p. 966
- retroperitoneal cavity p. 966

**Case Study**

**The Dispatch**
EMS Unit 14—respond to May’s Coffee Shop at 154 Bayside Village for a man who was struck by a car while jogging—time out is 0740 hours.

**Upon Arrival**
While still en route, you get gloves and eye protection ready for both you and your partner. When your partner pulls up to the diner’s parking lot, you spot the police unit. The police officer affirms that there is only one patient as you and your partner exit the unit and move toward him. The jogger is lying supine on the sidewalk, holding his abdomen and moaning in pain.

How would you assess and care for this patient?
*During this chapter, you will learn about assessment and emergency medical care for patients suffering from abdominal and genitourinary injuries. Later, we will return to the case study and put in context some of the information you learned.*
INTRODUCTION

Abdominal trauma is typically considered a critical injury because of the potential for severe bleeding and development of hemorrhagic shock. The abdomen contains vascular solid organs that have a tendency to bleed extensively, hollow organs that contain substances that can be spewed out and cause severe damage or infection, and vascular structures that can result in severe hemorrhage and blood loss if injured.

The key to assessment and management of abdominal trauma is to recognize that a potential abdominal injury has occurred and to understand the need for immediate emergency care and transport. It is not the role of the EMT to identify the specific organ that has been injured. The emergency care of the patient will not change based on what organ is bleeding or injured; however, the patient presentation might change. Pay close attention to the various signs and symptoms the patient may exhibit when an abdominal organ has been injured in order to recognize the condition as early as possible.

The urinary structures and organs are located in the abdominal cavity and will be included in the discussion of trauma to the abdominal organs. Genital trauma is primarily an external soft tissue injury that can lead to severe blood loss. Because the external genitalia are not contained within the abdominal cavity, this topic is discussed separately later in the chapter.

THE ABDOMEN

Anatomy of the Abdominal Cavity

Before reading further, you may find it helpful to review Chapter 7, “Anatomy, Physiology, and Medical Terminology,” for a description of the abdominal cavity and the organs it contains. A brief description follows.

The abdominal cavity contains the major organs of the digestive, urinary, and endocrine systems. The abdomen is separated from the chest cavity superiorly by the diaphragm. The inferior border is the heavy, bony pelvic ring. Tough, thick, flat muscles form the bulk of the anterior border along with the lower portion of the rib cage. Posteriorly, the spinal column and strong muscles provide protection.

The abdominal cavity is lined by a two-layer, sheath-like membrane called the peritoneum. The innermost lining—the visceral peritoneum—adheres to and supports the organs. The parietal peritoneum is the outer lining that adheres to the walls of the abdominal cavity. Between the two layers is a small amount of fluid that serves as a lubricant to reduce friction when the surfaces rub over each other. The potential space between the visceral and parietal peritoneum is called the peritoneal space. Some organs in the posterior abdominal cavity lie partially or completely behind the peritoneum. They are said to be retroperitoneal, or located in the retroperitoneal cavity. Organs contained within the retroperitoneal space are the duodenum, pancreas, inferior vena cava, aorta, kidneys, and ureters.

PATHOPHYSIOLOGY PEARLS

The peritoneal lining has very sensitive nerves that produce severe, constant pain when irritated by substances leaking into the abdominal (peritoneal) cavity.

Types of Abdominal Organs and Structures

The abdomen contains vascular structures as well as solid and hollow organs. It is important to understand the differences between these types of organs and structures because they cause various signs and symptoms when injured.

Hollow Organs. Hollow organs contained within the abdominal cavity include the following:

- Stomach
- Gallbladder
- Urinary bladder
- Ureters
- Internal urethra
- Fallopian tubes
- Small intestine
- Large intestine

Hollow organs are not as vascular as solid organs, but they typically contain various substances. Thus, if ruptured or lacerated they do not bleed very much, but they spill their contents into the abdominal cavity, causing an irritation and inflammation of the peritoneal lining known as peritonitis. The leaking contents might include gastric juices from the stomach, highly acidic and partially digested food from the upper small intestine, bacteria from the large intestine, or urine from the bladder. If the substance leaking out of the organ is acidic or contains irritating substances, it will typically cause immediate and excruciating pain. Leakage of bacteria does not usually produce immediate pain; however, as the peritoneal lining becomes infected the patient will begin complaining of pain. This delay in onset of pain may take several hours. The patient could have an injury to an abdominal organ but yet not complain of severe pain while on the scene. Meanwhile, leakage of bacterial substances could lead to severe and life-threatening infection.

Solid Organs. Solid organs within the abdominal cavity include the following:

- Liver
- Spleen
- Pancreas
- Kidneys

Solid organs usually contain a rich blood supply. A solid organ may bleed into the capsule that surrounds it for some time before the capsule ruptures and allows...
the blood to spill into the abdominal cavity. The major complication associated with the laceration or tearing of a solid organ is major bleeding and severe shock. In a patient who presents with evidence of abdominal trauma, look for signs and symptoms of hemorrhagic shock. Blood is not very irritating to the peritoneal lining and may not cause severe abdominal pain, even though the patient may be bleeding severely. However, the blood may irritate the diaphragm and cause referred pain to the shoulder. This referred pain to the shoulder is called Kehr sign.

**Vascular Structures.** Vascular structures that lie partially within the abdominal cavity include the following:

- Abdominal aorta and its branches
- Inferior vena cava

In addition to the abdominal aorta and inferior vena cava, there are many large arteries and veins that supply the abdominal organs. All of these vascular structures are primarily stationary, are very large, and carry large amounts of blood. If lacerated, ruptured, or torn, the aorta or vena cava will bleed massively and rapidly lead to severe hemorrhagic shock and death. The signs and symptoms associated with a major abdominal vascular injury are those of hemorrhagic shock. This patient may deteriorate very quickly while on scene and en route to the medical facility.

**Additional Structures**

**The Diaphragm.** The diaphragm is not an organ but a muscle that separates the thoracic and abdominal cavities. The diaphragm forms the upper border of the abdominal cavity and lower border of the thoracic cavity. During exhalation, the diaphragm would be located at approximately the level of the fourth or fifth intercostal space, which is at the nipple line. During inhalation, the diaphragm moves lower by as much as 3 inches.

The diaphragm could be injured from a penetrating injury or from a severe blunt force applied to the abdomen. The diaphragm is responsible for approximately 60 to 70 percent of the effort to breathe; therefore, injury to the diaphragm will likely cause respiratory distress. If the diaphragm injury is severe, the abdominal contents may enter the thoracic cavity. In this case, the breath sounds would be decreased on the side of the injured diaphragm.

**ASSESSMENT TIPS**

The diaphragm, which separates the thoracic and abdominal cavities, is located approximately at the level of the nipple line during exhalation, lower during inhalation. Injuries below the nipple line are likely abdominal and not thoracic, depending on the phase of respiration when the injury occurred.

**The Abdominal Wall.** An abdominal evisceration occurs when an open wound through the abdominal wall allows abdominal contents, usually the small intestine, to protrude and be exposed. Protect the exposed organs from further injury or contamination. Do not attempt to replace the organs. Specific management of an abdominal evisceration is discussed later in the chapter.

**Abdominal Injuries**

Abdominal injuries are caused by either blunt trauma or penetrating trauma. The mechanisms of injury are similar to those of chest injury. Blunt trauma to the abdomen is especially lethal because of the large number of organs that can be affected.

Injuries to the abdomen are classified as either open or closed. Open injuries result from penetrating trauma from bullets, knives, ice picks, sharp metal, broken glass, screwdrivers, and other sharp objects (Figure 35-1 ■).

Bullets, once they enter the body, can injure almost any organ or structure. If the patient is shot in the abdomen, the bullet could have entered the chest, fractured the pelvis, or lodged in the spinal column. The entrance wound may be to the anterior abdomen and the exit wound to the posterior thorax. The patient may have been shot in the chest, with the bullet traveling through the diaphragm and into the abdomen. With any gunshot wound, be highly suspicious that other organs, bones, and vessels have also been injured. Always search for an exit wound. If you focus on just the entrance wound, you could easily miss the potentially life-threatening exit wound.
Open wounds to the abdomen are much more dramatic and easier to find upon assessment than closed wounds. For example, a severe form of an open wound to the abdomen is an evisceration, in which organs are protruding through the skin. However, closed abdominal wounds could be much more dangerous. Blunt trauma applied to the abdomen can crush, tear, or rupture a large number of organs, causing severe internal bleeding. You must look at the mechanism of injury and physical assessment findings, as well as maintain a high index of suspicion that a closed abdominal injury exists.

Assessment-Based Approach: Abdominal Trauma

Assessment of the patient with a suspected abdominal injury is geared to identifying that a potential injury exists and not toward identifying the particular organ that has been injured. Consider the mechanism of injury, patient complaints, signs, and symptoms.

Scene Size-up

The scene size-up can provide clues as to whether the trauma was caused by blunt or penetrating forces. Once you have ensured your own safety, scan the scene and develop suspicions of what may have caused the injury. Look for evidence of knives, guns, sharp metal, and other objects that may have penetrated the body. Ask the police or any bystanders at the scene if a gun was involved or if gunshots were heard. If the penetrating object is located, estimate the length and width (stabbing) or caliber (gunshot). This may be important information for the physician. However, do not spend valuable time looking for a weapon and trying to identify its characteristics.

Remember: Do not expect abdominal wounds to be obvious if the patient is clothed. Suspicion of a penetrating wound should prompt you to expose and inspect the entire body for open wounds.

Blunt trauma is associated with motor vehicle crashes, falls, pedestrian–vehicle collisions, motorcycle collisions, assaults, heavy objects thrown at or falling on the patient, and crushing injuries from machinery or other heavy equipment. The motor vehicle collision is by far the most common cause of blunt trauma to the abdomen. Attempt to determine the following when a motor vehicle collision is involved:

- Type of vehicle
- Approximate speed the vehicle was traveling (fast, slow, stationary)
- Type of collision and point(s) of impact
- Whether the patient was the driver, a passenger, or a pedestrian
- Where the patient is found and his position
- Whether the patient was thrown from the vehicle
- Impact marks to the windshield, steering wheel, and dashboard

Secondary Assessment

During your secondary assessment, consider the patient’s complaints and the mechanism of injury. Whether the injury is due to blunt or penetrating trauma, it is
essential that you expose the entire body and perform a rapid secondary assessment to identify other potential injuries. Since abdominal injuries can produce severe pain, the patient may not complain of any other injuries. If you allow yourself to develop tunnel vision and not inspect other areas of the body, you can easily miss life-threatening injuries. First inspect the head, neck, and chest. If the patient has been shot in the abdomen, examine the chest for a possible exit wound or another gunshot wound. Remember that because of the excursion of the diaphragm during breathing, the boundary between abdomen and chest varies.

Apply a cervical spine immobilization collar if a spinal injury is suspected. Do not release manual in-line spinal stabilization until the patient is completely immobilized to a backboard.

Inspect the abdomen. Look for contusions, lacerations, abrasions, and punctures. Determine if the abdomen appears to be distended. (If it is, several liters of blood may have been lost into the abdominal cavity. It takes 1 to 2 liters of blood to expand the abdominal girth by 1 inch.) Inspect around the umbilicus (navel) and the flank areas for discoloration and bruising, which also indicate that bleeding is occurring inside the abdomen. This is a late sign and may be an indication that the patient had been bleeding for some time before contacting EMS. Look for bruising over the lower abdomen that could be caused by an improperly worn lap belt if the patient was involved in a motor vehicle collision.

Inspect and provide emergency medical care for any abdominal evisceration. Then palpate the abdomen, starting from the point farthest away from the pain. Note any tenderness or masses. If the patient has a decreased mental status, watch for a grimace as you palpate. The abdomen may be rigid from contraction of the abdominal muscles. The patient may be voluntarily contracting the muscles to guard against pain during your assessment, or the muscles may be involuntarily contracted by a reflex.

Assess the extremities for injury. Check and compare the strength of the pulses of both the upper and lower extremities. Abdominal aortic injury may cause the pulses of the lower extremities to be weaker than the upper extremities or even absent. If no pedal (foot) pulses are found, check for popliteal (back of the knee) or femoral (thigh) pulses. These should be equal to or stronger than the radial pulse, even in hemorrhagic shock. Keep in mind that blood loss and shock will reduce the pulse strength in the most distal pulses. Also assess motor and sensory function.

Log roll the patient and inspect the entire back and lumbar region for any signs of trauma. If the patient is suspected of having a spinal injury, log roll the patient onto a backboard at this time.

Assess baseline vital signs, especially for indications of blood loss and shock. A low blood pressure, tachycardia, or pale, cool, and moist skin are indicators that the patient is in shock. The breathing rate is typically fast and shallow in abdominal injuries because of the increase in pain associated with deep breathing.

From the responsive patient, obtain a history. The abdominal pain can be evaluated using the OPQRST mnemonic to help you. If the patient is unresponsive, ascertain as much information as possible from any bystanders at the scene. The signs and symptoms and events prior to the injury are extremely important points of information to gather.

**Signs and Symptoms.** Patients with abdominal injury may exhibit the following signs and symptoms:

- Contusions, abrasions, lacerations, punctures, or other signs of blunt or penetrating trauma
- Pain that may initially be mild, then worsening
- Tenderness on palpation to areas other than the site of injury
- Rigid abdominal muscles
- Lying with legs drawn up to the chest in an attempt to reduce the pain
- Distended abdomen
- Discoloration around the umbilicus or to the flank (late finding)
- Rapid, shallow breathing
- Signs of hemorrhagic shock (decreasing blood pressure, narrowing pulse pressure, increasing heart rate, and increasing respiratory rate)
- Nausea and vomiting (may contain blood)
- Abdominal cramping possibly present
- Pain that radiates to either shoulder from irritation of the diaphragm (Kehr sign)
- Weakness

A mechanism of injury involving either blunt or penetrating trauma, early signs and symptoms of hemorrhagic shock, shallow and rapid respirations, and abdominal pain and rigidity are all significant and early signs of a serious abdominal injury. Any patient who complains of abdominal pain should be taken seriously and assessed carefully.

**General Emergency Medical Care—Abdominal Trauma**

Emergency medical care is basically the same for both open and closed abdominal injuries: aggressive management of the airway, breathing, oxygenation, and circulation. Since you are limited in the emergency medical care you can provide for abdominal injury, early recognition and prompt transport is a key element.

1. **Establish and maintain an open airway and manual inline spinal immobilization if necessary.** Reassess the airway continuously. The patient may suddenly vomit, which can easily occlude the airway. Suction any vomitus, blood, or other secretions from the mouth. If the condition continues to deteriorate, it may be necessary to perform a jaw-thrust maneuver.
and to insert an oropharyngeal or nasopharyngeal airway.

2. **Maintain adequate oxygenation.** Administer supplemental oxygen to maintain an SpO₂ of 94% or greater or if signs of shock are present.

3. **Reassess the breathing status.** If the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.

4. **Treat for hemorrhagic shock.**

5. **Control any external bleeding.** Apply a dry, sterile dressing to open wounds to the abdomen, the exception being an abdominal evisceration. In case of an evisceration, see the guidelines in the next segment for preparing a dressing.

6. **Position the patient.** Place the patient in a supine position with legs flexed at the knees (legs brought up toward the chest) if no injury to the lower extremities, hips, pelvis, or spine is suspected. Remember not to give anything by mouth, even if the patient complains of thirst. Do not allow the patient to eat or drink any amount of food or liquid. If spinal injury is suspected, immobilize the patient to a backboard.

7. **Stabilize an impaled object.** Do not remove it. Dress the wound around the impaled object to control the bleeding. Stabilize the object with bulky dressings and bandages to prevent movement.

8. **Apply the pneumatic antishock garment (PASG), if intraperitoneal or retroperitoneal hemorrhage is suspected with hypotension.** Follow your local protocol.

9. **Transport as quickly as possible.**

**PATHOPHYSIOLOGY PEARLS**

Patients with abdominal injuries are not allowed to eat or drink any fluid in case they may need to have emergency surgery. The food or drink could cause them to vomit after receiving the anesthesia, risking aspiration.

**Emergency Medical Care—Abdominal Evisceration**

A large open wound to the abdomen may allow organs to protrude. Do not touch or attempt to replace the protruding organs. In caring for an evisceration, follow the general guidelines already discussed for abdominal injury, except dress the evisceration in the following way (EMT Skills 35-1A to 35-1C):

1. **Expose the wound.** Cut away clothing, if necessary. Do not touch or attempt to replace any of the organs.

2. **Position the patient** on his back and flex the legs up toward the chest if spinal injury is not suspected.

3. **Prepare a clean, sterile dressing** by soaking it with saline or sterile water. Apply the dressing over the protruding organs. Do not use absorbent cotton or any other material that might cling to the organs when wet, such as paper towels or toilet tissue.

4. **Cover the moist dressing with an occlusive dressing** to retain moisture and warmth. Plastic wrap will do. Avoid the use of aluminum foil, if possible, since it may lacerate the protruding organs. Secure the dressing in place with tape, cravats, or a bandage.

5. **Administer supplemental oxygen to maintain an SpO₂ of 94% or greater.** Be prepared to treat for shock.

**Reassessment**

During the reassessment en route, evaluate the effectiveness of your treatment and assess for further deterioration of the patient’s condition, repeating appropriate elements of the primary and secondary assessments. Reassess vital signs, and observe especially for indications of the presence or worsening of blood loss and shock: deteriorating mental status, falling blood pressure, tachycardia, or pale, cool, moist skin. Recall that a rapid, shallow breathing rate is typical with abdominal injuries from associated pain, so maintain oxygenation at an SpO₂ at 94% or greater.

**Summary: Assessment and Care—Abdominal Trauma**

To review possible assessment findings and emergency care for abdominal injuries, see Figures 35-3a, 35-3b, and 35-4.

**GENITAL TRAUMA**

While injuries to the genitilia are rarely life threatening, they are typically extremely painful and could be quite embarrassing for the patient.

- **Injuries to the male genitilia** include lacerations, abrasions, avulsions, penetrations, amputations, and contusions. They usually produce excruciating pain and cause great concern to the patient. The penis is very vascular and can bleed excessively. An injury to
### Assessment Summary

#### Abdominal Trauma

The following findings may be associated with an abdominal trauma.

#### Scene Size-up

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Automobile crash, bent steering wheel
- Sports accident, especially blow to abdomen
- Gunshot wound
- Stab wound
- Fight, especially with hard, direct blow to abdomen
- Crush injury
- Explosion

#### Primary Assessment

**General Impression**
- Patient lying very still with knees flexed up toward chest
- Obvious open wound to abdomen
- Severe abdominal pain

**Mental Status**
- Alert to unresponsive, based on type and degree of injury
- Unresponsiveness or decreasing mental status associated with hemorrhagic shock and poor cerebral perfusion

**Airway**
- Assume airway is obstructed if patient has altered mental status

**Breathing**
- Normal
- May be fast and shallow because of pain associated with breathing
- Labored breathing may be present if diaphragm is injured

**Circulation**
- Pulse and skin color vary depending on injury
- Pulse is increased in shock state and in association with severe pain
- Skin will be pale, cool, and clammy in shock state

**Priority Status:** Priority patient if abdominal trauma is associated with severe pain or signs and symptoms of hemorrhagic shock

#### Secondary Assessment

**Physical Exam**

**Head:**
- Pale oral mucous membranes in shock state
- Pupils may be sluggish to respond in shock state

**Chest:**
- Decreased breath sounds bilaterally if breathing is shallow because of pain

**Abdomen:**
- Contusions, lacerations, punctures, abrasions, or other evidence of trauma
- Inspect for distention
- Discoloration around umbilicus and in flank areas (late sign of intra-abdominal bleeding)
- Inspect for abdominal evisceration
- Palpate for rigidity and guarding
- Pain on palpation
- Palpate for masses

**Extremities:**
- Weak peripheral pulses indicating poor perfusion
- Difference in strength of pulses in upper and lower extremities indicating possible aortic injury

**Posterior Body:**
- Evidence of blunt or penetrating trauma

#### Baseline Vital Signs

**BP:** may be low because of blood loss
**HR:** tachycardia from severe pain and blood loss
**RR:** normal; may be increased because of pain, or labored if diaphragm injured
**Skin:** pale, cool, clammy if blood loss and shock
**Pupils:** may be sluggish to respond to light because of poor perfusion
**SpO₂:** reading may not be obtained if shock is present

---

 FIGURE 35-3a  Assessment summary: abdominal trauma.
Emergency Care Protocol

**ABDOMINAL TRAUMA**

1. Establish manual in-line stabilization. Do not release it until the patient is immobilized onto a backboard if spinal injury is suspected.
2. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive and has no gag or cough reflex.
3. Suction secretions as necessary.
4. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
5. If breathing is adequate, administer oxygen to maintain the \( \text{SpO}_2 \) at 95% or greater.
6. Control any major bleeding.
7. Treat the specific condition or wound:
   - **Impaled Object:** Stabilize the impaled object in place.
   - **Abdominal Evisceration:** Place a moist, sterile dressing over the entire wound, overlapping by 2 inches. Apply an occlusive dressing taped on all four sides. Flex knees up toward the chest.
   - **Open Wound to Abdomen:** Apply a dressing over the wound.
8. Treat for shock. Consider application of the pneumatic antishock garment (PASG) if intra-abdominal hemorrhage is suspected with severe hypotension (SBP < 90 mmHg) or if retroperitoneal hemorrhage is suspected with hypotension.
9. Immobilize to a backboard if you suspect spine injury.
10. Transport.
11. Perform a reassessment every 5 minutes if unstable and every 15 minutes if stable.

**FIGURE 35-3b** Emergency care protocol: abdominal trauma.

---

the penis or scrotum should be treated as a soft tissue injury, which can be controlled with direct pressure. Cold compresses may be applied to the scrotum to reduce the pain and swelling associated with injury. If the penis has been avulsed or amputated, apply direct pressure to control the bleeding. If the amputated or avulsed part is located, wrap it in a sterile dressing moistened with sterile saline, place it in a plastic bag, and keep it cool by placing the bag on a cold pack or ice that has been wrapped in a towel. Maintain oxygenation at 94% or greater, carefully assess for signs and symptoms of shock, and transport the patient with any amputated parts.

- **Injuries to the female genitalia** can occur from straddle injuries, sexual assault, blunt trauma, abortion attempts, lacerations following childbirth, and foreign bodies inserted into the vagina. Because a large number of nerves are located in this area, injuries usually produce excruciating pain and cause great concern to the patient. The female genital area is very vascular and can bleed profusely. Control any bleeding with direct pressure, using moistened compresses such as a sterile sanitary napkin. Never pack or place dressings inside the vagina. Carefully assess for signs and symptoms of shock, maintain oxygenation at 94% or greater, and transport.
Emergency Care Algorithm

Suspected spine injury?
- Yes
  - Manual in-line stabilization
  - Control bleeding
  - Alert and able to obey commands
  - Consider oxygen administration
  - Assess mental status
  - Assess breathing
  - Assess circulation
  - Secondary assessment

Suspect abdominal injury
- Yes
  - Trauma to abdomen? Rigid abdomen?
    - Yes
      - Pain or tenderness on palpation?
        - Yes
          - Treat for shock
        - No
          - Manage abdominal injuries
            - Impaled object
            - Stabilize object in place
            - Immobilize to backboard
            - Transport
            - Reassessment
        - No
          - Abdominal evisceration
          - Cover with moist sterile dressing
          - Apply a nonporous dressing
          - Cover with a moist sterile dressing
          - Immobilize to backboard
          - Transport
          - Reassessment
  - No
    - Signs and symptoms of shock?
      - Yes
        - Manage abdominal injuries
      - No
        - Open wound
        - Cover with moist sterile dressing

Any major bleeding?
- Yes
  - Control bleeding
  - Alert and able to obey commands
  - Consider oxygen administration
  - Assess mental status
  - Airway open?
    - Yes
      - Suction if necessary
      - Jaw thrust
      - Oro- or nasopharyngeal airway
    - No
      - PPV with O₂
      - Assess circulation
      - Rapid secondary assessment
- No
  - Any major bleeding?
    - Yes

          - Apply a nonporous dressing
          - Cover with a moist sterile dressing
          - Immobilize to backboard
          - Transport
          - Reassessment
Dressing an Abdominal Evisceration

35-1A Cut away clothing from the wound and support the knees in a flexed position.

35-1B Place a premoistened dressing over the wound (follow local protocol) and gently tape it in place. Do not attempt to replace intestines within the abdomen.

35-1C Apply an occlusive covering (follow local protocol). Tape it loosely to keep the dressing moist.

SUMMARY
Abdominal injuries may not present as dramatically as other injuries; however, the main concern is possible severe internal bleeding and hemorrhagic shock. Laceration or rupture of many of the abdominal organs can lead to severe bleeding and serious blood loss. An abdominal evisceration occurs when a portion of an abdominal organ protrudes through the open wound in the abdomen. The protruding organ must be covered by a moist, sterile dressing and then sealed with an occlusive dressing to hold in the moisture and heat.

Male and female genitalia injuries are managed as soft tissue injuries. These injuries are rarely life threatening.
Scene Size-up
You and your partner are at the scene of a patient struck by a car while jogging. A male patient, who introduces himself as Harvey Young, is lying supine on the sidewalk and holding his abdomen. The police have indicated that he is the only patient.

Primary Assessment
Your partner immediately takes manual in-line spinal stabilization. The patient is alert, responsive, and complaining of severe abdominal pain. He is talking with you, so you know his airway is open. His breathing appears to be adequate but is rapid. His skin is pale, cool, and clammy and his radial pulse is weak and rapid. The pulse oximeter displays an error message and he is exhibiting signs of shock so you apply a nonrebreather at 15 lpm.

You decide that the patient is exhibiting signs and symptoms of hemorrhagic shock; therefore, he is a priority transport. You quickly cut the clothes away from the patient to completely expose him to conduct a rapid secondary assessment.

Secondary Assessment
Mr. Young tells you he was jogging down the street when a car “came out of nowhere.” He explains that the car swerved but still hit him as he turned to try to get out of the way. Most of the impact was to his abdomen.

You begin the rapid secondary assessment looking for any other life-threatening injuries. He has multiple contusions and abrasions to the body. The pupils are equal and reactive to light. There is no blood or cerebrospinal fluid leaking from the nose, mouth, or ears. You do not find any evidence of trauma to the head or neck. The jugular veins are flat and the trachea is midline. You do not note any subcutaneous emphysema on palpation. Upon inspection of the chest, you do note some minor contusions and abrasions. The patient does not complain of any pain on palpation nor do you find any abnormalities. The breath sounds are equal and clear bilaterally. You note a large contusion to the left upper quadrant. Upon palpation, the patient complains of severe pain to the left upper quadrant. The abdomen is rigid. The pelvis is stable when palpated. You note contusions and abrasions to extremities; however, no deformity, pain, angulation, discoloration, or edema is found. The pulses are weak and rapid in all four extremities. The skin is pale, cool, and clammy. You log roll the patient and find minor contusions and abrasions to the posterior body. You place the patient onto the backboard.

As your partner completes the immobilization, you take the patient’s vital signs, which are pulse 126 bpm; blood pressure 102/78 mmHg; respirations 26; skin pale, cool, and clammy. Immediately after the immobilization is complete, you begin rapid transport to the trauma center.

En route you obtain a brief history. Mr. Young reports that he has no known allergies, takes no medications on a daily basis, and has no other medical problems or history. He last had a drink of water before jogging.

Reassessment
While you are en route to the hospital, you conduct a reassessment. You contact the hospital and provide an oral report. Upon arrival, you give the triage nurse a brief report and he has you transfer Mr. Young to a trauma room. You then begin your documentation of the call as your partner readsies the ambulance for the next patient.

Later in the week you find out from the triage nurse that Harvey Young ruptured his spleen and required surgery. He is expected to make a full recovery.

IN REVIEW
1. List the signs and symptoms associated with trauma to the abdomen.
2. Describe the general guidelines for emergency medical care of both open and closed abdominal injuries.
3. Describe emergency medical care for an abdominal evisceration.
4. Describe the general emergency care for injuries to the male or female genitalia.

CRITICAL THINKING
You arrive on the scene in a residential neighborhood and find a 48-year-old male patient lying on his right side on the garage floor. You see large pools of blood on the floor. You note a circular saw with blood on it and some wood on the floor also. The patient’s eyes are open and he is moaning in pain. The patient states he was cutting some wood when the saw kicked back and struck him in the abdomen. The patient’s respirations are 38 and shallow. His radial pulse is present but weak. His skin is pale, cool, and clammy. His heart rate is 126 bpm. After exposing the patient, you note a large, gaping laceration to the abdomen with what appears to be a portion of the small intestine protruding through the wound.

1. What immediate emergency care would you provide for the patient?
2. How would you manage the protruding abdominal organs?
3. What do the vital signs indicate?
4. How would you position the patient for transport?
CHAPTER 36

MULTISYSTEM TRAUMA AND TRAUMA IN SPECIAL PATIENT POPULATIONS

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Trauma** (Content Area: Multisystem Trauma; Special Considerations in Trauma)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely injured patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

36-1. Define key terms introduced in this chapter.
36-2. Discuss the increased morbidity and mortality associated with multisystem trauma.
36-3. Describe the importance of the golden principles of prehospital multisystem trauma assessment, care, and transport.
36-4. Summarize anatomical and physiological changes of pregnancy that create special considerations in assessing, managing, and transporting pregnant trauma patients.
36-5. Describe the relationship of maternal injuries to fetal distress and death.
36-6. Summarize anatomical and physiological changes in children that create special considerations in assessing, managing, and transporting pediatric trauma patients.
36-7. Summarize anatomical and physiological changes in the elderly that create special considerations in assessing, managing, and transporting geriatric trauma patients.
36-8. Discuss special considerations in assessing, managing, and transporting cognitively impaired trauma patients.
36-9. Discuss the assessment-based approach to multisystem trauma and trauma in special patient populations.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

abruptio placentae p. 979  multisystem trauma p. 977

---

**Case Study**

**The Dispatch**
EMS Unit 43—proceed to 587 Biltmore Lane—you have a 30-year-old patient who fell. Time out is 1730 hours.

**Upon Arrival**
As you arrive on the scene at a single-family residence, you are met by four small children screaming and crying. You approach the residence and hear a voice yell “Help me!” from inside. The children run past you into the house and lead you to the stairwell. There, you see an obviously pregnant woman lying on the floor at the base of the stairs next to a pile of laundry.

**How would you proceed to assess and care for this patient?**
In this chapter, you will learn about special considerations when caring for specific trauma populations. Later, we will return to the case study and apply the principles learned.
INTRODUCTION

In previous chapters you have learned how to properly assess and manage an adult trauma patient. However, not every trauma patient is the same. Some trauma patients have multiple body systems that have been injured, which makes their assessment and care more challenging. Other patients may be part of a special population such as pregnant women, children, elderly adults, and people with cognitive impairments that can also require additional assessment and management skills. If the patient is part of a special population, the EMTs should be able to incorporate their knowledge about that particular type of patient into their assessment and emergency care.

MULTISYSTEM TRAUMA

Traumatic injuries pose some of the greatest challenges to the EMT. With trauma, patients are subjected to significant forces that increase their risk for injuries to multiple organs within the body at the same time. Almost all trauma affects more than one body system. Typically a patient is considered to have multisystem trauma when more than one major system is involved. For example, a patient with multisystem trauma might have head and spinal injuries, chest and abdominal injuries, or chest and multiple extremity injuries. As an EMT, you should suspect multisystem trauma in any patient who has been subjected to a significant external force.

Multisystem trauma has a high incidence of morbidity and mortality. Trauma is the leading cause of death for young people 1 to 44 years of age. Because multiple organ systems are involved, numerous injuries and their complications should be anticipated by the EMT. The signs and symptoms associated with the injuries will vary based on the body systems that are affected. The emergency care that you will need to provide will also depend on the systems and injuries sustained by the patient. It is important to note that patients with multisystem trauma are at a greater risk of developing shock than trauma patients whose injuries affect only one system.

The definitive care for a patient with multisystem trauma may be surgery, which obviously cannot be performed in the prehospital environment. As an EMT, you are often the first member of a team of medical professionals who will assess and treat these patients. Once you have taken the patient to the hospital, the hospital staff and trauma team will continue to manage the patient’s care. Often a team of physicians, including specialists such as neurosurgeons, thoracic surgeons, and orthopedic surgeons, are needed to properly treat the patient’s injuries.

Golden Principles of Prehospital Multisystem Trauma Care

The following are golden principles for prehospital multisystem trauma care. Keep these principles in mind when you manage a patient with multisystem trauma:

- **Ensure safety of the rescue personnel and the patient.** Your personal safety is most important and should be maintained when you arrive on the scene and throughout your patient’s care. Remember that an injured EMT cannot provide care to others. Be sure to assess your environment and look for possible hazards that could put you or others at risk. Some of these dangers include passing automobiles, hazardous materials, hostile environments, unsecured crime scenes, and suicidal patients who may become homicidal.

- **Determine additional resources needed.** After arriving on the scene, determine if you need additional resources. Because multisystem trauma can result from various causes, the additional resources required might vary. The use of advanced life support (ALS) intercept and air medical resources for a multisystem trauma patient should be seriously considered. Know your local protocols and procedures for requesting these resources.

- **Understand kinematics.** Knowing the mechanism of injury can help the EMT anticipate what injuries the patient may have. Multisystem trauma can result from blunt trauma, penetrating trauma, motor vehicle collisions, blast injuries, deceleration injuries, or any other type or combination of mechanisms. As an EMT, always maintain a high index of suspicion that multiple systems are involved when you approach any trauma patient. Sometimes an obvious injury is not the one that has the most potential for harm. Do not develop “tunnel vision” by focusing on patients who complain and are screaming for your help. Other, quiet patients on the scene may be hypoxic or may have internal bleeding that has resulted in an altered level of consciousness and may not be able to call out for help.

- **Identify and manage life threats.** Airway, ventilation, and oxygenation are key to the successful management of a multisystem trauma patient. Each multisystem trauma patient should be assessed and that patient’s specific emergency care needs identified. For example, you should control arterial bleeding as soon as you find it, even if that precedes airway and ventilation assessment. A large amount of emergency care for the multisystem trauma patient can be provided en route to the receiving facility.

- **Manage the airway while maintaining cervical spinal stabilization.** Because multisystem trauma patients may have suffered a spinal injury, always establish and maintain spinal stabilization. Inspect
for possible airway obstructions and apply suction if necessary. Open the airway using the jaw thrust. The airway of the patient must remain open and clear throughout the duration of your care.

- **Support ventilation and oxygenation.** Determine if your patient is breathing adequately based on the rate and tidal volume. If the ventilation is inadequate, provide positive pressure ventilation. Patients with a low minute volume will need assisted ventilations. Administering high-concentration oxygen is necessary in the multisystem trauma patient to saturate the hemoglobin with as much oxygen as possible and to attempt to maintain delivery of oxygen to the cells. The patient’s oxygen saturation should be maintained greater than 94% at all times and should be monitored by pulse oximetry.

- **Control external hemorrhage and treat for shock.** Cellular oxygenation is impaired when a patient is bleeding profusely. The loss of hemoglobin reduces the ability of the blood to carry and deliver oxygen to the cells. This leads to cellular hypoxia and anaerobic metabolism. Because of this, it is necessary to stop major external hemorrhage rapidly. If the bleeding cannot be controlled by direct pressure, consider the use of a tourniquet. Multisystem trauma patients are at risk for developing shock. If any signs and symptoms of shock are present, initiate emergency care for shock (see Chapter 15, “Shock and Resuscitation”). Maintain a normal body temperature and prevent hypothermia by covering the trauma patient with blankets.

- **Perform a secondary assessment and obtain a medical history.** After treating immediate life threats, perform a rapid secondary assessment to identify any additional injuries that could potentially be life threatening. This is very important, especially when you are trying to determine if multiple body systems may have been injured. The signs and symptoms discovered during your assessment will vary according to the organs and systems that are involved and must be treated appropriately. Try to obtain a medical history from the patient or bystanders. Remember that you may be the only source of that information until family arrives at the hospital. Keep in mind that the traumatic injuries may have resulted because of an underlying medical condition. Also, underlying medical conditions and medications can alter the body’s ability to respond appropriately to the injury and blood loss. As an example, a patient who is taking beta blockers or calcium channel blockers will present with a heart rate that may appear within normal limits but does not correspond with other presenting signs and symptoms of shock and blood loss. It is important to convey this information to other health care providers.

- **Splint musculoskeletal injuries and maintain spinal immobilization on a long spine board.** Multisystem trauma patients may be found standing, sitting, prone, or supine when you arrive on the scene. All of these patients require cervical spine stabilization that must be maintained at all times. Proper cervical spine stabilization, log rolling techniques, and use of a backboard by the EMT can help protect the spinal cord and prevent additional injuries. Any musculoskeletal injuries should be splinted en route if the patient is unstable. The backboard acts like a splint and provides minimal stabilization until time and patient condition permit further fracture care. Splinting fractures at the scene for a multisystem trauma patient will delay transport, something that should not occur in trauma patients. Splinting possible fractures en route, however, may help minimize blood loss, minimize neurovascular damage, and prevent closed fractures from becoming open ones.

- **Make transport decisions.** Rapid extrication and rapid transport of the critically injured multisystem trauma patients is essential. The on-scene time is critical and should not be prolonged. The on-scene time is considered part of the platinum 10 minutes and the golden period between injury and definitive care at the hospital, a time span that should not be exceeded and should be minimized if possible. It is critical that you know your local trauma system capabilities and transport your patient to the closest appropriate facility capable of providing trauma care. Notify the hospital as early as possible so they can prepare for the patient’s arrival. Many of these patients require surgery for their injuries.

### TRAUMA IN SPECIAL PATIENT POPULATIONS

Trauma can occur in all populations. Some patients—like pregnant women, children, elderly adults, or patients who are cognitively impaired—require additional assessment considerations and some modifications in treatment for their traumatic injuries. Identifying and treating life-threatening injuries is a priority in all of these special patient populations.

#### Trauma in Pregnant Patients

Trauma occurs in approximately 6 to 7 percent of all pregnancies and is the leading cause of death for pregnant women. Pregnant patients can sustain all types of trauma and are especially susceptible to physical abuse and falls (Figure 36-1 ▼). Motor vehicle crashes account for about half of all injuries sustained during pregnancy.

There are two patients when you deal with a pregnant trauma patient: the mother and the fetus. The number of weeks the patient has been pregnant and the size of the fetus are important to the fetus’s chance of survival. Because it is difficult to assess the fetus in the
Assessment Considerations in the Pregnant Trauma Patient

Trauma to a pregnant woman, whether severe or minor, can have significant effects on the health of the fetus. It is estimated that 1 to 3 percent of minor traumas involving pregnant women result in fetal loss. The more severe the injury to the mother, the greater the chances of fetal injury. Fetal death rates are nine times higher than maternal death rates following trauma. The most common problem caused by maternal trauma is uterine contractions that may progress into labor. You must assess for crowning or bleeding in these trauma patients.

Abruptio placentae, or the separation of the placenta from the uterine wall, can also result from a traumatic injury (see Chapter 37, “Obstetrics and Care of the Newborn”). It is most common when the patient has suffered blunt trauma. Abdominal pain and vaginal bleeding are often present with this condition and pose a high risk of fetal and maternal death. Fetal injury and death can also result from penetrating trauma. Because the patient’s uterus has grown in size, it can help shield the mother against some abdominal injuries; however, it puts the fetus at greater risk for injury. For example, stab wounds to the uterus can produce 93 percent morbidity to the fetus.

Motor vehicle crashes account for a large number of maternal and traumatic injuries. Pregnant patients wearing their seat belts properly are more likely to have a favorable outcome when involved in a crash than those who don’t wear seat belts. The unbelted pregnant crash victim is twice as likely to have vaginal bleeding or to give birth, and fetal death is three to four times more likely. Uterine rupture is a rare event that sometimes occurs when the woman’s pelvis strikes the uterus in a vehicular crash. It can result in maternal and fetal death.

Fetal distress can also be caused by hypoxia or hypovolemic shock, which can result from any traumatic injury. Shock and internal blood loss in a third-trimester patient may be difficult to detect. Because of the cardiovascular changes in the pregnant patient, the signs of maternal hypotension resulting from traumatic bleeding may be delayed or masked. You must anticipate shock and not rely solely on vital sign changes to manage the patient aggressively. Shock is a frequent cause of death to both the fetus and the mother.

It is estimated that 41 percent of fetuses die when the mother suffers a life-threatening injury. A traumatic maternal cardiac arrest poses a significant risk to the fetus. A pulseless woman in the third trimester should be transported to the nearest appropriate medical facility for attempted resuscitation of the mother and fetus unless instructed otherwise by medical direction. Although the chance of the fetus surviving maternal cardiac arrest is poor, it still may be possible. Make sure you know and follow your protocols regarding this type of scenario.
Management Considerations for the Pregnant Trauma Patient

Most of the emergency care for a pregnant trauma patient is the same as for nonpregnant trauma patients and obstetric emergencies. Some additional management considerations for a pregnant trauma are:

- Full spinal immobilization is required for pregnant patients suspected of having spinal injury; however, you will need to tilt the long spine board to the left if the patient is in her third trimester or obviously pregnant. This will help prevent supine hypotensive syndrome by moving the uterus off the inferior vena cava. The pregnant patient should remain on her left side throughout transport.
- Airway, ventilation, and oxygenation are critical to the pregnant trauma patient. You should anticipate vomiting and have suction readily available. Assess if the patient is breathing adequately and if bilateral breath sounds are present. Assist the patient’s ventilations if they are inadequate. Administer oxygen by nonrebreather mask if the breathing is adequate or via the bag-valve mask in the patient with inadequate breathing. Administer supplemental oxygen to maintain the SpO2 reading as high as possible. Attempt to achieve 100% oxygen concentration delivery. The fetus is vulnerable to any reduction in oxygen and can become severely hypoxic before the pregnant patient shows signs of hypoxia. Therefore, always maximize oxygenation in the pregnant patient regardless of the SpO2 reading.
- Assess the patient’s circulation and check for major bleeding. If vaginal bleeding is present, absorb the blood flow with a pad and do not pack the vagina. Anticipate, prevent, and treat shock.
- Perform a visual exam at the vaginal opening to assess for crowning or bleeding. Remember that you have two patients. If labor occurs as a result of the trauma, you will want additional resources to help you manage both the mother and the newborn.
- Consider ALS intercept or air medical transport for major traumas involving pregnant patients. Follow your local protocol. Inform the trauma center as soon as possible that the patient involved in the trauma is pregnant. This will allow the receiving facility time to assemble a trauma team and other necessary resources to manage the fetus.
- The best method to care for the fetus is by anticipating injuries and shock and aggressively managing the mother.

Trauma in Pediatric Patients

Pediatric patients are frequently victims of major and minor trauma. Children may experience traumatic injuries from drowning, burns, falls, penetrating trauma, motor vehicle crashes, abuse, pedestrian versus vehicle collisions, as well as any other traumatic mechanism (Figure 36-2 ■). See Chapter 38, “Pediatrics,” for more information on assessment and emergency care of the pediatric trauma patient.

Half of all deaths in children ages 1 to 14 are the result of trauma. Motor vehicle collisions account for the majority of traumatic injuries as well as almost half of the traumatic deaths. Improper car seat usage or placement can greatly contribute to the injuries sustained by pediatric patients involved in motor vehicle collisions.

Children are at risk of being abused by adults and older children. Child abuse accounts for approximately 25 to 35 percent of pediatric trauma deaths. It also can result in significant injuries and impairments. Some findings that may prompt you to suspect abuse include:

- Bruises or burns in unusual shapes and locations
- An injury that doesn’t seem to correlate with the cause provided
- More injuries than usual for a child that same age
- Multiple injuries in various healing stages
- Delay in seeking emergency care

Shaken baby syndrome is one of many causes of brain injury. Other injuries can also result in life-threatening emergencies for abused children.

Trauma involving a pediatric patient is one of the most difficult types of calls for EMTs to respond to. Knowing that the young patient has endured a traumatic injury can be especially stressful for you as well as for the family and bystanders. It is important to act professionally, competently, and compassionately throughout the call, remembering that the assessment and care you provide to these patients directly impact their outcomes.
Anatomical and Physiological Considerations in the Pediatric Trauma Patient

Pediatric patients have anatomical and physiological characteristics that play a significant role in trauma assessment and management. Traumatic forces are more widely distributed in pediatric patients than in adults, and this makes them more prone to suffering multisystem trauma. The child’s body surface area is greater and the child has poorly developed thermoregulation mechanisms as compared to an adult’s, and, therefore, the child can lose heat faster. Pediatric patients have heavy heads and weak neck muscles that increase their risk of head and cervical spinal injuries. Their internal organ placement makes them more susceptible to injuries to the spleen and liver.

Infants and children have greater chest wall flexibility than adults, which can allow for injuries with few external signs of trauma. You must look closely for signs and symptoms of a chest wall injury in pediatric trauma patients, and maintain a high index of suspicion that severe underlying trauma exists. The growth plates in children are not fully developed, and trauma to these plates may impact the bones’ normal growth. Children also have higher energy requirements and can fatigue faster than adults.

Assessment Considerations in the Pediatric Trauma Patient

Children respond differently to injury than adults. Their physiological response and vital signs are influenced by their age and the severity of their injury.

The pediatric assessment triangle (PAT) developed by the American Academy of Pediatrics or, alternatively, the initial impression components found in the American Heart Association’s Pediatric Advanced Life Support (PALS) assessment can help you form a general impression.

The PAT triangle is composed of three sides: appearance, work of breathing, and circulation to skin. The PALS initial impression has three components that are very similar to the PAT: consciousness, breathing, and color. Both the PAT and the PALS assessments collect the same information in the general impression of the pediatric patient:

- **The appearance or consciousness component** refers to assessing the child’s overall mental status (unresponsive, irritable, alert), body position, and muscle tone.
- **The breathing component** relates to the work of breathing as determined by a visual assessment of the effort of breathing, absence of breathing, or decreased respiratory effort plus any audible sounds associated with the patient's respiration.
- **The circulation or color component** is assessed by observing the patient’s skin color (cyanosis, pallor, mottling).

See Chapter 38, “Pediatrics,” for a full discussion of forming a general impression of the pediatric patient.

A patent airway, adequate ventilation, oxygenation, and circulation are essential to the pediatric trauma patient. Any diaphragmatic impairment can compromise the patient’s ventilation. Inspect for accessory muscle use, which is more prominent during respiratory distress. Adequate oxygenation does not reflect sufficient ventilation. Therefore, the rate and quality of the patient’s ventilations must be assessed.

Subtle changes in the pediatric trauma patient’s heart rate, blood pressure, or perfusion status may indicate cardiorespiratory failure. A slow pulse rate in these patients may indicate hypoxia, which is not tolerated well by a child. The brachial pulse should be assessed in an infant less than 1 year of age. Remember that normal blood pressures may be present in pediatric patients with compensated shock. Blood pressure readings are unreliable in children 3 years of age or less. Because of these characteristics, you should rely on other signs and symptoms such as skin color, temperature, and condition; mental status; and capillary refill to assess the pediatric patient’s perfusion status.

Management Considerations for the Pediatric Trauma Patient

Most of the management for a pediatric trauma patient is the same as for adults. Some management considerations for a pediatric trauma patient are:

- Spinal immobilization is required for suspected spinal injuries and should be maintained throughout care. Pad beneath the child who is less than 8 years of age from the shoulders to the hips during cervical spine immobilization to prevent flexion of the neck.
- Open the airway and assess for any possible obstructions from injury, teeth, blood, or vomitus. Gurgling or stridor may indicate an upper airway obstruction.
- Assess the breathing rate and tidal volume. Look at both the chest and the abdomen when doing so. Carefully provide ventilations if either the rate or the tidal volume is inadequate or if bradycardia is present. Pediatric trauma patients can fatigue very quickly.
- Administer supplemental oxygen to maintain an SpO₂ of 94% or greater.
- Assess the circulation and control any external bleeding by direct pressure.
- Manage hypovolemia and shock as you would for an adult.
- Prevent hypothermia. These patients are susceptible to heat loss.
- Transport to an appropriate facility, preferably one that can manage pediatric trauma patients.
- Continually reassess the pediatric trauma patient.

Trauma in Geriatric Patients

Geriatric or elderly patients account for 10 to 14 percent of all trauma patients. The risk of death and significant
injury in the elderly is greater than for younger patients. Falls, most of which occur at home, are the most common cause of injury in the elderly and account for 40 percent of all elderly traumas. As many as one quarter of these falls are the result of medical conditions such as strokes, syncope, and hypovolemia. The most common injury associated with elderly falls is fractures. Loss of strength, sensory impairment, medications, and medical illnesses increase the risk of falls in this population. All elderly traumas should be investigated as to the reason for the fall. See Chapter 39, “Geriatrics,” for more information on assessment and emergency care for the geriatric patient.

Burns, penetrating trauma, pedestrian versus vehicle collisions, vehicle crashes, and elder abuse can also cause traumatic injuries in elderly patients. Motor vehicle collisions are the second most common cause of trauma in the elderly. Older drivers are more likely to be killed or injured in these accidents than younger drivers. Most crashes involving the elderly occur during the day and close to their home. Auto versus pedestrian accidents are the third most common injury in this age group and carry the highest fatality rate. Poor eyesight and hearing, decreased mobility, and longer reaction times make elderly patients more susceptible to motor vehicle collisions and pedestrian accidents than their younger counterparts.

Anatomical and Physiological Considerations in the Geriatric Trauma Patient

Physiological changes are a natural part of aging; however, such changes in the pulmonary, cardiovascular, neurological, and musculoskeletal systems make older patients more susceptible to trauma and less able to cope with its effects. Circulation changes can lead to the inability to maintain vital signs during hemorrhage; for example, the elderly trauma patient’s blood pressure drops sooner than a younger adult’s. With aging, the brain shrinks, which can lead to a higher risk of cerebral bleeding following head trauma. Skeletal changes can cause curvature of the upper spine that may require padding during supine spinal immobilization.

Geriatric patients are more susceptible to injury than other adults, even in cases of minor trauma. As noted in Chapter 30, “Musculoskeletal Trauma and Nontraumatic Fractures,” many elderly patients have osteoporosis, a medical condition characterized by weakening of the bone tissue, which places these patients at increased risk for fractures and other injuries, even with minor traumatic force or no traumatic force at all. Minor chest trauma can cause lung injury. Decreased muscle size in the abdomen may mask abdominal trauma in the elderly. Thinner skin in the elderly results in more easily inflicted soft tissue injuries.

Assessment Considerations in the Geriatric Trauma Patient

Elderly patients have a decreased ability to respond to trauma when compared to a younger patient. Preexisting medical conditions may affect the traumatic injuries sustained and influence the patient’s outcome. Multiple medications are more common in this age group and may also affect the patient assessment and outcome. Medications can especially affect the patient’s vital signs and blood-clotting capabilities.

As with other trauma patients, an altered mental status in the elderly trauma patient may indicate a severe injury. You should not attribute a patient’s altered mental status to age and should suspect a head injury. Many elderly patients use dentures, which may cause an airway obstruction in the trauma patient. Elderly patients may have a decrease in their cough reflex and may require suctioning. Chest wall injuries may quickly lead to respiratory failure in this population. You should monitor the elderly trauma patient’s oxygenation, using pulse oximetry. Elderly patients who were hypertensive prior to an injury may have normal blood pressures when they are in shock. Pelvic and hip fractures are common in this population.

Management Considerations for the Geriatric Trauma Patient

The management for an elderly trauma patient is similar to that provided to other adults. However, you should understand how the changes in the patient prior to the injury may impact the patient’s presentation and outcome. Some management considerations for elderly trauma patients include the following:

- Spinal immobilization is required for suspected spinal injuries and should be maintained throughout care. Add padding around the spaces in the back if necessary. In addition, improvisation may be required for the inflexible cervical spine.
- Open and maintain a clear airway. Suctioning is important in the elderly due to a decreased cough reflex.
- Provide and support ventilation as needed. Administer supplemental oxygen to maintain an SpO2 of 94% or greater.
- Prevent hypothermia.
- Splint fractures. Remember that traction splints are not used to treat hip fractures.
- Provide rapid transport to the closest appropriate facility. The American College of Surgeons recommends that all trauma patients older than 55 years of age be taken to trauma centers.

Trauma in Cognitively Impaired Patients

Cognitively impaired patients are more susceptible to trauma than patients who do not have cognitive
Impairment. Some of the conditions that may result in cognitive impairments are vascular dementia, autistic disorders, brain injuries, strokes, Alzheimer’s disease, blindness, deafness, acquired developmental delays, and Down syndrome (Figure 36-3). Many other causes of cognitive impairments exist that may affect your patient’s assessment and treatment.

It can be difficult to recognize patients with cognitive impairment when you begin your assessment. Some patients have no physical signs of their mental condition. They may be confused or unresponsive, making assessment of their condition difficult. Never assume that the altered mental status of your trauma patient is due to a previous cognitive impairment or medical condition. Always maintain a high index of suspicion that your patient may have suffered a traumatic head injury.

Anatomical and Physiological Considerations in the Cognitively Impaired Trauma Patient

The anatomical and physiological considerations related to a cognitively impaired trauma patient depend on the underlying cause of each individual’s impairment. Many patients have sensory loss related to aging and disease or other congenital or acquired conditions. This may increase their risk of injury and can alter their response to an injury. Some patients with dementia experience cardiovascular changes that make them prone to injury. Other patients have a loss in musculoskeletal strength due to aging or impairment that can lead to falls and other injuries. Memory loss from Alzheimer’s disease or other cognitive impairments will alter the patient assessment.

Assessment Considerations in the Cognitively Impaired Trauma Patient

Include the following considerations in your assessment of a cognitively impaired trauma patient:

- Patients with cognitive impairments are poor historians; that is, they are not good at recalling or relating their past medical history or events of the trauma. You should address them with respect and initially approach them in the same fashion as you would any other patient; however, you will often have to rely on others to provide information about the patient’s past history. Many of these patients may be bedridden, under nursing home care, or living in group homes. It may be necessary for you to obtain consent from a legal guardian or parent to provide them care (see Chapter 3, “Medical, Legal, and Ethical Issues”).
- The psychological implications of trauma may be different in this population. Many of these patients may not know what is happening even before the trauma. They may be confused or upset. The traumatic event may make it more difficult for them to communicate and cooperate with you.
- Understand that their pain perception may be altered. This may affect some of the responses that would normally be associated with injury.
- The trauma assessment will provide the most pertinent information about your patient. Because many of these patients will not be able to tell you what is wrong, it is important that you constantly reevaluate them.
- Always maintain a high level of suspicion that your patient’s presenting signs and symptoms have resulted from trauma. Do what is in the best interest of the patient, and treat as if the patient has a head injury.

Management Considerations for the Cognitively Impaired Trauma Patient

Cognitively impaired trauma patients need special care. The following are a few management considerations for this population, in addition to your normal trauma care:

- It is often necessary to involve the patient’s caregivers in emergency treatment. Like children, these patients may be more cooperative if a trusted caregiver is present. These caregivers may be able to provide you with important information about the patient’s conditions.
- Err on the side of caution and do what is in the best interest of the patient. Manage the patient as if he has a head injury.

ASSESSMENT-BASED APPROACH: MULTISYSTEM TRAUMA AND TRAUMA IN SPECIAL PATIENT POPULATIONS

You have studied many of the elements of assessment that apply to multisystem trauma and trauma in special populations in earlier chapters. The primary goal for all of
these patients is to identify and manage life-threatening injuries. We review and develop these assessment elements on the following pages, taking into consideration some adjustments for these special populations.

**Scene Size-up**

Because traumatic injuries can occur from so many different mechanisms, ensuring a scene that is safe for you and others is of utmost importance. Look for a possible mechanism of injury and maintain a high index of suspicion that more than one major body system is affected in your patient. Identify if your patient belongs to any special populations and use your knowledge about that population throughout your assessment. Unresponsiveness or altered mental status, especially in trauma patients, should always suggest the possibility of head injury. Never assume that mental status changes in a trauma patient are due to drug or alcohol intoxication or previous medical conditions. However, caregivers can give insight into the patient’s baseline mental state.

**Primary Assessment**

When performing the primary assessment on a trauma patient, you should suspect a cervical spine injury. Forces applied to the head may have been strong enough to injure the cervical spine as well, especially in pediatric patients. Be aware that other traumatic forces may have caused additional spinal injuries. Manual in-line stabilization of the spine should be your first step and should be maintained throughout your care.

Assess your patient’s mental status, using the AVPU mnemonic. Utilize tools such as the Glasgow Coma Scale and the pediatric assessment triangle to provide additional information about the patient’s mental status. This will provide a baseline when you reassess your patient. If the patient has an altered mental status, note what type of stimuli, if any, the patient responds to.

Establish an airway, using a jaw-thrust maneuver, while holding in-line spinal stabilization. Ensure that the airway is free from obstructions like blood, vomit, or dentures. Suction the airway if necessary. Remember that elderly and pregnant patients may vomit easily.

Maintain the patient’s airway and assess the breathing rate and quality. Provide oxygen by nonrebreather mask at 15 lpm if breathing is adequate in the multisystem trauma patient or in those presenting with signs of hypoxia, respiratory distress, or poor perfusion. If the patient’s breathing is inadequate, provide positive pressure ventilations via bag-valve mask with supplemental oxygen. Determine the appropriate ventilation rate based on the patient’s age. If the pediatric patient is bradycardic, you should provide assisted ventilations. Monitor the patient’s oxygenation via pulse oximetry. A pregnant trauma patient’s SpO₂ should be maintained at close to 100% at all times.

Assess the patient’s circulatory status and check the pulse. In infants, check the brachial pulse. In children, remember that the capillary refill and skin condition will provide valuable information about your patient’s condition. Look for major bleeding and control it with direct pressure. To control major vaginal bleeding in a pregnant patient you should use a pad and never pack the vagina.

**Secondary Assessment**

When dealing with trauma patients who belong to special populations, perform a rapid secondary assessment to identify signs of trauma and injuries to the body. When multiple body systems are involved in the trauma, the patient is more likely to have an unfavorable outcome. It is important to note that patients in these special populations may not complain of pain or other symptoms of trauma as you would normally expect. The patient’s age, physiological changes, medical conditions, and cognitive abilities may influence his responses to both you and the assessment.

Following the rapid secondary assessment, check vital signs and obtain a history. If the patient is alert and oriented, you or your partner might decide that one of you will gather the history while the other performs the rapid trauma assessment and obtains vitals.

**Physical Exam**

Perform a rapid physical exam. Keep in mind that multiple systems may be affected by the trauma. If your patient is pregnant, you have two patients to consider.

**Vital Signs**

Check and record vital signs every 5 minutes, staying alert to any changes. The normal vital signs are based on the patient’s age (see Chapter 9, “Life Span Development”). Remember that in pregnant women and the elderly you may have what appear to be normal vital signs, even though your patient is in shock. Even the slightest changes in a pediatric trauma patient’s vital signs may indicate impending cardiorespiratory failure and must be managed aggressively.

**History**

The history can provide vital information about the mechanism of injury. Patients, especially children, those with cognitive impairments, or those with an altered mental status, may not be able to provide you with the information you need. You may have to obtain this information from others at the scene. The following are some questions that are relevant when assessing special trauma populations:

- When and how did the incident occur?
- What is the patient’s chief complaint?
• Does the patient have any signs or symptoms associated with the trauma?
• Is the patient pregnant? If so, how far along is she? Is there any vaginal bleeding or crowning?
• How old is the patient?
• Does the patient take any medications? Is the patient allergic to anything?
• What is the patient’s medical history? Is there a history of previous trauma or a cognitive impairment?

**Signs and Symptoms**

Signs and symptoms will vary based on the patient and the trauma. Special trauma patients may not respond to injury the same way that another trauma patient would. Document any signs and symptoms accurately.

**Emergency Medical Care**

Consider and apply the following to your trauma patient’s care:

1. **Take Standard Precautions.**
2. **Establish and maintain manual in-line spinal stabilization.**
   - Maintain neutral positioning of the head and neck manually, even after a cervical collar is applied, until the patient is completely immobilized to a backboard.
   - If the patient is pregnant and in her third trimester, tilt the backboard to the left.
   - If the patient is a child (typically less than 8 years of age), pad beneath the child from the shoulders to the hips during cervical immobilization to prevent flexion of the neck.
   - If the patient is elderly, add padding around the spaces in the back if necessary.
3. **Maintain a patent airway, and adequate breathing and oxygenation.**
   - Use a jaw thrust to open the airway.
   - Remove any foreign bodies from the mouth, and suction blood and mucus.

4. **Monitor the airway, breathing, pulse, and mental status for deterioration.** Any patient who deteriorates must be transported immediately.
   - Remember, bradycardia in the pediatric patient requires ventilation.
5. **Control bleeding.**
   - If the pregnant patient is bleeding from the vagina, use a pad to collect the blood flow.
   - If major bleeding is not stopped with direct pressure, consider the use of a tourniquet.
6. **Treat for shock.**
   - Cover any special population trauma patient with blankets to prevent hypothermia.
7. **Identify any other injuries and treat them appropriately.**
   - A lot of treatment can be performed en route to the receiving facility if you have a critical patient.
   - Make sure that you splint injuries appropriately.
8. **Transport immediately.**
   - Notify the receiving facility specifically what type of trauma patient you are bringing to their facility.
   - Consider the use of ALS intercept or air medical transport for these patients. Follow your local protocol.

**Reassessment**

Provide reassessment during transport, paying close attention to the mental status, airway, breathing, and circulation of all these patients. Repeat the vitals every 5 minutes.
Chapter Review

SUMMARY

As an EMT, you should suspect multisystem trauma in any patient who has been subjected to a significant external force. In many traumas, more than one body system has been affected, which can affect the patient’s presentation and injuries. When this occurs, the EMT must identify what life threats exist and utilize golden principles of trauma care to help manage them appropriately.

Special populations of patients, such as pregnant women, elderly patients, children, and patients with cognitive impairments, require additional assessment and management considerations when they are involved in trauma. The EMT must identify the special needs of these trauma patients and incorporate knowledge of these patients into the care provided. These populations are more susceptible to injury than others and often have worse outcomes when compared to other trauma patients. Some of the injuries sustained by special trauma patients are influenced by the anatomical and physiological changes these patients experience. It is important for the EMT to know what changes are to be expected and to use that knowledge to help anticipate and manage the injuries that these patients may have.

Case Study Follow-up

Scene Size-up

You have been dispatched to a 30-year-old female patient who fell. As you arrive on the scene of a single-family residence, you are met by four small children screaming and crying. You look around to ensure the scene is safe, and you do not see anything that would suggest it is not. As you and your partner approach the residence with your equipment in hand, you hear a woman yell “Help me!” from inside. The children run past you into the house and lead you to the stairwell. There, you see an obviously pregnant woman lying at the base of the stairs on the floor next to a pile of laundry. You notice a couple of toys on the floor between you and your patient. You remove the toys from the stairwell and proceed to your patient who is lying supine on the floor.

Primary Assessment

You immediately establish in-line spinal stabilization and ask the woman her name and what happened. She replies that she is Hope Miller and that she tripped on a toy when she was carrying the laundry downstairs to the washer. She states that she is seven months pregnant and is now bleeding and having contractions. Her airway is open and clear. She is breathing 23 times a minute with an adequate tidal volume. Your partner places her on a nonrebreather mask with supplemental oxygen and the pulse oximeter to monitor the SpO2. You feel her pulse and note that it is 120 beats per minute and thready. You identify that she does have some vaginal bleeding, but crowning is not present. You place a pad next to the vagina to absorb the blood flow. You suspect this patient may be in shock.

Secondary Assessment

Your partner performs a rapid trauma assessment and takes vital signs. Vital signs are blood pressure 100/62 mmHg, pulse 120 bpm, and respirations 23 per minute. Lungs are clear and equal bilaterally. In addition to the vaginal bleeding and contractions (which are strong and about 10 minutes apart), she has neck pain, abdominal pain and tenderness, and pain and swelling to the right side of her face. There are no signs of injury to the rest of her body.

In the meantime, you obtain a history from Mrs. Miller. It reveals that she has been pregnant five times and has four living children. She has never had any complications with her pregnancies and has been receiving prenatal care. She does not take any medications outside of prenatal vitamins, and she is allergic to penicillin.

Once the exam and history findings are recorded, you and your partner prepare the patient for rapid transport. You apply a cervical spine immobilization collar and log roll her onto a backboard. When immobilization is complete, you tilt the backboard to the left side and treat her for shock. You call the trauma center in advance so they can prepare for your patient’s arrival.

With Mrs. Miller’s permission, the children are left with a neighbor who has come to the home to see if she can help. Mrs. Miller is taken to the ambulance and rapidly transported to the receiving trauma facility.

Reassessment

En route to the hospital, you monitor Mrs. Miller’s airway, breathing, circulation, and level of responsiveness. You reassess her vitals every 5 minutes throughout the transport. You also continue to document her contractions and the number of pads that she saturates with blood.

During transport, you note no change in Mrs. Miller’s condition. You apply an ice pack to her swollen right cheek. At the emergency department, she is transferred to the trauma team staff. You and your partner complete a prehospital care report and prepare the ambulance for another call.
IN REVIEW

1. List three principles associated with multisystem trauma care.
2. Describe how to manage a third-trimester pregnant patient who has been injured.
3. Identify three anatomical or physiological changes that may influence an elderly trauma patient’s care.
4. List three causes of cognitive impairments.

5. Describe how a cognitive impairment may affect your assessment of a trauma patient.
6. Explain why normal vital signs may appear when pregnant women or elderly patients are in shock.
7. List three injuries that pediatric patients are more susceptible to than adults.
8. Describe how an elderly trauma patient’s past medical history and medications may influence your assessment.

CRITICAL THINKING

You arrive on the scene of a nursing home and find a 93-year-old male patient who fell out of his wheelchair after he won a bingo game in the recreation area. The patient is lying prone on the cement floor with obvious bleeding from his face and mouth. The patient moans as you approach him but does not respond verbally to any of your questions. His respirations are irregular at a rate of approximately 28 per minute with minimal chest rise and fall. Your partner indicates the radial pulse is strong and the heart rate is 96 bpm. The nursing staff states he has a history of myocardial infarctions, congestive heart failure, lordosis, osteoporosis, and two strokes. They give you a medication list, tell you that he is to be transported to the local emergency department, and then leave.

1. What immediate emergency care would you provide for the patient?
2. Do you consider this patient to be a high priority? Why?
3. What additional assessment and management considerations do you have for this patient based on his age?
4. What role do you believe his past history may have on his current condition?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Special Patient Populations (Content Area: Obstetrics; Neonatal Care)

**COMPETENCY** • Applies fundamental knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

**OBJECTIVES** • After reading this chapter, you should be able to:

- 37-1. Define key terms introduced in this chapter.
- 37-2. Describe the anatomy of pregnancy, the menstrual cycle, and the prenatal period.
- 37-3. Describe physiological changes in pregnancy, including changes to the following systems:
  - a. Reproductive
  - b. Respiratory
  - c. Cardiovascular
  - d. Gastrointestinal
  - e. Urinary
  - f. Musculoskeletal
- 37-4. Describe the pathophysiology, assessment, and emergency care of patients with antepartum emergencies, including:
  - a. Spontaneous abortion
  - b. Placenta previa
  - c. Abruptio placentae
  - d. Ruptured uterus
  - e. Ectopic pregnancy
  - f. Preeclampsia/eclampsia
  - g. Pregnancy-induced hypertension
  - h. Supine hypotensive syndrome
- 37-5. Describe the assessment-based approach to antepartum emergencies.
- 37-6. Describe the stages of labor.
- 37-7. Describe the assessment-based approach to a patient in active labor with normal delivery.
- 37-8. Describe the steps of assisting with a normal prehospital obstetric delivery.
- 37-10. Describe the assessment-based approach to a patient in active labor with abnormal delivery.
- 37-11. Take steps to manage abnormal prehospital obstetric deliveries, including:
  - a. Prolapsed umbilical cord
  - b. Breech and limb presentations
  - c. Multiple births
  - d. Meconium staining
  - e. Premature birth
  - f. Post-term pregnancy
  - g. Precipitous delivery
  - h. Shoulder dystocia
  - i. Preterm labor
  - j. Premature rupture of membranes
- 37-12. Take steps to manage postpartum complications, including:
  - a. Postpartum hemorrhage
  - b. Embolism
- 37-13. Demonstrate the steps of assessing and managing the newborn, including:
  - a. Initial care, including drying, wrapping, suctioning, and positioning
  - b. Apgar scoring and stimulation to breathe if necessary
  - c. Apgar scoring
- 37-14. Recognize signs that indicate the need for neonatal resuscitation.
- 37-15. Apply the concepts of the neonatal resuscitation pyramid to the care of neonates in need of resuscitative measures.
INTRODUCTION

Childbirth is a normal, natural process that is typically conducted in the hospital. However, the EMT may need to perform the delivery of a baby in the prehospital setting.

Care of patients experiencing an emergency involving the reproductive organs is not a common event. However, you must be prepared to deal with these emergencies in a professional, effective, and compassionate way. Review assessment and emergency medical care procedures for these types of emergencies as often as you can.

ANATOMY AND PHYSIOLOGY OF THE OBSTETRIC PATIENT

Anatomy of Pregnancy

You may want to review the material on the reproductive system in Chapter 7, "Anatomy, Physiology, and Medical Terminology." A general description of the major organs and structures involved in pregnancy (Figure 37-1) follows.

The ovaries are the female gonads or sex glands. There are two ovaries, one on each side of the uterus, in the upper portion of the pelvic cavity. The ovaries are responsible for secreting the hormones estrogen and progesterone and for development and release of the mature egg necessary for reproduction. The mature egg that is released from the ovary each month is referred to as the ovum. Estrogen and progesterone are hormones that prepare the uterus for implantation of a fertilized ovum and maintain the uterus during pregnancy.

The two fallopian tubes, also known as uterine tubes, are thin flexible structures that extend from the uterus to the ovaries. The end near the ovary is funnel shaped with fingerlike projections. This end is not directly connected to the ovary and is open to the abdominal cavity. The opposite end is connected to the uterus. Upon ovulation, the ovum is released from the ovary and received in the funnel-shaped end of the fallopian tube. Fertilization of the ovum with sperm typically occurs in the distal third of the fallopian tube. The ovum, whether fertilized or not, is transported down the

Case Study

The Dispatch
EMS Unit 118—respond to Taggert’s Laundromat on West Martin Street—a 30-year-old female in labor. Time out is 1926 hours.

Upon Arrival
Upon arrival, a man runs out of the laundromat and tells you, “There is some woman in there about to have a baby. Boy, is she screaming!” You and your partner proceed into the laundromat to find a female sitting on the floor in the corner, her anxious husband holding her hand. As you approach her, she says in a gasping breath, “I think the baby is coming.”

How would you proceed?
During this chapter, you will learn how to recognize and provide emergency medical care for obstetric and gynecologic emergencies. Later, we will return to the case study and put in context some of the information you learned.
The uterus is the pear-shaped organ that contains the developing fetus, the unborn infant. Its special arrangement of smooth muscle and blood vessels allows for great expansion during pregnancy and forcible contractions during labor and delivery. The uterus also is capable of rapid contractions after delivery, which help to tone up the uterus, constrict blood vessels, and prevent hemorrhage. The top portion of the uterus is referred to as the fundus, the middle portion is the body or corpus, and the narrow tapered neck is the cervix. The uterine wall is made up of three layers: endometrium, myometrium, and perimetrium. The endometrium is the innermost lining. Each month, estrogen and progesterone build up the lining for implantation of a fertilized ovum. If the ovum is not fertilized or does not implant, the lining is shed during the menstrual period. The myometrium is the thick middle layer of smooth muscle. The smooth muscle contracts from the fundus downward during labor to expel the fetus. The perimetrium is a serous membrane that partially covers the corpus of the uterus.

The cervix connects with the vagina. The cervix contains a plug of mucus that seals the uterine opening during pregnancy, preventing contamination from entering the uterus. The plug is discharged when the cervix starts to dilate, or open, and appears as pink-tinted mucus in the vaginal discharge. The expulsion of the plug signals the first stage of labor and is known as the **bloody show**.

The placenta, also known as the “organ of pregnancy,” is a disk-shaped inner lining of the uterus that begins to develop after the ovum is fertilized and attaches itself to the uterine wall. Rich in blood vessels, the placenta is the sole organ through which the fetus receives oxygen and nourishment from the mother and discharges carbon dioxide and waste products. The exchange is made between the mother’s and infant’s bloodstreams within the placenta; however, the blood of the fetus and the blood of the mother do not mix, except during birth or miscarriage.

**PATHOPHYSIOLOGY PEARLS**

The normal implantation site for the placenta is superior and posterior within the fundus of the uterus. An abnormal site of implantation may lead to complications later in the pregnancy and during delivery.

After the infant is born, the placenta separates from the uterine wall and is delivered as the **afterbirth**. It usually weighs about a pound, or generally one-sixth of the infant’s weight.
The **umbilical cord** is the unborn infant’s lifeline, attaching the fetus to the placenta. It contains one vein and two arteries in a spiral arrangement that is covered by a protective substance called Wharton jelly. The vessels in the umbilical cord are unique: the vein carries oxygenated blood and nutrients to the fetus, and the arteries carry deoxygenated blood and waste products back to the placenta. The structure of the cord—and the blood traveling through it—keep it from kinking. When the infant is born, the umbilical cord resembles a sturdy rope about 22 inches long and 1 inch in diameter.

The **amniotic sac**, sometimes referred to as the **bag of waters**, is filled with the amniotic fluid in which the infant floats, insulating and protecting it throughout the pregnancy. The amount of amniotic fluid varies from 500 to 1,000 milliliters. At the onset of labor, the sac usually tears. This “rupturing of the bag of waters” is one of the first indications to the pregnant mother that her labor is starting. The amniotic fluid helps to lubricate the birth canal and remove any bacteria. During labor, part of the amniotic sac is forced ahead of the infant, serving as a resilient wedge to help dilate the cervix.

The lower part of the birth canal is called the **vagina**. About 8 to 12 centimeters in length, the vagina originates at the cervix of the uterus and extends through to an external opening of the body. During pregnancy, the vagina undergoes changes that prepare it for passage of the infant. The smooth muscle layer of the vagina allows it to stretch gently to accommodate the infant during delivery.

### Menstrual Cycle

The female goes through a monthly menstrual cycle that is controlled by estrogen and progesterone. The menstrual cycle lasts from 24 to 35 days with an average of 28 days. The first day of the menstrual cycle begins with menstruation. Menstruation is the sloughing of the endometrial tissue that was preparing for implantation of the fertilized ovum. Menstruation is marked by vaginal bleeding of about 60 to 80 mL over 3 to 5 days. Contained in the blood is tissue and mucus that was built up in the endometrium. Once menstruation is over, estrogen levels increase and again begin to prepare the endometrium for implantation of a fertilized ovum. On the 14th day of the cycle, ovulation occurs and the mature ovum is released from the ovary. The ovum descends through the fallopian tube within the next 5 to 7 days. If it is fertilized, it implants itself in the prepared endometrial lining of the uterus. If it is not fertilized, it is discharged with the outer layer of endometrial tissue during menstruation, which occurs 14 days after ovulation.

### Prenatal Period

Ovulation is the release of the mature ovum from the ovary. The ovum is picked up by the fallopian tube and moves down toward the uterus. The fertilized egg implants in the wall of the uterus and the pregnancy begins. Approximately 3 weeks after implantation of the fertilized egg on the uterine wall, the placenta develops.

During the pregnancy, the stages of development of the baby are known by different terms. The first 14 days after conception are called the pre-embryonic stage. The embryonic stage is from day 15 to 8 weeks. The fetal stage begins at 8 weeks and ends with delivery of the baby, which is termed a neonate. Pregnancy is also referred to as gestation. Gestational age refers to the age of the fetus in weeks from the time of fertilization of the ovum through delivery. As an example, you might refer to a fetus in a pregnant patient in her 36th week of pregnancy as being in the 36th week of gestation. If a physician or nurse were to ask “What is the gestational age of the fetus?” it is the same as the number of weeks of fetal growth during the pregnancy.

A full-term pregnancy lasts approximately 280 days from the first day of the last normal menstrual cycle. Each 3-month period of the approximately 9-month pregnancy is referred to as a trimester. Thus, months 1 through 3 (weeks 1 to 12) are the first trimester, months 4 through 6 (weeks 13 to 27) are the second trimester, and months 7 through 9 (weeks 28 to 40) are the third trimester. Most emergencies that you will deal with occur during the first or third trimester. However, a patient can experience some of these emergencies during the second trimester.

### Physiological Changes in Pregnancy

Many physiological changes occur in pregnancy. Most are due to alterations in the circulating hormones, expanding of the uterus, and the increased metabolic demands on the mother. These physiological changes, grouped by body system, can be summarized as follows:

#### Reproductive System

- The prepregnant uterus weighs about 2 ounces and holds about 10 mL. At the end of pregnancy the uterus weighs more than 2 pounds and holds 5,000 mL.
- The pregnant uterus is extremely vascular and contains about one-sixth of the total blood volume of the mother.
- A mucus plug forms in the opening to the cervix (os) to protect the fetus from infection.
- The breasts enlarge and become more nodular in preparation for lactation (milk production).
**Respiratory System**
- Oxygen demand of the mother increases.
- The respiratory tract resistance decreases as a result of hormones causing smooth muscle dilation.
- The tidal volume increases by 40 percent.
- The respiratory rate increases only slightly.
- There is an increase in oxygen consumption of approximately 20 percent.

**Cardiovascular System**
- Cardiac output increases.
- Maternal blood volume increases by 45 percent. There is also an increase in red blood cell (RBC) content and plasma; however, the plasma volume increase is greater than the RBCs, causing a relative anemia. The pregnant patient is given iron supplements to increase oxygen binding on the RBC. This blood volume increase delays the signs and symptoms of shock in the pregnant patient, as discussed in Chapter 36, “Multisystem Trauma and Trauma in Special Patient Populations.”
- The maternal heart rate increases by 10 to 15 bpm.
- Blood pressure decreases slightly during the first and second trimester and returns to normal during the third trimester.

**Gastrointestinal System**
- Nausea and vomiting commonly occur during the first trimester as a result of hormone changes and the change in the need for carbohydrates.
- Bloating and constipation may occur from a decrease in peristalsis in the gastrointestinal tract.

**Urinary System**
- Renal blood flow increases.
- Glomerular filtration increases by approximately 50 percent during the second trimester and remains elevated.
- The urinary bladder is displaced superiorly and anteriorly, increasing the risk of injury.
- An increase in urinary frequency is common in the first and third trimester due to compression of the bladder by the uterus.

**Musculoskeletal System**
- The pelvic joints loosen as a result of hormone changes.
- There is a change in the center of gravity for the mother caused by the heavy uterus. The patient compensates and therefore often experiences lower back pain.

**ANTEPARTUM (PREDELIVERY) EMERGENCIES**

Antepartum emergencies are those that occur in the pregnant patient prior to the onset of labor. These complications often involve the potential for severe hemorrhage and fetal death. The following are specific antepartum emergencies you may encounter in a pregnant patient.

**Antepartum Conditions Causing Hemorrhage**

Hemorrhage is one of the leading causes of death in the pregnant patient. The uterus during pregnancy is very vascular; thus, it is prone to severe bleeding if injured. Uterine bleeding may or may not be associated with vaginal bleeding, depending on the site of bleeding and the position of the fetus. If bleeding occurs behind the placenta where the margins of the placenta are intact, there will be no vaginal bleeding, even though the patient may lose a significant amount of blood and present in hypovolemic shock. If the margin of the placenta is torn away from the uterine wall, the patient will likely present with vaginal bleeding. If the uterine bleeding occurs late in pregnancy, the fetus may be engaged low in the pelvis and vaginal canal, which would block external blood flow. Vaginal bleeding may sometimes occur late in the pregnancy, with or without pain. If the bleeding is excessive, it can be a life-threatening emergency for the mother and fetus. The bleeding may be due to spontaneous abortion, placenta previa, abruptio placenta, ruptured uterus, or an ectopic pregnancy. Be especially alert to the early signs and symptoms of shock (hypoperfusion).

**Spontaneous Abortion**

A spontaneous abortion, or miscarriage, may occur for any number of reasons and is defined as delivery of the fetus and placenta before the fetus is viable (before it can live on its own). Viability is usually considered to begin after the twentieth week of pregnancy. Approximately 80 percent of spontaneous abortions occur prior to the 12th week of gestation, which is during the first trimester of pregnancy.

**Pathophysiology.** Spontaneous abortion occurs in 15 to 20 percent of all recognized pregnancies. The cause is usually genetic (50 percent of cases), or it may be caused by a uterine abnormality, infection, drugs, or maternal disease. Cramping and vaginal bleeding are usually present at 8 to 12 weeks of gestation.

The patient history is extremely important in spontaneous abortion. It is obviously important to ask about pregnancy history, which is generally unreliable, but it is also important to ask about a confirmed pregnancy. Ask the patient about uterine cramping and vaginal bleeding. Do not mistake a spontaneous abortion for a heavy period.

**Assessment.** The signs and symptoms of a possible spontaneous abortion include:
- Cramplike lower abdominal pain similar to labor
- Moderate to severe vaginal bleeding, which may be bright or dark red
- Passage of tissue or blood clots
An elective abortion is different from a spontaneous abortion. The spontaneous abortion is a naturally occurring expulsion of the fetus that is generally related to a genetic abnormality. An elective abortion is the termination of the pregnancy upon request of the mother in a medical setting.

**PATHOPHYSIOLOGY PEARLS**

Any tissue that is retained within the uterus following a spontaneous abortion may lead to severe bleeding and infection. Transport any patient with a suspected spontaneous abortion.

**Emergency Care.** In addition to the general guidelines for emergency medical care described later for antepartum emergencies, ask when the patient’s last menstrual period began. Provide emotional support to the mother and the members of her family throughout treatment and transport. Intense grief over loss of the pregnancy is normal and expected in both parents.

**ASSESSMENT TIPS**

Some patients may mistake the vaginal bleeding and abdominal cramping from a spontaneous abortion for a menstrual period. Ask the patient about other early signs of pregnancy.

**Placenta Previa**

Placenta previa, which occurs in about 1 in 250 births, is a major cause of third-trimester bleeding.

**Pathophysiology.** Placenta previa is associated with abnormal implantation of the placenta over or near the opening of the cervix (the os) (Figure 37-2 ■). The placenta is normally implanted in the fundus (top portion) of the uterus and posteriorly. When the fetus changes position in the uterus, or the cervix begins to efface (thin) and dilate, the placenta is prematurely torn away from the lower portion of the uterine wall.

This results in bleeding, which can be excessive because of the rich blood supply. The bleeding is not associated with any abnormal uterine contraction or abnormal pain.

There are three types of placenta previa:

- **Total.** In a total placenta previa, the placenta completely covers the os. This blocks the birth canal and can prevent delivery of the baby. As the cervix dilates and effaces, significant bleeding may occur.
- **Partial.** In a partial placenta previa, the placenta covers the os of the cervix partially, but not completely. As with the total placenta previa, the partial placenta previa may obstruct delivery of the baby.
- **Marginal.** In a marginal placenta previa, the placenta is implanted near the neck of the cervix. When the cervix effaces and dilates, it may cause the placenta to partially tear.

Predisposing factors for a placenta previa are:

- Multiparity (more than two deliveries)
- Rapid succession of pregnancies
- Greater than 35 years of age
- Previous placenta previa
- History of early vaginal bleeding
- Bleeding immediately after intercourse

**Assessment.** The hallmark sign of placenta previa is third-trimester vaginal bleeding that is painless. The uterus typically remains soft and nontender on palpation. It was once thought that the bleeding with placenta previa was characteristically bright red; however, it is now understood that the color of the blood does not differentiate between placenta previa and other conditions. The bleeding may be bright, dark, or an intermediate color. In addition to the vaginal bleeding, also look for signs of hypovolemic shock.

**Emergency Medical Care.** Follow the same guidelines as for any antepartum emergency, which will be discussed later. Your major concern is blood loss for the mother and hypoxia and distress for the fetus. This is a situation where, regardless of the SpO₂ reading and oxygenation status of the pregnant patient, oxygen is administered via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus. Treat for shock. Transport immediately.

**Abruptio Placentae**

An abruptio placentae is the abnormal separation of the placenta from the uterine wall prior to birth of the baby. It occurs in approximately 1 in 120 births.

**Pathophysiology.** Small arteries located in the lining between the placenta and uterus are prone to rupture. When they rupture and bleed, the accumulating blood begins to tear and separate the placenta from the uterine wall (Figure 37-3 ■). As the bleeding continues, the placenta continues to tear away from the uterine wall.
Separation of the placenta causes two major problems:

- Poor gas, nutrient, and waste exchange between the fetus and the placenta
- Severe maternal blood loss

There are two types of abruption:

- **Complete.** In a complete abruption, the placenta completely separates from the uterine wall. A complete abruptio placentae carries a 100 percent fetal mortality rate.
- **Partial.** In a partial abruptio placentae, the placenta is partially torn from the uterine wall. Because it remains partially attached, it is associated with a 30 to 60 percent, rather than a total, fetal mortality rate.

The predisposing factors for an abruptio placentae are:

- Hypertension
- Use of cocaine or other vasoactive drugs
- Preeclampsia
- Multiparity (several births)
- Previous abruption
- Smoking
- Short umbilical cord
- Premature rupture of the amniotic sac
- Diabetes mellitus

**Assessment.** The signs and symptoms associated with an abruptio placentae are as follows:

- Vaginal bleeding is associated with constant abdominal pain (the hallmark sign).
- Abdominal pain due to muscle spasm of the uterus may be mild, sharp, or acute.
- Pain may be found in the lower back.
- Uterine contractions are usually present.
- Abdomen is tender on palpation.
- Bleeding can be dark red or bright red; however, the color of the blood does not differentiate the condition from others.

- Vaginal bleeding may be severe, minimal, or absent depending on the location of the head of the fetus.
- Signs and symptoms of hypovolemic shock are present.

If the head of the fetus is already in the birth canal, it will block the bleeding from escaping through the vaginal canal. Therefore, you may find a patient with a complete abruption, who has severe bleeding from separation of the placenta from the uterus but has no vaginal bleeding. The patient could be in severe hypovolemic shock with no external bleeding. Thus, the amount of vaginal bleeding does not directly correlate with the amount of internal bleeding the mother is experiencing. It has been reported that 2,500 mL of blood can be concealed in the uterus. Maternal blood loss and resulting hypovolemia and fetal distress and death are the problems associated with abruptio placentae.

**ASSESSMENT TIPS**

Because the head of the fetus may be blocking a large amount of blood flow from the vaginal opening, use the clinical signs and symptoms of shock to gauge the severity of blood loss.

**Emergency Medical Care.** The emergency medical care for the patient suffering from an abruptio placentae is the same as in the placenta previa. The primary treatment is to administer oxygen regardless of the SpO₂ reading and oxygenation status of the pregnant patient via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus, treat for shock, and provide immediate transport.

**Ruptured Uterus**

**Pathophysiology.** As the uterus enlarges during pregnancy, the uterine wall becomes extremely thin, especially around the cervix. This can lead to a spontaneous or traumatic rupture of the uterine wall, thereby releasing the fetus into the abdominal cavity (Figure 37-4). Mortality to the mother from a ruptured uterus is usually 5 to 20 percent; infant mortality is over 50 percent. A ruptured uterus requires immediate surgery.

**Assessment.** The following history and assessment findings should alert you to this emergency:

- History of previous uterine rupture
- History or findings of abdominal trauma
- History of a large fetus
- Having borne more than two children
- History of prolonged and difficult labor (which may force a large infant out through the uterine wall)
- History of prior cesarean section or uterine surgery
- A tearing or shearing sensation in the abdomen
- Constant and severe abdominal pain
- Nausea
- Signs and symptoms of shock (hypoperfusion)
Pathophysiology. In a normal pregnancy the ovum, or egg, is implanted in the uterus. In an ectopic pregnancy (Figure 37-5), the egg is implanted outside the uterus in one of the following locations: in a fallopian tube (approximately 90 percent), on the abdominal peritoneal covering, on the outside wall of the uterus, on an ovary, or on the cervix. The placenta eventually invades surrounding tissue and, unable to accommodate the growing embryo, the tissue ultimately ruptures. Ectopic pregnancy is the third leading cause of maternal death, responsible for 6 percent of maternal mortality. Ectopic pregnancy occurs in 2 percent of all pregnancies and is most common in women 25 to 34 years of age.

The predisposing factors for an ectopic pregnancy are:

- Previous ectopic pregnancies
- Pelvic inflammatory disease (PID)
- Adhesions from surgery
- Tubal surgery, including elective tubal ligation
- Intrauterine device

Assessment. The following history and assessment findings should alert you to an ectopic pregnancy:

- Dull, aching-type pain that is poorly localized and becomes sudden, sharp, or “knife-like” abdominal pain, localized on one side of the lower quadrants
- Shoulder pain from blood in the abdominal cavity that irritates the diaphragm
- Vaginal bleeding that may be heavy, light, or absent
- Lower abdominal pain, possibly radiating to one or both shoulders
- Tender, bloated abdomen
- A palpable mass in the abdomen (either the embryo or a blood clot)—very rare
- Weakness or dizziness when sitting or standing
- Decreased blood pressure
- Increased pulse rate
- Signs of shock (hypoperfusion)
- Discoloration around the navel, if the rupture occurred hours earlier
- Urge to defecate

The site of implantation in the fallopian tube determines the length of time before the patient will experience pain or other associated symptoms and before rupture may occur. Rupture may occur from 2 to 12 weeks after fertilization. Most commonly, the rupture will occur in 5 to 9 weeks.

Emergency Medical Care. For treatment follow the general guidelines for emergency medical care of a predelivery emergency. The primary treatment is to administer oxygen regardless of the SpO₂ reading and oxygenation status of the pregnant patient via a nonrebreather mask at 15 lpm to maximize oxygenation of the fetus, treat for shock, and provide immediate transport.

Antepartum Seizures and Blood Pressure Disturbances

Seizures During Pregnancy

Seizures during pregnancy can be a life-threatening emergency for the mother and the fetus. Provide emergency medical care the same as for any seizure patient. It is especially important to protect the pregnant patient from injuring herself. Transport the patient on her left...
Preeclampsia/Eclampsia

Preeclampsia, once known as toxemia during pregnancy, is a common condition, affecting about 1 in 20 pregnant women.

**Pathophysiology.** Preeclampsia occurs most frequently in the last trimester and is most likely to affect women in their 20s who are pregnant for the first time. Women with a history of diabetes, heart disease, kidney problems, or high blood pressure are at the greatest risk, as are those whose mothers or sisters have had preeclampsia. Eclampsia is a more severe form of preeclampsia and includes coma or seizures. The exact cause of preeclampsia and eclampsia is not clearly understood. One theory is that a disorder of the placenta causes the vessels throughout the body to spasm, leading to a reduction in blood flow to organs.

**Assessment.** Preeclampsia is characterized by high blood pressure and swelling in the extremities. History and assessment findings also include the following:

- History of hypertension, diabetes, kidney (renal) disease, liver (hepatic) disease, or heart disease
- No previous pregnancies
- History of poor nutrition
- Sudden weight gain (2 pounds a week or more)
- Altered mental status
- Abdominal pain
- Blurred vision or spots before the eyes
- Excessive swelling of the face, fingers, legs, or feet
- Decreased urine output
- Severe, persistent headache
- Persistent vomiting
- Elevated blood pressure usually greater than 140/90 mmHg or a systolic increase of over 30 mmHg and/or a diastolic increase of over 15 mmHg of prepregnancy pressure

**Pregnancy-induced hypertension (PIH)** is defined as a blood pressure in a pregnant woman that is greater than 140/90 mmHg on two or more occasions at 6 hours apart. If the patient has a lower blood pressure prior to the pregnancy, an increase in the systolic blood pressure of greater than 30 mmHg and a diastolic blood pressure greater than 15 mmHg above the baseline blood pressure is used to define the condition. When edema and protein in the urine are found with the elevated blood pressure, it is defined as preeclampsia.

Preeclampsia is characterized by high blood pressure, swelling, headaches, and visual disturbances. Eclampsia includes the signs and symptoms of preeclampsia with the addition of life-threatening seizures or coma. During a seizure, the placenta can separate from the uterine wall (abruption), causing death of the fetus and severe maternal hemorrhage. Death of the mother can also result from cerebral hemorrhage, respiratory arrest, kidney failure, or circulatory collapse.

**Emergency Medical Care.** For treatment, follow the general guidelines for emergency medical care of a predelivery emergency. Administer oxygen at 15 lpm by nonrebreather mask regardless of the SpO2 reading and oxygenation status of the patient to maximize oxygenation of the fetus, and keep suction close at hand. If a seizure begins, you may need to provide positive pressure ventilation during the seizure to prevent oxygen deprivation. Since light, noise, and movement can set off seizures in patients with preeclampsia, transport the patient in as calm and quiet a manner as possible.

**ASSessment TIPS**

The cause of preeclampsia is unknown; however, it is thought to be a result of vasospasm increasing the mother’s blood pressure and decreasing blood flow to the fetus. Preeclampsia typically occurs in the last 10 weeks of pregnancy or during labor or within the first 48 hours after delivery. In fact, preeclampsia can occur up to 2 weeks after delivery. Eclampsia (seizure or coma) is often preceded by visual disturbances, such as seeing spots or flashing lights. Epigastric pain or right upper quadrant pain also often indicates an impending eclamptic seizure.

**Supine Hypotensive Syndrome**

**Pathophysiology.** Supine hypotensive syndrome is typically a third-trimester complication that occurs when the weight of the fetus compresses the inferior vena cava when the patient is in a supine position. This reduces the blood flow to the right atrium, which decreases the preload. The decrease in preload reduces the stroke volume and in turn reduces the cardiac output. The decrease in cardiac output reduces the systolic blood pressure and perfusion.

**Assessment.** The patient commonly complains of dizziness or light-headedness when in a supine position. In severe cases, the patient may experience a decrease in blood pressure, tachycardia, and pale, cool, clammy skin. It is extremely important to assess the patient for blood loss.

**Emergency Medical Care.** To avoid supine hypotensive syndrome, any patient who is in her twentieth week of gestation or later should be placed in a sitting position, if appropriate, or lying on her side, or supine with the right hip elevated, which takes the uterus off the vena cava. (It has traditionally been thought that it is necessary to place the patient on her left side to relieve the pressure on the vessel, since the inferior vena cava is located more...
on the right side of the body. However, it has been shown that placing the patient on either side is actually enough to relieve the pressure and reverse the supine hypotensive syndrome.) With the weight of the fetus removed from the inferior vena cava, there is an increased venous return to the right atrium, which increases preload, stroke volume, cardiac output, systolic blood pressure, and perfusion.

Assessment-Based Approach: Antepartum (Predelivery) Emergency

Scene Size-up

Information provided by the dispatcher may be the first indication that the patient is experiencing a potential obstetric emergency (an emergency having to do with pregnancy or childbirth). However, the stress and anxiety of the emergency may prevent the patient from relaying information accurately. Your scene size-up is very important in this situation. As a general rule, any women of childbearing age (about 12 to 50 years old) could potentially be experiencing an obstetric emergency. Use a high index of suspicion when assessing such a patient.

Primary Assessment

After taking Standard Precautions and making sure the scene is safe, perform an initial assessment, including the mental status, airway, breathing, and circulation of the patient. Use the same assessment and treatment techniques as for a patient who is not pregnant.

Secondary Assessment

Gather a history. Some patients may not realize that they are pregnant and experiencing an obstetric emergency. In this case, information collected in the history should provide the best evidence that the patient may be pregnant.

Include the following questions as appropriate:

- Have you ever been pregnant before?
  - If so, how many pregnancies?
  - How many pregnancies resulted in live births?
  - Were the births vaginal or by cesarean section?
  - Any complications with any of the births?
  - Date of last normal menstrual period?

When reporting this information to the hospital, you should use the terms gravida and para. Gravida refers to pregnancy. When a Roman numeral is added after gravida, it indicates the number of pregnancies. For example, a gravida I is a patient who is pregnant for the first time. This is also referred to as a primigravida. A patient who is pregnant for the third time is reported as a gravida III. Para refers to a woman who has given birth. Para I would indicate a mother who gave birth for the first time or once to one or more children. Para III would indicate a mother who has given birth three times. If the first-time mother delivers twins, she would be gravida I, para 1, because para refers to the number of delivery events and not to the number of children. A primipara is a mother who gave birth for the first time. Para is not used until after the birth has occurred.

- Are you experiencing any pain or discomfort?
  - What is the quality of the pain (dull, crampy, sharp, and so forth)?
  - How intense is the pain?
  - Did the pain have a sudden or a gradual onset?
  - Does the pain radiate?
  - Can you point to the pain with one finger?
  - Is the pain constant? Does it come in regular or irregular intervals?
  - What is the duration of the pain or cramps?
  - How often do the cramps occur?
  - Are you nauseated? Have you thrown up?
  - Is the pain related to a menstrual cycle or sexual intercourse?

PATHOPHYSIOLOGY PEARLS

A sudden onset of intense, sharp, constant abdominal pain during delivery that does not subside between contractions may be an indication that the uterus has ruptured or was torn during the labor process, which will result in severe bleeding from the uterus and hypovolemia.

- When was your last normal menstrual period?
  - Date?
  - Was the volume and color of blood normal?
  - Have there been any episodes of bleeding between menstrual periods?
  - Have your periods been regular?
- Have you missed a menstrual period?
  - Is there any chance of pregnancy?
  - Is there any breast tenderness, an increase in urination, fatigue, nausea, or vomiting? (All are early indicators of pregnancy.)
- Have you had an unusual period? (Bleeding may be associated with implantation of the fetus and be misconstrued as a period.)
- Have you had any unusual vaginal discharge?
  - What color was it?
  - Did it have an abnormal or foul odor?
  - How much was discharged?
- When (if patient knows she is pregnant) is your due date?
  - Have you had any prenatal care?
  - How many pregnancies have you had?
  - How many children do you have?
  - Did you have any complications with previous pregnancies?

Examine the abdominal region. Look for any abnormal distention or signs of injury. Palpation can help to determine the location of the pain as well as identify if
there is any abdominal guarding, tenderness, or abnormal masses. If there is abdominal pain, consider conditions related to an acute abdomen.

Also obtain a set of baseline vital signs.

**Signs and Symptoms.** Pregnancy is a normal process that is usually event free. However, problems may occur, such as spontaneous abortion, abruptio placenta, placenta previa, preeclampsia or eclampsia, other causes of vaginal bleeding not associated with the birth, or trauma.

In general, a pregnant patient may be experiencing an antepartum emergency if she presents with one or more of the following:

- Abdominal pain, nausea, vomiting
- Vaginal bleeding, passage of tissue
- Weakness, dizziness
- Altered mental status
- Seizures
- Excessive swelling of the face and/or extremities
- Abdominal trauma
- Shock (hypoperfusion)
- Elevated blood pressure (hypertension)

**Note:** Pregnancy may mask early signs and symptoms of shock (hypoperfusion). The initial indications may be subtle or even absent. This is because a woman’s blood volume is normally increased during pregnancy, which will mask a fall in blood pressure associated with shock. Also, the mother’s body will shunt blood away from the fetus and redirect it back to the vital organs of the mother. So even though the mother seems well, the fetus could be in extreme distress. Any pregnant patient who is currently experiencing, or experienced prior to the birth, any signs or symptoms of shock (hypoperfusion) needs to be seen by a physician.

**Emergency Medical Care**

In general, provide the pregnant patient with the same emergency medical care you would provide to any patient with the same signs and symptoms.

**Pathophysiology Pearls**

As the cardiac output decreases during supine hypotensive syndrome, the perfusion of the brain also decreases. This produces the symptoms of light-headedness, dizziness, or actual fainting that occur with the patient in the supine position. Typical syncope or fainting occurs with the patient in a standing or seated position (in fact, typical fainting will self-correct once the patient is supine)—in contrast to fainting from supine hypotensive syndrome.

General guidelines for emergency medical care of a predelivery emergency include the following:

1. **Ensure adequate airway, breathing, oxygenation, and circulation.** Administer oxygen at 15 lpm by nonrebreather mask if any state of poor perfusion or hypoxia is suspected, regardless of the SpO₂ reading, complaints of the patient, and signs exhibited. Due to the physiological changes that occur during pregnancy, the pregnant patient could be in a state of poor perfusion from blood loss without exhibiting obvious signs or symptoms. To compensate for the blood loss, the pregnant patient’s body may constrict the vessels supplying the uterus that is housing the fetus. This will reduce fetal circulation and lead to fetal hypoxia, even if the pregnant patient is not exhibiting signs and symptoms. Therefore, it is necessary to maximize oxygenation of the fetus by applying a high concentration of oxygenation to the pregnant patient. Provide positive pressure ventilation with supplemental oxygen if breathing is inadequate.

2. **Care for bleeding from the vagina.** If there is vaginal bleeding, place a sanitary pad over the vaginal opening. Never pack the vagina in an attempt to control bleeding. Never touch the vaginal area or insert your fingers into the vagina. If the pad becomes soaked with blood, replace it. Save and transport with the patient any passed tissue or any evidence of blood loss (such as bloody sheets, towels, sanitary pads, or underwear).

**Assessment Tips**

- Most sanitary pads hold approximately 20–30 mL of blood. Ask the patient how often she has changed the pad to gauge the severity of the bleeding. However, keep in mind that the best method to estimate the extent of blood loss is by the patient’s clinical signs and symptoms.

3. **Treat for shock (hypoperfusion), if indicated.**
4. **Provide emergency medical care as you would for the nonpregnant patient based on any other signs and symptoms.**
5. **Transport the patient on her side.** If the pregnant patient is in her twentieth week of gestation or later, transport her on her side or with her right hip elevated if she is placed in a lying position. If she is on a backboard, tilt the board to the left.

**Reassessment**

Perform a reassessment en route to the hospital. Repeat the primary assessment. Repeat vital signs. Check any interventions, being especially careful about oxygen mask fit and adequate flow of oxygen. Be attentive for and treat any signs of developing shock (hypoperfusion). If the patient is stable, repeat reassessment every 15 minutes, if unstable every 5 minutes.

**Note:** If a pregnant patient dies in or as a result of an accident, CPR started immediately or within the first few minutes may save the life of the infant by continuing the oxygenation and circulation of the mother’s blood. If you do begin CPR, it must be continued throughout transport and until you reach the medical facility where the infant may be delivered surgically. The key
to saving the infant is to prevent the mother’s condition from deteriorating in the field. That is, protect the airway; support breathing, oxygenation, and blood pressure; transport rapidly; and notify the receiving facility as soon as possible. Vigorous resuscitation of a mother to save a fetus is acceptable even if you believe that the mother will not be successfully resuscitated.

### Summary: Assessment and Care—Antepartum (Predelivery) Emergency

To review possible assessment findings and emergency care for an antepartum obstetric emergency, see Figures 37-6 and 37-7.

---

**Assessment Summary**

**ANTEPARTUM (PREDELIVERY) OBSTETRIC EMERGENCY**

The following findings may be associated with an antepartum (predelivery) obstetric emergency.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Blood in toilet or around patient
- Bleeding from the vagina
- Bloody tissue or blood clots

**Primary Assessment**

**General Impression**

- Does patient appear to be pregnant?
- Posture: lying still with knees to chest indicates severe abdominal pain, or supine
- Any evidence of seizure activity?
- Is umbilical cord or fetal body part other than the head present at vaginal opening?

**Mental Status**

- Alert to unresponsive based on condition and potential blood loss

**Airway**

- Potentially closed airway if mental status is altered

**Breathing**

- Increased if associated with anxiety, pain, or blood loss

**Circulation**

- Heart rate may be increased
- Peripheral pulses may be weak or absent associated with blood loss
- Skin may be cool, clammy, and pale

**Status: Priority patient if associated with shock, significant vaginal bleeding, or abnormal presenting part**

---

**Secondary Assessment**

**History**

Signs and symptoms:
- Abdominal pain, may be crampy
- Vaginal bleeding, may be profuse or minimal, dark or bright red
- Weakness, dizziness
- Seizure activity
- Peripheral edema
- Signs and symptoms of shock
- Fainting while lying supine (supine hypotensive syndrome)

**History:**

- What is the onset, provocation, quality, radiation, severity, and duration of the pain?
- When was your last menstrual period?
- Have you missed a menstrual period?
- Have you had any unusual vaginal discharge?
- When is your due date?
- Have you had previous problems with pregnancies?
- Have you been seeing a physician for this pregnancy?
- Do you get dizzy or faint while lying flat on your back?
  - (supine hypotensive syndrome)

**Physical Exam**

**Head, neck, and face:**

- Edema to face and neck (may indicate preeclampsia)

**Abdomen/genitalia:**

- Large, palpable masses
- Is the abdomen/uterus rigid, soft, or tender?
- Any evidence of crowning or abnormal presenting part?
- Any passed tissue from the vagina?
- Vaginal bleeding, dark or bright red, may or may not be associated with pain

**Extremities:**

- Edema to hands and feet (may indicate preeclampsia)

**Baseline Vital Signs**

- BP: may be normal, decreased in shock, or increased in preeclampsia
- HR: may be normal or increased in shock
- RR: may be normal or increased
- Skin: may be normal or pale, cool, and clammy in shock
- Pupils: may be dilated and sluggish
- SpO₂: >94% if no excessive bleeding is associated with the emergency
Labor and Normal Delivery

Labor is the term used to describe the process of birth. It consists of contractions of the uterine wall, which expel the fetus and the placenta out of the uterus and vagina. Normal labor can be divided into three stages—dilation, expulsion, and placental (Figure 37-8). The length of each stage varies in different women and under different circumstances.

Toward the end of a full-term pregnancy, in the third trimester, the fetus moves into a head-down position. When the head descends through the broad upper inlet of the mother's pelvis, the uterus moves downward and forward. Mothers can feel the difference and say that the infant has “dropped.” This position is the one most common for the infant's passage through the cervix to the vagina.

First Stage: Dilation

The first stage of labor is from the beginning of true labor (contractions) to complete cervical dilation. During this first and longest stage, the cervix becomes fully dilated at 10 cm, which allows the infant’s head to progress from the body of the uterus to the birth canal. Through uterine contractions, the cervix gradually dilates (stretches) and effaces (thins) until the opening is large enough to allow the infant to pass through. The contractions usually begin as an aching sensation in the small of the back. Within a short time, the contractions become cramplike pains in the lower abdomen. These recur at regular intervals, each one lasting about 30 to 60 seconds. At first, the contractions occur about 10 to 20 minutes apart and are not very severe. They may even stop completely for a while and then start again. Appearance of the plug of mucus (the bloody show) may occur before or during this stage of labor. Also before or during this stage, the amniotic sac may rupture, resulting in a brief flow of fluid from the vagina.

Stage one may continue for as long as 18 hours or more for a woman having her first child. Most typical for the first-time mother is 8 to 10 hours for this first stage of labor. Women who have had a child before may experience only 5 to 7 hours of first-stage labor. (Realize that the duration of these stages can vary widely from patient to patient.) The dilation stage ends when contractions are at regular 3- to 4-minute intervals, last at least 60 seconds each, and feel very intense.

Braxton-Hicks Contractions. Braxton-Hicks contractions, often referred to as false labor, are painless, short-duration, irregular contractions that may occur as early as the 13th week of gestation. These contractions are thought to be a conditioning process for the uterus in preparation for the actual labor. It is also thought that Braxton-Hicks contractions improve placental blood flow. There is no cervical dilation or effacement with the contractions. Prior to true labor, the Braxton-Hicks contractions may become more frequent and intense; however, they typically remain irregular. There is no way to absolutely differentiate Braxton-Hicks from true labor in the prehospital setting; thus, any patient with contractions should be transported.

Assessment Tips

Contractions that follow a pattern of greater intensity, longer duration, and a shortening interval between them indicate true labor.
Mechanism of injury present?
Yes → Consider manual in-line stabilization
No → Consider maternal and fetal injury

Assess mental status
Alert and able to obey commands
Yes → Consider maternal and fetal injury
No → Assess breathing

Assess circulation
Secondary assessment
Vaginal bleeding?
Yes → Place sanitary pad over vaginal opening
No → Patient pregnant?
Yes → Position on left side
No → Is she crowning?
Yes → See Delivery Emergency Protocol
No → Secondary assessment

FIGURE 37-7 Emergency care algorithm: antepartum (predelivery) obstetric emergency.
**Second Stage: Expulsion**

The second stage of labor begins with complete cervical dilation and ends with the delivery of the baby. During this stage, the infant moves through the vagina (the birth canal) and is born (Figure 37-9). Contraction are closer together—2 to 3 minutes apart—and last longer—60 to 90 seconds each. As the infant moves downward, the mother experiences considerable pressure in her rectum, much like the feeling of a bowel movement. When the mother has this sensation, it is usually an indication that delivery is imminent. The mother often complains of the feeling that she needs to defecate. There probably will be more bloody discharge from the vagina at this point. The perineum, the area of skin between the vagina and the anus, bulges significantly—a sign of impending birth.

**PATHOPHYSIOLOGY PEARLS**

The perineum is primarily skin, muscle, and other soft tissue that may be traumatically torn during a field delivery. Soon after, the infant’s head appears at the opening of the birth canal. This is called crowning. At this point, the mother should be coached to push with each contraction. The shoulders and the rest of the infant’s body follow. For the patient in whom this is the first delivery, the second stage typically will last 50 to 60 minutes. In the patient who has delivered more than two children, the second stage may last only 20 to 30 minutes.

**ASSESSMENT TIPS**

The feeling of the urge to defecate during labor is a result of the pressure being placed on the rectum. This is another sign of imminent delivery. The tightening and bearing-down sensations will become stronger and more frequent. The mother will have an uncontrollable urge to push down, which she may do. The mother may experience low back pain.

The top of the head is the presenting part in a normal delivery, called a cephalic delivery. The face will be positioned downward.
Third Stage: Placental

The third stage of labor begins following the delivery of the baby and ends with the expulsion of the placenta. During this stage, the placenta separates from the uterine wall and is expelled from the uterus. The placenta is usually delivered 5 to 20 minutes following the birth of the baby. The mother will continue to have contractions, even though not as severe, until the placenta is expelled. The signs that the delivery of the placenta is imminent are (1) there is a sudden increase in bleeding from the vagina, (2) the uterus becomes smaller in size, (3) the umbilical cord begins to lengthen, and (4) the mother has an urge to push. Never tug or pull on the umbilical cord in an attempt to facilitate delivery of the placenta.
Signs and Symptoms. Delivery can probably be expected within a few minutes, if the following signs and symptoms are present:

- Crowning has occurred.
- Contraction are 2 minutes apart or closer, and they are intense and last from 60 to 90 seconds.
- The patient feels the infant’s head moving down the birth canal (sensation of the urge to defecate).
- The patient has a strong urge to push.
- The patient’s abdomen is very hard.

If birth is imminent with crowning, contact medical direction for a decision to commit to delivery on site. If delivery does not occur within 10 minutes, contact medical direction for permission to transport. If you determine that you must assist in the delivery of the infant, remember:

- Take all appropriate Standard Precautions, including gloves, gown, and eye protection.
- Do not touch the patient’s vaginal area, except during delivery and in the presence of your partner.
- Do not allow the patient to use the bathroom. If the patient does move her bowels or urinate, replace soiled linens with clean ones.
- Do not hold the mother's legs together. Do not do anything to attempt to delay or restrain the delivery, unless it is an abnormal delivery, which is discussed in a later section.

- Use a sterile obstetrics (OB) kit. Recommended equipment includes (Figure 37-10):
  - Surgical scissors or scalpel (for cutting the umbilical cord)
  - Cord clamps or cord ties
  - Umbilical tape or sterilized cord
  - Bulb syringe
  - Towels, five or more
  - Gauze sponges, 2 × 10
  - Sterile gloves
  - One infant blanket
  - Individually wrapped sanitary napkins, three or more
  - Large plastic bag, at least one
  - Germicidal wipes

If you are to assist the mother in delivery, stay calm and explain to her that you are trained to help. As much

**PATHOPHYSIOLOGY PEARLS**

Pulling or tugging on the umbilical cord in an attempt to deliver the placenta may cause the uterus to invert. If inverted, the uterus will not be able to contract and tone up effectively. This will lead to serious hemorrhage.

**Assessment-Based Approach: Active Labor and Normal Delivery**

**Scene Size-up, Primary Assessment, and Secondary Assessment**

For a woman in labor or having a normal delivery, the scene size-up, primary assessment, and secondary assessment are essentially the same as you would provide in an antepartum (predelivery) emergency, as just described. If you determine that the patient is in active labor (review the stages of labor described earlier in the chapter), your assessment and treatment goals will focus on assisting the mother with delivery and providing initial care to the neonate (the newborn infant).

As a general rule, it is best to transport a mother in labor so that the delivery can take place at a hospital. However, if delivery is imminent, you will need to prepare to assist in the delivery at the scene. In order to determine if you should transport or commit to a delivery on scene, answer the following questions:

- What is the age of the pregnant patient?
- How many times has the patient been pregnant?
- Is this the patient’s first delivery? If not, how many deliveries has she experienced?
- How long has the patient been pregnant? What is the estimated due date?
- Has there been any bleeding or discharge (bloody show)?
- Has the amniotic sac ruptured? If so, when and what color is the fluid?
- Has fetal movement been present or absent?
- Are there any contractions or pain present?
- What is the frequency and duration of contractions?
- Is crowning occurring with contractions?
- Does the patient feel the need to push?
- Does the patient feel as is she is having a bowel movement with increasing pressure in the vaginal area?
- Is the abdomen (uterus) hard upon palpation?
- Did the pregnant patient take any medication? If so, what was taken and when was it taken?

**Note:** There are three cases in which you must assist in the delivery of the infant: if you have no suitable transportation; if the hospital or physician cannot be reached due to bad weather, a natural disaster, or some other kind of catastrophe; or if delivery is imminent. The answers to the preceding questions can help you determine if delivery is about to happen. Also see the following signs and symptoms for indications that delivery is imminent.

![Disposable Obstetrics (OB) Kit](https://www.bradybooks.com/images/37-10.jpg)

**FIGURE 37-10** Disposable obstetrics (OB) kit.
as possible, ensure the mother’s comfort, modesty, and peace of mind. Try to limit distractions and onlookers. Most importantly, recognize your own limitations. If you get into a situation you cannot handle, call medical direction for help and permission to transport.

**Emergency Medical Care**

Take all appropriate Standard Precautions. Wear protective gloves, gown, and eye protection. The amount of blood and body fluid exposure during delivery is usually significant. Handle blood- and fluid-soaked dressings, pads, and linens carefully, and bag them in moisture-proof bags to prevent leakage. Seal and label the bags.

Emergency medical care of the patient in active labor for a normal delivery (EMT Skills 37-1) is as follows:

1. **Position the patient.** Have the patient lie on a firm surface with her knees drawn up and spread apart. Elevate the patient’s buttocks several inches with a folded blanket, sheet, towels, or other clean objects. The patient’s feet should be flat on the surface beneath her, which will help her brace herself. She should be several feet in from the edge of the surface to help provide extra support for the slippery infant as it is born. Support the mother’s head, neck, and shoulders with pillows or folded blankets so she does not feel like she is slipping “downhill.”

2. **If there are no signs of hypoxia or if the SpO2 reading is 94% or greater, still apply a nasal cannula to the pregnant patient at 2 to 4 lpm to provide additional oxygenation of the fetus during the labor and delivery process.**

3. **Create a sterile field around the vaginal opening if time permits.** Use sheets from the OB kit, sterile towels, or paper barriers. Remove the patient’s clothing or push it up above her waist. Place one sheet under the woman’s hips, unfolding it toward her feet, and another sheet over her abdomen and legs. Place your OB kit or equipment close enough to reach, but away from the birth canal so it will not be contaminated by the vaginal discharge, blood, and amniotic fluid.

4. **Monitor the patient for vomiting.** Have your partner or a close family member stay at the patient’s head. If she vomits, this person can be ready to turn her head to one side and clean out her mouth manually or with suction.

5. **Continually assess for crowning.** The vaginal wall and perineum will bulge with each contraction. The top of the head will appear at the vaginal opening.

**Assessment Tips**

- If crowning is occurring, then the head suddenly disappears, and the mother begins to complain of sharp, intense, constant abdominal pain, suspect a possible uterine rupture.
- If the uterus ruptures during delivery, the fetus might be expelled into the abdominal cavity.

6. **Place your gloved fingers on the bony part of the infant’s skull when it crowns.** Exert very gentle pressure to prevent an explosive delivery. Avoid touching and exerting pressure on the infant’s face and on any soft spot (fontanelle) on the head. With a sterile dressing, exert gentle pressure horizontally across the perineum to reduce the risk of traumatic tears.

7. **Tear the amniotic sac if it is not already ruptured.** Use your fingers to rupture the sac, and then push it away from the infant’s head and face as they appear.

8. **Determine the position of the umbilical cord.** As the infant’s head is delivered, determine if the umbilical cord is around the infant’s neck. If so, this is referred to as a **nuchal cord.** A nuchal cord must be managed immediately as it is found. Use two fingers to slip the cord over the infant’s shoulder. If you cannot move the cord, place two clamps 2 to 3 inches apart and cut between the clamps. Remove the cord from around the neck.

9. **Suction fluids from the infant’s airway only if obvious obstruction to breathing exists or if positive pressure ventilation is necessary.** According to the 2010 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, it is recommended that suctioning the nose and mouth in the newborn immediately following birth, even with a bulb syringe, be performed only when secretions are present that obstruct spontaneous breathing or if positive pressure ventilation is necessary.

**Pathophysiology Pearls**

Suctioning the newborn’s nasopharynx can lead to bradycardia during the initial newborn care and resuscitation. Also, there is evidence indicating that suctioning secretions may lead to a reduction in airway resistance, which reduces the newborn’s effort to breathe. Therefore, based on the latest evidence, clear the airway by applying suction with a bulb syringe only if obstruction to spontaneous ventilation is present or if positive pressure ventilation must be performed.

If suction is to be applied, make sure you compress the bulb syringe before you bring it to the infant’s face. Insert the tip of the compressed bulb 1 to 1.5 inches into the infant’s mouth, slowly releasing the bulb to allow mucus and fluids to be drawn into the syringe. Avoid touching the back of the mouth. Remove the syringe, then discharge the contents onto a towel, and repeat. Use the same procedure to suction each nostril. Note any dark greenish substance (meconium) in the amniotic fluid or on the baby or in the airway.

10. **As the torso and full body are expelled, support the newborn with both hands.** Never pull the infant from the vagina. The newborn will be slippery with a whitish, cheeselike substance (vernix caseosa) over its body. However, do not put your fingers in the infant’s armpit; pressure there can damage nerve centers. Receive the newborn in a clean or sterile towel to help you hold it safely.
11. **Grasp the feet as they are born.** Do not pull on the umbilical cord as you lift or receive the infant.

12. **Dry, wrap, warm, and position the infant, and suction if necessary.** Dry the infant with towels. Remove the wet towels well away from the infant’s body to avoid inadvertent cooling. Place the infant in a warm, dry blanket and on its back with the head in a sniffing position to maintain an open airway. A towel could be placed under the small of the back of the mother to warm the area during the delivery. Once the neonate is delivered and dried, remove the towel from under the mother and wrap it around the infant to provide warmth and insulation. Keep the infant at or above the level of the mother’s vagina until the umbilical cord is cut. Clear the airway only if necessary.

13. **Assign your partner to monitor and complete initial care of the newborn.** You should complete emergency medical care of the mother.

14. **Clamp, tie, and cut the umbilical cord as pulsations cease** (Figure 37-11). Place two clamps or ties on the cord about 3 inches apart. The first clamp should be approximately four finger widths (6 inches) from the infant’s abdomen. Use sterile surgical scissors or a scalpel to cut the cord between the two clamps. Periodically check the end of the cord for bleeding, and control any that may occur by placing another clamp or tie proximal to the one you have already placed on the cord.

15. **Observe for delivery of the placenta.** While preparing the mother and infant for transport, continue to watch for delivery of the placenta. It usually is delivered within 10 minutes of the infant, and almost always within 20 minutes. When the placenta appears at the vagina, grasp it gently. Never pull. Instead, slowly and gently guide the placenta and the attached membranes from the vagina. Do not delay transport while waiting for the delivery of the placenta.

**PATHOPHYSIOLOGY PEARLS**

A piece of placenta that is retained within the uterus may cause the mother to continue to bleed.

16. **Transport the delivered placenta.** When the placenta has completely delivered, place it in the plastic bag contained within the OB kit for transport to the hospital. A physician will examine it to confirm that delivery was complete. Be sure to turn off the air conditioning in the back of the ambulance so you don’t cause the infant to become hypothermic during transport.

17. **Place one or two sanitary pads over the vaginal opening.** When covering the vaginal opening, inspect the perineum (the area between the vaginal opening and the anus). This area is frequently torn during the delivery. If it is bleeding, apply sterile dressings and direct pressure to control the bleeding. Then lower the patient’s legs and help her hold them together. Elevate her feet if necessary.

18. **Record the time of delivery and transport the mother, infant, and placenta to the hospital.** Keep mother and infant warm. Transport gently. Note that there will be vaginal bleeding after delivery. Up to 500 mL of blood loss is normal and well tolerated by the mother. However, if blood loss appears to be excessive, provide oxygen to the mother and massage the uterus as follows. Massage helps to stimulate contractions, which decrease the uterine size and help to stop bleeding.

   1. Place the medial edge of one hand (fingers extended) horizontally across the abdomen, just above the symphysis pubis. This will help prevent the uterus from prolapsing with the massage.
   2. **Cup your other hand around the uterus.** Use a kneading or circular motion to massage the area. It should feel like a hard grapefruit.
   3. **Allow the infant to suckle on the mother’s breast.** This will release oxytocin, a naturally occurring hormone that causes the uterus to contract.
   4. **If bleeding continues to appear to be excessive, check your massage technique, continue massage, and transport immediately.**

**PATHOPHYSIOLOGY PEARLS**

Oxytocin is a naturally occurring hormone that is released from the posterior pituitary gland. It causes the smooth muscle of the uterus to contract and tone up. Toning the uterine muscle will cause the vessels to constrict, and the bleeding will cease.

**Reassessment**

During the reassessment, regardless of the estimated amount of blood loss after delivery, if the mother appears to be suffering shock (hypoperfusion), treat and transport immediately. You can initiate uterine massage during transport.

ABNORMAL DELIVERY

Assessment-Based Approach: Active Labor with Abnormal Delivery

Scene Size-up, Primary Assessment, and Secondary Assessment

Just as you would perform a scene size-up, primary assessment, and secondary assessment on a patient having a normal delivery, so would you assess a patient who is experiencing a delivery emergency.

Signs and Symptoms. In general, you can recognize an abnormal delivery emergency by observing one or more of the following signs or symptoms:

- Any fetal presentation other than the normal crowning of the fetus head
- Abnormal color or smell of the amniotic fluid
- Labor before 38 weeks of pregnancy
- Recurrence of contractions after the first infant is born (indicating multiple births)

Emergency Medical Care and Reassessment

In general, emergency medical care of the mother and newborn is similar to that of a normal delivery. Exceptions are outlined as follows and include an emphasis on immediate transport, administration of high-concentration oxygen, and continuous monitoring of vital signs during the reassessment.

Intrapartum Emergencies

An intrapartum emergency is one that occurs during the period from the onset of labor to the actual delivery of the neonate. There are several conditions that may lead to an abnormal delivery. In almost all of these conditions, delivery is not possible. A continued attempt at delivery puts the pregnant patient and fetus at great risk for injury or even death. Thus, immediate transport is a key in the emergency care of abnormal delivery emergencies.

Prolapsed Cord

After the amniotic sac ruptures, the umbilical cord, rather than the head, may be the first part presenting at the vaginal opening. This is called a prolapsed cord (Figure 37-12). In this situation the umbilical cord may get compressed against the walls of the vagina and the bony pelvis by the pressure of the infant’s head or buttocks. As a result the infant’s supply of oxygenated blood can be cut off. This is a true emergency. Predisposing factors include prematurity, multiple births, and premature rupture of the amniotic sac.

For a prolapsed cord, follow these guidelines:

1. Instruct the patient NOT to push to avoid additional compression of the umbilical cord. During the contractions, instruct the patient to “pant like a dog” to prevent her from contracting her abdominal muscles and pushing. It is important that you coach the patient during the contractions because her natural urge is to push.
2. Position the patient on the stretcher in a “knee-chest” position (kneeling and bent forward, face down, head down, chest to knees) with the stretcher in a Trendelenburg position if possible.

3. Insert a sterile, gloved hand into the vagina, and gently push the presenting part of the fetus, head or buttocks, up, back, or away from the pulsating cord. (Note: This is the one time it is permissible to insert your hands into the mother’s vagina.) Do not try to push the cord back into the vagina. Follow local protocol and seek medical direction.

4. Cover the umbilical cord with a sterile dressing moistened with a sterile saline solution.

5. Transport the patient rapidly while maintaining pressure on the head or buttocks to keep pressure off the cord, and monitor pulsations in the cord. (Pulsations should be present.)

**Breech Birth**

A breech birth presentation is one in which the fetal buttocks or lower extremities are low in the uterus and are the first to be delivered (Figure 37-13 ■). Delivery may be prolonged for these newborns, who are at great risk of delivery trauma. The mother is also at risk for delivery trauma. There is an increased risk of a prolapsed cord, compression of the cord, or an anoxic insult during delivery where oxygenation is cut off to the fetus. Transport immediately upon recognition of a breech presentation. Administer oxygen to the mother, and keep the mother in a supine head-down position with her pelvis elevated so gravity will discourage the movement of the fetus into the birth canal.

A breech delivery is best managed in the hospital. You should not attempt to deliver a breech presentation in the field. However, if the delivery is unavoidable, perform the following emergency care:

1. Position the mother with her buttocks at the edge of a firm surface or bed.

2. Have her hold her legs in a flexed position.

3. As the infant delivers, do not pull on the legs, but support them.

4. Allow the entire body to be delivered as you simply support it. Continue with care for the neonate as in the normal delivery.

A complication of breech delivery is that the body is delivered but the head cannot be delivered. If this occurs, insert your index and middle gloved fingers into the vagina, forming a “V” along the vaginal wall with the baby’s nose and mouth between the fingers. Push against the vaginal wall to create a space for respiration. Immediately transport while maintaining this position.

**PATHOPHYSIOLOGY PEARLS**

Breech presentations are often associated with premature births, placenta previa, multiple births, and uterus and fetal abnormalities.

**Limb Presentation**

When one arm or one leg is the first to protrude from the birth canal, it is considered a limb presentation (Figure 37-14 ■). Under no circumstances would you attempt a field delivery of a limb presentation. Transport immediately, because a cesarean section will be required to deliver the fetus. Administer oxygen to the mother, and place the mother in a knee-chest position with her pelvis elevated. Never pull on the infant by its arm or leg and, again, never attempt delivery in this situation. Have the mother pant if she has the urge to push with contractions.

**PATHOPHYSIOLOGY PEARLS**

Limb presentation is most often seen when the fetus is lying transversely across the uterus. Touching the presenting limb may stimulate the fetus to gasp for a breath and aspirate amniotic fluid.
Multiple Births

In a multiple birth (twins, triplets, and so on) each infant may have its own placenta or the infants may share a placenta. Even if the mother is unaware that she is carrying more than one infant, you should be prepared for a multiple birth if one or more of the following is observed:

- The abdomen is still very large after one infant is delivered.
- Uterine contractions continue to be extremely strong after delivering the first infant.
- Uterine contractions begin again about 10 minutes after one infant has been delivered.
- The infant’s size is small in proportion to the size of the mother’s abdomen.

Follow the general guidelines for emergency medical care in a normal delivery, with the following exceptions: Be prepared to care for more than one infant. Call for assistance. Note that about one-third of the deliveries of the second infant will be breech, so assess carefully and take immediate action. If the second infant is not breech, handle the delivery as you would for a single infant. Expect and manage hemorrhage following the second birth. If the second infant has not delivered within 10 minutes of the first, transport the mother and the first infant to the hospital for delivery of the second infant. Multiple-birth babies have a tendency to be low birth weight and may require additional resuscitation.

Meconium

During a difficult labor the fetus may undergo significant distress. One result of this distress is the passing of a bowel movement in the amniotic fluid, causing the normally clear fluid to turn greenish or brownish yellow. This coloring is called meconium staining. It is an indication that the fetus experienced a hypoxic event. If the infant aspires into its lungs any of the meconium-stained fluid, infection and aspiration pneumonia can result. Meconium staining is most often seen in breech births. If meconium is present but the newborn has a good cry or vigorous activity, do not suction. If the baby is depressed or nonvigorous, do not dry or stimulate until you have aggressively suctioned the airway until clear to avoid aspiration of the meconium.

**PATHOPHYSIOLOGY PEARLS**

When the fetus becomes hypoxic, the digestive tract increases movement (peristalsis) and the anal sphincter relaxes, causing the meconium to be released into the amniotic fluid. In a breech delivery, the uterus contracts against the fetus's head and stimulates the parasympathetic nervous system, which increases the peristalsis in the intestines, making meconium staining more likely to occur. Typically, the thicker and darker the color of the meconium the higher the risk for more fetal problems.

Premature Birth

An infant weighing less than 5 pounds, or an infant born before its 38th week of development, is defined as a premature infant and requires special care. Because of their underdevelopment, premature babies are more susceptible to hypothermia and respiratory distress. You can generally tell by appearance whether an infant is premature (Figure 37-15). A premature infant is thinner and smaller, and its skin has a reddened and wrinkled appearance. There will be a single crease across the sole of the foot, there will be fuzzy scalp hair that is very fine, and the external ear cartilage will not be fully developed. A premature infant, because of its incomplete development, may require more vigorous resuscitation than a full-term infant.

Provide this additional care for a premature infant:

1. Be sure to dry the infant thoroughly and avoid heat loss. Keep the infant warm by using warmed blankets or a plastic bubble-bag swaddle, making sure that the head is covered but the face is unobstructed.
2. Use gentle suction if it is necessary to clear the airway.
3. Prevent bleeding from the umbilical cord. A premature infant cannot tolerate losing even the smallest amount of blood.
4. Administer supplemental oxygen if necessary by blowing oxygen across the infant’s face, with the end of the...
oxygen tube approximately 1 inch above the infant’s mouth and nose. Never blow the oxygen directly into the face. Support ventilation if breathing is inadequate.

5. Premature babies are highly susceptible to infection. Prevent contamination and do not let anyone breathe into the infant’s face.

6. Wrap the infant securely to keep it warm, and heat the vehicle during transport.

**Postterm Pregnancy**

In postterm pregnancy, the gestation of the fetus extends beyond 42 weeks. Postterm pregnancy causes postmaturity syndrome, a deterioration of conditions necessary to support the well-being of the fetus. At 42 weeks, the placenta begins to decline, leading to a decrease in oxygenation and nutrient delivery to the fetus from decreased placental blood flow. The postmature baby is more prone to insufficient oxygen and nutrient delivery, hypoxia, a hardened skull that causes a more difficult delivery, and the presence of meconium from increased bowel maturity. The postmature fetus is at greater risk for intrapartum hypoxia because of the inability of the placenta to meet the demands of the fetus during labor.

**Precipitous Delivery**

A precipitous delivery is one in which the birth of the fetus occurs after less than 3 hours of labor. Precipitous delivery is most often seen in patients who have delivered several children (multipara). Since the delivery occurs so rapidly, there is an increased risk of trauma to the fetus, trauma to the mother, and tearing of the umbilical cord. The delivery would be conducted in the same manner as any other; however, it may occur rapidly and without much warning. The care for the neonate is the same as in a normal delivery.

**Shoulder Dystocia**

A shoulder dystocia is when the fetal shoulders are larger than the fetal head. The head delivers, but then it retracts back into the vagina because the shoulders are caught between the symphysis pubis and the sacrum (Figure 37-16 ■). The retraction into the vagina is referred to as a “turtle sign.” It occurs in larger birth-weight babies, as seen in diabetic mothers and those who are past their due dates. If a shoulder dystocia occurs, do not pull on the head of the fetus in an attempt to deliver. Transport immediately. Have the mother pant to reduce the force and pressure of contractions. Place the mother on her back with her knees drawn up as close to her chest as possible. This is known as the McRobert position (Figure 37-17 ■). This maneuver moves the symphysis pubis anteriorly and superiorly and drops the sacrum, creating a larger opening for delivery of the shoulders.

**Preterm Labor**

Preterm labor, also known as premature labor, occurs after the twentieth but prior to the 37th week of gestation. This is a different condition from preterm birth. Preterm labor refers specifically to the onset of labor. It does not always lead to birth of the baby if the labor can be stopped. A mother with a history of preterm labor is usually placed on bed rest during the pregnancy. Preterm labor carries a higher incidence of abnormal presentations of the fetus during delivery. Cocaine and other drugs are known to induce labor. If you suspect preterm labor, keep the mother calm and do not allow her to push. Place the patient on oxygen. Consider calling an advanced life support unit.

**Premature Rupture of Membranes**

Premature rupture of membranes (PROM) is the spontaneous premature rupture of the amniotic sac prior to the onset of true labor and before the end of the 37th week of gestation. Although this is not an emergency, there is an increased risk of infection of the uterus and its contents. Amniotic fluid acts as a lubricant during delivery; thus, premature rupture of the amniotic sac prevents adequate lubrication of the vaginal canal at the time of birth, which may lead to a more difficult delivery.
Normal

Shoulder Dystocia

Anterior shoulder impacted behind pubic symphysis

Dangers Include:
- Entrapment of cord
- Inability of child’s chest to expand properly
- Severe brain damage or death if child is not delivered within minutes

FIGURE 37-16 Shoulder dystocia.

Before McRobert Positioning

Diagonal orientation of symphysis makes shoulder delivery difficult

Summary: Assessment and Care—Active Labor and Delivery

To review possible assessment findings and emergency care for an obstetric emergency associated with active labor and delivery, see Figures 37-18 and 37-19.

Postpartum Complications

The term postpartum refers to the period following delivery. Postpartum complications involve only the mother. Hemorrhage is the most dangerous of the postpartum conditions.

Assessment Summary

**OBSTETRIC EMERGENCY—ACTIVE LABOR AND DELIVERY**

The following findings may be associated with an obstetric emergency occurring during active labor or delivery.

**Scene Size-up**

Pay particular attention to your own safety. Look for:
- Mechanism of injury
- Blood in toilet or around patient
- Bleeding from vagina
- Bloody tissue or blood clots
- Fetus protruding from vagina
- Mucus discharged, tinged with blood
- Amniotic fluid
- Meconium staining

**Primary Assessment**

**General Impression**

Does the patient appear to be in a full-term pregnancy?
- Posture: lying still with knees to chest indicates severe abdominal pain, or supine
- Any evidence of seizure activity?
  - Is the umbilical cord or fetal body part other than the head present at the vaginal opening?
  - Does the patient appear to be having contractions that are intense, regular, frequent, and with a duration of about 60 seconds?

**Mental Status**

Alert

**Airway**

Open and usually not obstructed

**Breathing**

Increased due to pain

**Circulation**

Heart rate may be increased

**Status**:

Priority patient if associated with shock, significant vaginal bleeding, or abnormal presenting part, or if greater than 10 minutes is spent attempting to perform delivery

**Secondary Assessment**

**History**

Signs and symptoms:
- Abdominal pain due to contractions

**True labor contractions**:
- Regular
  - Occur at about 2- to 3-minute intervals
  - Last about 30-90 seconds
  - Are intense

**False labor (Braxton-Hicks) contractions**:
- Irregular
  - Interval time varies
  - Duration varies
  - Intensity varies
  - May be relieved by walking

Vaginal discharge of amniotic fluid, clear with yellowish tint

Crowning

**Question**:

Onset, provocation/palliation, quality, radiation, severity, and duration of pain
- When was your last menstrual period?
- Have you had any unusual vaginal discharge or bleeding?
- When is your due date?
- Have you had previous problems with pregnancies?
- Have you been seeing a physician for this pregnancy?
- Is this your first delivery?
- Do you feel as if you are having a bowel movement?

**Physical Exam**

**Abdomen/genitalia**:
- Obvious protruded abdomen
- Evidence of crowning or abnormal presenting part?
- Any passed tissue from the vagina?
- Vaginal bleeding, dark or bright red, may or may not be associated with pain
- Amniotic fluid present
- Meconium staining to amniotic fluid

**Baseline Vital Signs**

- BP: may be normal or increased
- HR: may be normal or increased
- RR: may be normal or increased
- Skin: normal
- Pupils: normal size, equal, and reactive to light
- $\text{SpO}_2$: >94%
anaphylactic reaction and can lead to cardiopulmonary failure. The condition, which is not amniotic fluid, fetal cells, hair, or other material enter skin. Amniotic fluid embolism (AFE) may occur when pain, hypotension, cyanosis, and pale, cool, clammy venous system can lead to a pulmonary embolism. The clot formation in the blood. Clot formation in the pregnant or postpartum patient is at greater risk for hemorrhage following delivery can be managed with oxygen therapy, fundal massage, and immediate transport. 2 weeks after the delivery. In the prehospital setting, hemorrhage can occur up to a large baby. Prolonged labor and precipitous delivery can lead to failure of the uterus to tone. If the uterus fails to return to a normal size, hemorrhage can occur up to 2 weeks after the delivery. In the prehospital setting, hemorrhage following delivery can be managed with oxygen therapy, fundal massage, and immediate transport.

**Postpartum Hemorrhage**

Postpartum hemorrhage is defined as the loss of greater than 500 mL of blood following delivery. The most common cause of postpartum hemorrhage is failure of the uterus to regain its muscle tone (uterine atony). Postpartum hemorrhage is most common in multigravida patients following multiple births or delivery of a large baby. Prolonged labor and precipitous delivery can lead to failure of the uterus to tone. If the uterus fails to return to a normal size, hemorrhage can occur up to 2 weeks after the delivery. In the prehospital setting, hemorrhage following delivery can be managed with oxygen therapy, fundal massage, and immediate transport.

**Embolism**

The pregnant or postpartum patient is at greater risk for an embolism because of the increased blood volume and coagulation properties of the blood. Clot formation in the venous system can lead to a pulmonary embolism. The patient with a pulmonary embolism may present with shortness of breath, syncope, tachycardia, sharp chest pain, hypotension, cyanosis, and pale, cool, clammy skin. Amniotic fluid embolism (AFE) may occur when amniotic fluid, fetal cells, hair, or other material enter the mother’s circulation. The condition, which is not completely understood, may be more associated with an anaphylactic reaction and can lead to cardiopulmonary compromise. Your emergency care for embolism or AFE will focus on ensuring adequate ventilation and maximizing oxygenation. Provide oxygen via a nonrebreather mask at 15 lpm. If the patient’s breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen connected to the ventilation device.

**CARE OF THE NEWBORN**

**Assessment-Based Approach: Care of the Newborn**

Newborn infants, also referred to as neonates, can lose body heat quickly. Protecting them against heat loss preserves their energy and avoids the complex problem that hospitals face in trying to rewarm a cold infant. Immediately dry the infant. Be sure to dry the head well and cover it. Then wrap the newborn in a blanket or a plastic bubble-bag swaddle. Suction to clear the airway only if necessary. Position the newborn on his back with the neck slightly extended in a sniffing position. Place some padding under the shoulders to maintain the head and neck in a slight sniffing position. Do not hyperextend or flex the neck; this may cause airway obstruction.

**Assessment**

Perform a thorough assessment of the infant. You can use the Apgar scoring system to get a good overall indication...
Is delivery imminent? (Crowning, contractions intense, 2–3 minutes apart, duration of 30 to 90 seconds, urge to push)

- Yes
  - Is the head the presenting part?
    - Yes
      - Prepare for delivery
    - No
      - Amniotic sac intact?
        - Yes
          - Rupture sac with your fingers
          - Cord around the neck?
            - Yes
              - Able to slip the cord over the head?
                - Yes
                  - Is meconium present?
                    - Yes
                      - Continue to suction mouth and nose until all is removed
                    - No
                      - Deliver body of newborn
                - No
                  - If secretions are present, suction nose and mouth
        - No
          - Reassessment

- No
  - Perform a secondary assessment
  - Place patient on left side
  - Transport
  - Reassessment

Place patient in knee chest position or elevate the hips
Cover the presenting part with a moist sterile dressing

If secretions are present, suction nose and mouth

Warm, dry, position, suction, and stimulate newborn infant (See Emergency Care Protocol for Newborn)

Cut umbilical cord

Has the placenta been delivered?
- Yes
  - Has it been greater than 10 minutes?
    - Yes
      - Attempt to deliver within ten minutes
    - No
      - Transport
  - No
    - Reassessment

Cream = assessment
Green = key decision points
Blue = interventions
of the baby’s condition. The score should be determined at 60 seconds after birth, and then repeated in 4 minutes to obtain a 1-minute and a 5-minute score following birth. A change in the Apgar score may indicate improvement (higher score), worsening (lower score), or no change. To assess the newborn using the Apgar scoring system, you can use the letters in Apgar as a mnemonic to remember the parts of the assessment, as follows:

- **Appearance.**
  - If the skin of the newborn’s entire body is blue (cyanotic) or pale, award 0 points.
  - If the newborn has blue hands and feet with pink skin at the core of the body (a condition called acrocyanosis), award 1 point.
  - If the skin of the extremities as well as the trunk is pink, award 2 points.

- **Pulse.** Heart rate is one of the most important signs of whether oxygen is reaching the newborn’s tissues following birth. Count the heart rate for at least 30 seconds, preferably with a stethoscope. If you do not have a stethoscope, feel the pulse of the umbilical cord where it joins the abdomen or at the brachial artery.
  - If no pulse is present, award 0 points.
  - If the heart rate is under 100 (also a serious finding), award 1 point.
  - If the heart rate is over 100, award 2 points.

- **Grimace (reflex irritability).** Gently flick the soles of the newborn’s feet, or observe the facial expressions during suctioning if performed.
  - If the newborn displays no reflexive activity to your stimulation, award 0 points.
  - If the newborn displays only some facial grimace, award 1 point.
  - If your stimulation causes the newborn to grimace and cough, sneeze, or cry, award 2 points.

- **Activity.** This score refers to extremity reflexes/movement, or the degree of flexion of the arms and legs and the resistance to straightening them. The normal newborn’s elbows, knees, and hips are flexed, and you should encounter some degree of resistance when you try to extend them.
  
- If during your assessment the newborn is limp and displays no extremity movement, award 0 points.
- If the newborn only displays some flexion without active movement, award 1 point.
- If the newborn is actively moving around, award 2 points.

- **Respiration.** Another important assessment sign is the newborn’s breathing effort. The newborn should have regular respirations and a vigorous cry. Distress is indicated by irregular, shallow, gasping, or absent respirations.
  - If the newborn displays no respiratory effort, award 0 points.
  - If the newborn displays only a slow or irregular breathing effort with a weak cry, award 1 point.
  - If the newborn displays good respirations and a strong cry, award 2 points.

At the conclusion of the assessment, you should have a numeric value that ranges from 0 to 10. Use the following guidelines to determine the significance of your finding:

- 7–10 points—The newborn should be active and vigorous. Provide routine care.
- 4–6 points—The newborn is moderately depressed. Provide stimulation and oxygen.
- 0–3 points—The newborn is severely depressed. You will probably need to provide extensive care including oxygen with bag-valve-mask ventilations and CPR, as described later.

Be sure to stimulate the newborn if he is still not breathing adequately. You can stimulate respirations by gently flicking the soles of the feet or by rubbing the back in a circular motion with three fingers (Figure 37-20). En route to the hospital, provide continual assessment for the newborn. Pay particular attention to body temperature, airway, breathing, and oxygenation status; heart rate; color; and activity level. Contact medical direction to update them on the mother’s and newborn’s condition.

**Signs and Symptoms.** Most newborns require no resuscitation beyond temperature maintenance, mild stimulation, and suctioning. Of those who require additional resuscitation, most need oxygen or bag-valve-mask
ventilations. A minority of newborns are so depressed that they will also need chest compressions or resuscitative medications.

Certain physical abnormalities, medical complications, or even distressed deliveries can lead to a severely depressed newborn in need of immediate and aggressive treatment. The signs of a severely depressed newborn are:

- Respiratory rate over 60 per minute
- Diminished breath sounds
- Heart rate over 180 per minute or under 100 per minute
- Obvious signs of trauma from the delivery process
- Poor or absent skeletal muscle tone
- Respiratory arrest, or severe distress
- Heavy meconium staining of amniotic fluid and a nonvigorous newborn
- Weak pulses
- Cyanotic body (core and extremities)
- Poor peripheral perfusion
- Lack of or poor response to stimulation
- Apgar score under 4

**Emergency Medical Care**

If one or more of the preceding signs are noted during your assessment following birth, you should gather the necessary equipment for neonatal resuscitation. It is important to remember that newborns cannot tolerate periods of inadequate oxygenation without serious effects. However, it is also important to recognize that the oxygenation and correlated SpO2 reading after delivery is expected to be much less than that of an infant, child, or adult patient. The preductal (measured in the right hand or extremity) SpO2 reading and blood oxygenation will be much lower immediately after birth (SpO2 of 60%–65%) and will steadily improve within the first 10 minutes (See Table 37-1). The establishment and maintenance of an adequate airway, ventilation, and oxygenation is “cornerstone” treatment for any newborn infant who does not exhibit vigorous activity following birth.

Most newborns do not require aggressive treatment. Approximately 80 percent require no resuscitation beyond keeping them warm and keeping the airway clear of secretions if necessary. Newborn bradycardia (HR <100 bpm), labored breathing, apnea, or persistent cyanosis will typically respond to blow-by oxygen or to bag-valve-mask ventilations with supplemental oxygen. A small number of newborns may require chest compressions, and an even smaller number may require the medications or intubation that an advanced life support team can provide. The relative frequency of need for resuscitative measures is often shown as an inverted pyramid with the simple care most newborns require at the top (Figure 37-21).

A rapid assessment of the newborn will identify the need for intervention beyond normal care, which can be determined by evaluating the following three criteria:

1. Is this a term gestation?
2. Does the newborn have a good cry or is he breathing adequately?
3. Does the newborn have good muscle tone?

If the answer to all of the three questions is “yes,” the newborn should not require resuscitation beyond normal newborn care and can be kept with the mother for transportation, provided the mother is not experiencing any life-threatening complications.

- If you have answered “yes” to all three questions, provide the following newborn care:
  1. Dry the infant.
  2. Clear the airway only if necessary.
  3. Wrap the baby in dry linens or commercial products designed to keep the newborn warm.
  4. Place the newborn on the mother to provide extra warmth.

- If you have answered “no” to any of the three questions, the newborn will require one or more additional interventions. In this situation, initial newborn stabilization steps that include drying and warming might also include:
  - Clearing the airway, stimulation, and supplemental oxygenation
  - Positive pressure ventilation

**FIGURE 37-21** The inverted pyramid for neonatal resuscitation shows that the majority of newborns will respond to simple routines of care; only a few will require aggressive resuscitation.
- Chest compressions
- Administration of fluids or medications

The initial assessment, reassessment, and intervention with positive pressure ventilation if necessary should not take longer than 60 seconds. The 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care refers to this as the “Golden Minute.” Additional intervention beyond these initial steps is determined through the assessment of the respiration (apnea, gasping or labored or unlabored breathing) and the heart rate (> or <100 bpm).

The entire time the newborn is in your care, you must continuously reevaluate the following:
- Heart rate
- Respiration
- Oxygenation (determined by SpO2 monitoring)

Based on the 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, assessment and initial management of the newborn should be conducted as outlined in Table 37-2:

**Interventions.** Interventions recommended, as needed and as listed in Table 37-2, may include the following.

<table>
<thead>
<tr>
<th>Assessment</th>
<th>Response</th>
<th>Intervention</th>
</tr>
</thead>
<tbody>
<tr>
<td>Term gestation?</td>
<td>Yes</td>
<td>Dry, wrap to warm, keep with mother, clear airway if necessary, and continue to assess heart rate, respirations, and oxygenation.</td>

<td>Continue to assess heart rate, respirations, and oxygenation.</td>
</tr>
<tr>
<td>Oxygenation</td>
<td>Less than the normal limit following birth</td>
<td>Administer blow-by oxygen. Continue to assess heart rate, respirations, and oxygenation.</td>
</tr>
</tbody>
</table>

• **Blow-by Oxygen.** To provide blow-by oxygen, hold the tube 1 inch from the infant's nose and mouth and direct the oxygen flow, at 5 lpm or greater, across the mouth and nose (Figure 37-22). Make sure the infant is kept warm and the airway remains clear.

• **Positive Pressure Ventilation.** Clear the airway by suction. Provide ventilations by bag-valve mask at the rate of 40 to 60 per minute (EMT Skills 37-2A). You should maintain a tight face mask seal and provide the ventilations with just enough force to raise the infant's chest. Reassess after 30 seconds of ventilation. If the breathing has not improved and the heart rate is less than 100/minute, continue ventilations and reassess every 30 seconds. If ventilation is required for more than 2 minutes and the infant's stomach becomes distended and impedes ventilation, it may be necessary to insert a gastric tube to relieve the distention.

• **Chest Compressions.** If, despite adequate ventilations, the infant's heart rate drops to less than 60 beats per minute, continue ventilations and begin chest compressions. Circle the torso with your fingers and place both thumbs on the lower third of the infant's sternum. If the infant is very small, you may need to overlap the thumbs. If the infant is very large, compress the sternum with the ring and middle fingers placed one finger's depth below the nipple line. Compress the chest approximately one-third the depth of the chest at 120 compressions per minute (EMT Skills 37-2B). Deliver a 3:1 ratio of compressions to ventilations.

**Summary: Care of the Newborn**
To review emergency care for the newborn, see Figures 37-23 and 37-24.

---

**Emergency Care Protocol**

**NEWBORN INFANT**

1. If meconium is present, aggressively suction the airway until clear.
2. Dry the newborn with towels.
3. Wrap the newborn in warm towels or blankets. Be sure to cover the head and prevent hypothermia.
4. Position the newborn on his back, or in a lateral recumbent position if there is a large amount of secretions. Slightly extend the neck in a sniffing position. Place a small pad under the shoulders to maintain the airway position. Do not hyperextend or flex the neck.
5. Stimulate the newborn by rubbing his back or flicking the soles of the feet if breathing or activity is inadequate.
6. Perform an Apgar score 1 minute after birth.
7. If breathing is inadequate, perform positive pressure ventilation for 30 seconds to 1 minute. Continue PPV as necessary.
8. Assess pulse.
   - **If heart rate is greater than 100/minute,** assess color (see step 9).
   - **If heart rate is less than 100/minute but greater than 60/minute,** begin PPV at 40–60 ventilations per minute for 30 seconds to 1 minute. Then reassess heart rate. If heart rate remains less than 100/minute, continue PPV with oxygen until rate exceeds 100/minute.
   - **If heart rate drops to less than 60/minute,** perform aggressive ventilation and begin chest compressions to a depth of one-third the depth of the chest at a rate of 120/minute and a ratio of 3:1 chest compressions to ventilations.
   - If at any time heart rate drops below 60/minute, begin chest compressions and continue PPV.
9. Assess color. If the body is cyanotic but breathing is adequate and heart rate is greater than 100/minute, administer oxygen based on the SpO2 reading. If the heart rate is less than 100/minute, return to step 8.
10. Continue to reassess the airway, suctioning secretions, and reassess breathing, heart rate, and skin color. Ensure the infant is dry, wrapped, and warm.
11. Perform another Apgar score 5 minutes after birth.
12. Transport.

FIGURE 37-24 Emergency care algorithm: newborn care and resuscitation.
37-1A  Crowning. The vertex of the head is showing in the vaginal opening.

37-1B  Once the head is delivered, check if the umbilical cord is around the neck (nuchal cord). Deliver the shoulders with the next contraction.

37-1C  Once the shoulders are delivered, the entire torso is likely to be delivered quickly.

37-1D  Maintain a good grasp of the newborn and keep the baby level with the mother’s body.

37-1E  Provide newborn care. Dry and warm.

37-1F  Clamp and cut the umbilical cord.
Deliver the placenta.

Provide blow-by oxygen based on the SpO₂ reading.

**EMT SKILLS 37-2**

**Neonatal Resuscitation**

**37-2A** To provide positive pressure ventilation, use a bag-valve mask. Maintain a good mask seal. Ventilate with just enough force to raise the infant’s chest. Ventilate at a rate of 40–60 per minute for 30 seconds. Then reassess.

**37-2B** To provide chest compressions, circle the torso with the fingers and place both thumbs on the lower third of the infant’s sternum. If the infant is very small, you may need to overlap the thumbs. If the infant is very large, compress the sternum with the ring and middle fingers placed one finger’s depth below the nipple line. Compress the chest one-third the depth of the chest at the rate of 120 per minute and a ratio of 3:1 compressions to ventilations.
SUMMARY

The uterus is the primary organ of pregnancy. It is composed of smooth muscle and has the ability to stretch drastically to house the growing fetus and other fluid and tissues and also to contract forcefully to expel the fetus during labor. The uterus is a very vascular organ and will bleed heavily if ruptured or torn. There are three stages of labor: dilation, expulsion, and placental. The duration of the stages of labor varies, depending on the number of pregnancies and births of the mother.

When assessing an obstetric or gynecologic patient, in addition to the typical history questions, it is important to gather information about the menstrual cycle and prior obstetric history. This may provide some clues as to the condition the patient may be experiencing—especially whether the patient may be pregnant.

Predelivery emergencies may include spontaneous abortion, seizures, vaginal bleeding, and trauma. Supine hypotensive syndrome is a concern in any patient in her third trimester, thus it is important to transport any pregnant patient in the third trimester with her hip elevated or on her side to take the weight of the fetus off the inferior vena cava.

Delivery is best achieved in the hospital. If delivery is imminent, you may need to proceed with the delivery process in the field. Be sure to take the necessary Standard Precautions. Prepare the mother, have your obstetric kit readily available, and proceed with the delivery. Clear the airway only if necessary. Pay particular attention to drying the infant and keeping him warm. Some neonates may need stimulation, blow-by oxygen, and ventilation. Very few will need chest compressions and medications. Once the neonate is delivered, perform an Apgar score 1 minute and 5 minutes after birth.

You may encounter abnormal deliveries in the prehospital setting to include a prolapsed cord, breech birth, limb presentation, multiple births, meconium, and premature births. Be sure to understand the emergency care for each of these conditions. Other predelivery emergencies may include placenta previa, abruptio placentae, preeclampsia, eclampsia, ruptured uterus, Braxton-Hicks contractions, shoulder dystocia, and precipitous delivery.

Case Study Follow-up

Scene Size-up
You have been dispatched to the scene of a 30-year-old female experiencing active labor. She and her husband tell you that she was having contractions earlier that day, but they were short and slightly irregular, so she figured she would have time to get her laundry done before going to the hospital. Meanwhile, your partner has enlisted the help of some bystanders to bring in the stretcher and additional equipment from the ambulance.

Primary Assessment
Your general impression is that the patient, Ruth Baker, is experiencing uterine contractions and is in active labor. From the appearance of her slacks, it looks as if her water has already broken. You start to ask her questions, but every time she tries to answer you, her husband, Randy, cuts her off and finishes answering. Seeing this, your partner takes him aside and begins to question him about events prior to the emergency. This allows you to direct your attention to the patient.

You determine that she is alert and oriented with a patent airway and adequate breathing. Her pulse is strong and regular, and her skin is warm and slightly sweaty. There is no evidence of bleeding so far. At this time you apply the pulse oximeter. It provides a reading of 98%. You choose to place the patient on a nasal cannula at 4 lpm in case you have to perform a delivery.

Secondary Assessment
During your history, you learn that this is Mrs. Baker’s third child and the other pregnancies progressed without any complications. You ask her about her due date, and she tells you, “Not for 2 more weeks.” The police have arrived and, at your request, they disperse the crowd so that you can continue the assessment with some privacy. Currently, contractions are occurring every 2 minutes, with a 50-second duration.

The patient cries out, “I think the baby is coming.” You rapidly perform a visual inspection of the perineum and identify crowning, with the head bulging out further with each contraction. You also notice that the amniotic fluid appears to be clear.

At this point you advise the patient that delivery will take place here, and you ask her not to bear down until you have positioned her properly. Your partner notifies dispatch to send another unit for backup.

You move Mrs. Baker to a supine position on the floor with her hips raised off the ground with some folded sheets. You then position Mr. Baker behind his wife so that he can support her during the delivery. Once she is positioned, and your equipment is ready, you encourage her to start pushing with the next contraction.

You continually support the infant during delivery, and verbally support Mrs. Baker to help her relax as best she can. As soon as the infant’s head is born, you are very
Case Study Follow-up continued

careful to support the head. After full delivery of the infant, you clamp and cut the cord as appropriate while your partner begins to dry the infant. You dry the baby and wrap it in towels your partner has warmed in one of the laundromat dryers. Because the crying is not vigorous, you suction the nose and mouth.

Your initial Apgar score of the newborn boy is 7, and after brief stimulation, the respiratory rate increases to 46 per minute with an adequate depth. The infant starts to cry and is more vigorous in muscular activity. The pulse oximeter reads 78% 12 minutes after birth, so, you provide blow-by oxygen.

Reassessment

You place both the mother and the child in the back of your ambulance. The father sits up front. Your partner has turned up the heat to be sure your two patients are warm enough. You ask Joe Garwood, an EMT from the backup unit, to accompany you to the hospital to care for the mother while you focus your attention on the newborn. En route, the mother continues to have some minor vaginal bleeding and then delivers the placenta, which Joe places in a plastic bag for the emergency department staff. He then goes on to perform a uterine massage and bleeding soon stops.

The mother, although tired from the birthing process, is in good spirits and has no unusual complaint or distress. Her mental status is normal, vitals are stable, and she spends the rest of the trip thinking about the possible names for a boy that she and her husband have been discussing.

You repeat the Apgar score a second time and the newborn scores a 10. The baby has “pinked up” so that his color is now normal at the core and the extremities. His respirations are adequate at a rate of 48 per minute, and the heart rate is 146 and regular. The infant is actively moving around and has a good, strong cry. The SpO2 has increased to 98%. You remove the blow-by oxygen and the SpO2 is maintained. You notify the hospital of the condition of the mother and newborn and arrive 10 minutes later.

After transferring care to the emergency department staff, you complete your prehospital care report and head back to the ambulance to get it ready for the next call. On your way out of the hospital, you stop to congratulate the new father and learn from him that the newborn will be named Jacob Allen Baker.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

IN REVIEW

1. List the signs and symptoms that would indicate a predelivery emergency, and describe the general guidelines for emergency medical care.
2. Describe signs that would indicate an imminent delivery.
3. Describe how to properly position a mother in active labor and how to create a sterile field around the vaginal opening.
4. Describe the emergency medical care for a patient in active labor for a normal delivery.
5. Describe how you would recognize an abnormal delivery.
6. Describe the specific steps you would take to provide emergency medical care for (a) a prolapsed cord, (b) a breech birth or limb presentation, (c) a multiple birth, (d) meconium staining, and (e) a premature birth.
7. Describe the initial care that is required for the majority (80 percent) of newborns that do not require aggressive resuscitation.
8. Describe the indications and procedures for neonatal resuscitation.

CRITICAL THINKING

You arrive on the scene and find a 23-year-old female patient complaining of contractions. She is obviously pregnant. She states she is due in 2 weeks. She is alert but uncomfortable. Her respirations are 24 per minute. Her radial pulse is 128 per minute and her skin is warm and slightly moist. She indicates the contractions began in the middle of the night, about 6 hours ago, and have progressively worsened in intensity and increased in duration. The contractions are also more frequent. This is her first pregnancy. She has no allergies, is on a beta2 agonist metered-dose inhaler, and has a history of asthma. Her last oral intake was approximately 2 hours ago when she had two pieces of toast and some juice. She has been lying in bed because of the discomfort. She states that when she lies on her back she feels very light-headed. Her blood pressure is 108/62 mmHg and her SpO2 is 98% on room air. Upon inspection, you note the vaginal walls and perineum are bulging and the infant’s head is present at the vaginal opening. You note the sheets are soaked in fluid, and there is a light green tarry substance in the fluid.

1. What signs would lead you to believe the labor is true labor and not Braxton-Hicks?
2. Why is she experiencing light-headedness?
3. How would you proceed with the emergency care of the patient?
4. What signs are indicative of imminent delivery?
5. What is the significance of the green substance in the fluid on the sheets?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Special Patient Populations (Content Area: Pediatrics)

**COMPETENCY** • Applies fundamental knowledge of growth, development, and aging and assessment findings to provide basic emergency care and transportation for a patient with special needs.

### OBJECTIVES

**38-1.** Define key terms introduced in this chapter.
**38-2.** Explain the special considerations in dealing with the caregiver of a sick or injured child.
**38-3.** Describe the major developmental characteristics and modifications of patient assessment and management techniques recommended for patients in each of the following age groups:
   - a. Neonates
   - b. Infants
   - c. Toddlers
   - d. Preschoolers
   - e. School-age children
   - f. Adolescents

**38-4.** Describe the major anatomical and physiological differences in children with regard to the following:
   - a. Airway
   - b. Head
   - c. Chest and lungs
   - d. Respiratory system
   - e. Cardiovascular system
   - f. Abdomen
   - g. Extremities
   - h. Metabolic rate
   - i. Skin and body surface area

**38-5.** Discuss the normal vital signs for children in various age groups.
**38-6.** Use the Pediatric Assessment Triangle (PAT) to determine a pediatric patient’s status.
**38-7.** Discuss special considerations for the following elements of the pediatric secondary assessment:
   - a. Physical exam
   - b. Vital sign assessment
   - c. History taking

**38-8.** Recognize signs of respiratory distress, respiratory failure, and respiratory arrest in pediatric patients.

**38-9.** Discuss the guidelines for emergency care of the following:
   - a. Respiratory emergencies
   - b. Foreign body airway obstruction

**38-10.** Describe the presentation and emergency medical care for pediatric patients with the following conditions:
   - a. Croup
   - b. Epiglottitis
   - c. Asthma
   - d. Bronchiolitis
   - e. Pneumonia
   - f. Congenital heart disease
   - g. Shock
   - h. Cardiac arrest

**38-11.** Explain the assessment steps and emergency care protocol for a respiratory or cardiopulmonary emergency in the pediatric patient.

**38-12.** Describe the presentation and emergency medical care for pediatric patients with the following conditions:
   - a. Seizures, including status epilepticus
   - b. Altered mental status
   - c. Drowning
   - d. Fever
   - e. Meningitis
   - f. Gastrointestinal disorders
   - g. Poisoning
   - h. Apparent life-threatening emergencies (ALTE)
   - i. Sudden infant death syndrome (SIDS)

**38-13.** Describe special considerations in the scene size-up, emergency medical care, and assisting family members in case of suspected SIDS and the importance of the presence of parents during pediatric resuscitation.
38-17. Explain the importance of injury prevention programs to reduce pediatric injuries and deaths.

38-18. Discuss the purpose of the federal Emergency Medical Services for Children (EMSC) program and the concept of family-centered care.
38-19. Discuss factors that can increase EMS providers’ stress on pediatric calls and ways of managing the stress that may be associated with a pediatric call.

KEY TERMS • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- abuse p. 1078
- adolescent p. 1026
- compensated respiratory distress p. 1042
- decompensated respiratory failure p. 1042

- emotional abuse p. 1077
- fontanelle p. 1030
- infant p. 1026
- neglect p. 1077
- neonate p. 1026
- physical abuse p. 1076
- preschooler p. 1026
- respiratory arrest p. 1044
- school-age child p. 1026
- sexual abuse p. 1076
- sudden infant death syndrome (SIDS) p. 1068
- toddler p. 1026

Case Study

The Dispatch
EMS Unit 101—respond to 24313 South Avenue for an 11-month-old infant—unknown medical emergency. Time out is 1651 hours.

Upon Arrival
As you turn onto the busy street, you see a man frantically waving at you and pointing to the residence. You position your ambulance in front of the house, out of traffic flow. The man, who you assume to be the infant’s father, is almost in tears as he says to you, “Oh god—please hurry, something is wrong with Jason. I don’t think he’s breathing.” Almost simultaneously, the mother bursts out of the front door running toward you, carrying an infant in her arms. She runs to you, crying, and thrusts the infant into your arms. Every fiber in your body tightens as you realize the infant is blue, limp, and not breathing.

How would you proceed to assess and care for this patient?
During this chapter, you will learn about special assessment and emergency care considerations when dealing with pediatric patients. Later, we will return to the case and apply the procedures learned.

INTRODUCTION

Nearly 45,000 children die in the United States each year. Approximately one in four children will sustain an injury during their childhood that requires medical attention. Trauma is the leading cause of fatal injuries in children under the age of 14, particularly motor vehicle crashes, drowning, burns, poisonings, and falls. Of medical problems, respiratory problems are the most serious.

If asked, experienced EMS providers would probably concur that dealing with infants and children is one of the most (if not the most) stressful situations they encounter. This is mainly due to the relative infrequency of dealing with pediatric patients, the particularities of assessment and treatment, and having to deal with the emotions of the pediatric patient and the distressed parents as well as their own feelings. In spite of the stress of pediatric calls, however, as an EMT you must be able to keep your emotions from interfering with the task at hand: assessing and treating the young patient.

While your assessment approach to the ill or injured child will be somewhat different from your approach to an adult, the basic treatment goals are the same. Most of the emergency care will focus on managing the airway, ventilation, oxygenation, and circulation. The difference from treating adults is that, for most conditions in the pediatric patient, the time to intervention is an even more critical factor in the morbidity and mortality of the condition.

DEALING WITH CAREGIVERS

When a child is critically ill or injured, you may have more than one person to care for. The parent or other caregiver may also need attention. Some caregivers are calm, cooperative, and even helpful (especially if they
are experienced). Others may be perceived by the EMT as a hindrance. It is not uncommon for a caregiver to be upset, to cry, to blame himself, or to get mad at someone—even you. You need to listen carefully and remain nonjudgmental. While taking the history and inquiring about the circumstances of the event, let caregivers verbalize their emotions. Conclude with something brief and supportive like, “Thanks for telling me this. We’ll do the very best we can for Susie.” Remember that calm, supportive interaction with the child’s family is in the child’s best interest: calm caregivers = a calm child; agitated caregivers = an agitated child.

Emotionally distressed caregivers need to see that you are competent, calm, and confident. Do not allow yourself to display doubt or indecision, which would certainly reduce their confidence in you.

In addition to the guilt, anger, concern, and apprehension that caregivers may be feeling, be aware that caregivers may not understand emergency medical procedures. Keep the caregiver informed about what you are doing and about the condition of the child. Usually it is best to keep your language jargon free, but use your judgment. Some caregivers, especially if they are professionals or highly educated, may feel more reassured if you use technical terminology. Do not lie to the caregiver. If the child is very seriously injured, do not say “Everything will be OK.” A false reassurance like this is not only unethical, it will make matters worse when the true condition of the child is revealed.

You will probably need to question the caregivers and other witnesses to get a history of the incident. Ask the caregivers how the child normally acts and whether a particular characteristic you may discover during assessment is normal for this child. While caregivers typically don’t have medical training, they are experts on what is normal for their child; listen to what they say. If possible, enlist their help in treating the child—allowing them to hold the child, when appropriate, or assist in administering oxygen. This approach allows the caregivers to feel that they are participants in their child’s care, not just bystanders.

DEALING WITH THE CHILD

Developmental Characteristics

What you can expect from a pediatric patient depends to some degree on age. Many growth and development considerations come into play. Children can be classified in the following age groups:

- **Neonate**—a child from birth to 1 month of age
- **Infant**—a child from 1 month to 1 year of age
- **Toddler**—a child between 1 and 3 years of age
- **Preschooler**—a child between 3 and 6 years of age
- **School-age child**—a child between 6 and 12 years of age
- **Adolescent**—a child between 12 and 18 years of age

The reason for becoming familiar with this classification is simple. Each age group has specific emotional and physical characteristics that may complicate assessment and treatment. Of course the children within each age group are not all alike, but knowing the general characteristics of the group can help you to develop a strategy for assessment and care.

Be aware, however, that pain is difficult to assess in most of these age groups. Young children often lack the body awareness and vocabulary to describe the location and nature of the pain they are experiencing. Pain, especially when accompanied by bleeding, is usually so frightening that they cannot separate the emotional component from the physical. Ask the caregivers, if possible, how the child usually responds to pain to get some idea of how typical the reactions are. It is important to realize that all patients feel pain, even the neonate and young infant. Be considerate when providing emergency care to all age groups when pain is or may be involved.

**Neonates (Newborn to 1 Month of Age)**

Newborn babies are totally dependent on others for their survival. Although neonates are a subgroup of infants, the first month of life is a very different time as far as growth and development are concerned. Birth defects (or congenital anomalies) and unintentional injuries are common causes of emergencies in this age group.

**Infants (1 Month to 1 Year of Age)**

Up to 6 months, babies will usually let you undress them, lay them on a warm, flat surface, and touch them with warm hands and equipment (stethoscope, splints, and so on) (Figure 38-1). Infants can recognize their caregiver’s face and voice and are emotionally tied to that person. Older infants (>6 months) will be distressed and almost always cry if separated from their caregiver, a response commonly referred to as “stranger anxiety.” Complete your scene size-up and primary assessment as thoroughly as possible while you view the infant from across the room. Then, if possible, allow a familiar person to hold the baby while you complete your examination unless the infant is critically injured or ill. Your assessment should start with the feet or the trunk and end with the head if the infant is not critically ill or injured. Initial stimulation around the highly sensitive area of the face will frighten infants and small children and may precipitate extreme anxiety and crying.

**Toddlers (1 to 3 Years of Age)**

Toddlers may be more challenging to assess than infants and neonates. They have numerous “do not like...” considerations that will challenge your skills:

- They do not like to be touched, so limit your touch to necessary assessment and management needs.
to the chest with your stethoscope but not looking di-
rectly at or talking to the child can help. Respect their
“space” and think of your exam as an intrusion. Earn
their respect and they will engage you and even help
you; if you disrespect the child, watch out—the “terrible
twos” are called that for a reason.

Preschoolers (3 to 6 Years of Age)

Children in this age group have concrete thinking and
interpret literally what they hear. At the same time,
they have vivid imaginations and are able to drama-
tize events. They still believe that an illness or injury is
their own fault and will view it as punishment. They are
modest, resisting your attempt to unclothe them for as-
sessment. While their vocabulary is larger, they may still
confuse common words. You should explain medical
procedures slowly and in simple terms they can under-
stand: “Now I’m going to press on your tummy to see
if everything’s okay. Tell me if it hurts.” Or, “Now I’m
going to shine my light in your eyes.” Allow the child
to see your equipment in full view before you use it, if possible, and let the child touch the stethoscope or
other equipment. Put it first on the child’s leg or the
caregiver’s hand so that the preschooler can see it is not
threatening. If you use a stethoscope with a rubber ring
on the diaphragm, it will not be as cold.

Have a caregiver present, if possible. Have the care-
giver hold the child in his lap if the child is not critically
ill or injured. Otherwise, the child will almost certainly
squirm, thrash, and even try to run away. If necessary,
set a few ground rules: “It’s okay to cry. I know this
hurts. But biting and kicking are not okay.”

Children these ages are aware of death and are afraid
of pain, blood, and permanent injuries. They also fear

loss of body integrity. Be tactful and direct in dealing with physical fears. Cover bleeding injuries as soon as possible. Explain the obvious: “Your arm is hurt, but it can be fixed. We’ll take you to the hospital where they can help fix you.” Be sensitive to a child who is toilet trained and becomes overwhelmed by a bowel or bladder accident brought on by the illness or injury. Let the child hold his security object.

**School-Age Children (6 to 12 Years of Age)**

Usually children from age 6 on are more cooperative, even curious. They are able to rationalize. This age group can be the easiest to manage, because most school-age children have an understanding of what EMS is about. They understand that you are there to help them. They also have a simple understanding of their body. It is easy to engage their interest in the procedures or your equipment. They will be fascinated by the contents of each cabinet in the ambulance. However, keep in mind that an illness or injury may cause children to regress emotionally. A 6-year-old may throw a temper tantrum like a 2-year-old after an injury. On the other hand, the child may act exceptionally mature. Maturity levels are highly individualized and variable at this age.

Honesty is very important with school-age children. Treat them with respect and try to make them partners in their care. Information is reassuring to them and may need to be repeated until they understand, so explain each procedure in detail using appropriate language (Figure 38-3). Concerns about death and disability emerge at this age.

Children this age and even younger know that they need to take care of what they are wearing and sometimes get very anxious if you cut their clothes. Modesty and body image also are issues at this age. Explain gently but firmly, “I need to cut this sleeve off so that I can look at your arm.” Be aware that pain, the sight of blood, permanent injuries, and disfigurement are still real fears for them. Take advantage of their increased vocabulary skills by explaining their physical injuries.

**Adolescents (12 to 18 Years of Age)**

Adolescents use concrete thinking but are developing their abstract thinking skills. Children in this age group generally believe that nothing bad can happen to them or, in other words, that they are invincible. They may take risks that lead to trauma. However, if injured or ill, they will still fear the possibility of disability and disfigurement.

Some experts suggest using a relaxed, rather than a professional, approach when performing a history and secondary assessment—especially if the situation involves conflict with an authority figure such as a teacher, police officer, or caregiver. If the adolescent is critically ill or injured, a rapid and systematic approach to assessment and emergency care is necessary.

Asking the same questions to the adolescent when he is alone with you may generate very different answers than when he is with an authority figure. Smile, speak softly, and speak slowly. If the adolescent trusts you, he will be more likely to give you truthful information. Most adolescents, either patients or their peers, will be reluctant to disclose information about their sexual history, drug use, personal habits, and illegal activities; ask for only the information that you need, and explain why you need it. Sometimes the presence of a peer, caregiver, or close friend is both physically and emotionally reassuring. Acknowledge the patient’s friends, and allow them to help by notifying caregivers, holding equipment, and so on. You may need to explain to the patient that it is all right to react to pain, since you need to know what hurts.

Adolescents are preoccupied by their bodies and extremely concerned about modesty. An injury intensifies this preoccupation. They may ask about their greatest fears—for example, whether a facial cut will leave a scar or whether a broken leg signals the end of their basketball career. Be honest—up to a point. If available, have a same-sex provider conduct examinations of the genital area. Such exams are rarely necessary in the prehospital setting, generally required only when there is severe bleeding from the genital area. When it is necessary, if at all possible save this exam for last.

Occasionally you may encounter an adolescent who appears to be overreacting to the illness or injury. This age group is capable of hysterical reaction and may become involved in “mass hysteria.” Be tolerant of this reaction and try not to get caught up in it or become angry.

**Anatomical and Physiological Differences**

As mentioned earlier, most emergencies involving children are managed similarly to those involving adults experiencing the same emergency. However, there are certain modifications you may need to make based on the anatomical and physiological development of children. For the average, normally developing child, the
following considerations are appropriate. For an infant or child with special health care needs, the anatomical and physiological differences may be quite different from the norm and using the caretaker to help with the assessment is critical. When you are treating a child, be aware of some of the following special conditions and situations. Also be aware that the most significant of these differences typically concern the airway (Figure 38-4 ■). There are various charts that identify ranges of normal vital signs for pediatric patients. A rough estimate of a normal heart rate, respiratory rate, and systolic blood pressure is listed in Table 38-1. Pediatric blood pressures will be discussed in greater detail later in the chapter.

**Airway**

- **Infants have proportionally larger tongues** than adults as compared to the size of the mouth. You need to carefully assess the airway in a child with an altered mental status because it is easy for his airway to become occluded by his tongue. Also, the larger tongue leaves little room for airway swelling.
- **The diameter of a newborn’s trachea is only about 4 to 5 mm, or about one-third the diameter of a dime, or the size of a straw, compared to 20 mm for the adult trachea.** Injury and inflammation to the trachea (caused by inhaling steam or toxic fumes, for example) can cause life-threatening airway swelling not only faster but with less exposure to the fumes/gas/steam than in an adult.
- **The pediatric trachea is much more pliable than the adult trachea** because children’s tracheal rings are underdeveloped (with the exception of the first tracheal ring). The increased pliability of the trachea may lead to complete or partial occlusion of the airway when the neck is hyperextended or hyperflexed or when infants are working hard to breathe.
- **Pressure on the soft tissue under the chin can easily cause the tongue to be displaced back into the pharynx, leading to an airway obstruction.** Pressure on the soft tissue may occur during the chin-lift or jaw-thrust maneuver when opening or maintaining an airway.
- **Newborns and infants are obligate nose breathers.** That is, they prefer to breathe through their nose and not their mouth. They do not automatically open their mouth when secretions, blood, or other substances obstruct their nose. If the nares are obstructed or inflamed because of infection, the newborn or infant can easily develop respiratory distress.
- **The smallest area of the upper airway is at the level of the cricoid cartilage** and not at the level of the vocal cords. If the child’s head is larger in proportion to the body than an adult’s head. The temperature control mechanism is immature and unstable in babies.

![FIGURE 38-4](image)

Anatomical and physiological considerations in the infant and child.
cords as seen in the adult. This is true until about 6 years of age.

- The epiglottis is much higher in the airway than in an adult. This may lead to a higher incidence of aspiration, especially when the neck is hyperextended.

**Head**

- Children’s heads are proportionally larger than adults’. This predisposes them to head injuries when involved in falls, auto accidents, and other types of trauma. The large occiput (back) of the child’s head causes the neck to flex forward if the child is supine on a flat surface. To prevent this during immobilization, the EMT should place a small amount of padding under the shoulders to maintain neutral alignment of the airway and cervical spine (Figure 38-5 ■). Until a child’s body proportionately catches up with the head at approximately 8 or 9 years of age, padding is necessary. Adult dimensions are reached at about age 10.

- Infants younger than 6–7 months old typically cannot fully support their own heads. Always support a baby’s head when you pick him up.

- Infants have a “soft spot” on the head from incomplete closure of the skeletal plates that make up the skull. Typically, the anterior soft spot (anterior fontanelle) closes between 12 and 18 months of age. The posterior soft spot (posterior fontanelle) closes by 2 months of age. Be careful when handling an infant not to press on or poke into the fontanelle.

Assessment of the fontanelle—to determine if the fontanelle is sunken, indicating dehydration, or if the fontanelle is bulging, indicating increased pressure

within the skull—is not very accurate and may be difficult to perform in the prehospital setting. To identify a possible increase in intracranial pressure, it is much more important to recognize a decreased mental status. (It is often thought that because the skull is not completely fused together, an infant can tolerate higher intracranial pressures. However, if the swelling is acute—that is, with a rapid onset, over hours to days—the dura will not allow the swelling and will result in brain compression.) To identify possible dehydration, it is more important to recognize tachycardia and mottling as well as the caregiver reporting a decrease in tear production and urination (fewer wet diapers).

**Chest and Lungs**

- The child's ribs are much more pliable than the adult's. This means that the rib cage cannot protect the internal organs as effectively. While this flexibility decreases the likelihood of rib fractures, it increases the likelihood of internal organ damage with blunt trauma to the chest.
- The child's ribs are more horizontal than they are rounded. The horizontal nature of the ribs allows very little leverage to increase the anterior and posterior diameter of the chest. This prevents the degree of lift that is necessary for an attempt to increase the volume of air within the chest. Thus, the child must rely much more on the diaphragm to compensate for changes in demands on breathing.
- Lung tissue is much more fragile, which may lead to a higher incidence of pulmonary contusion with blunt trauma to the chest.
- The chest will move minimally with respiration in the healthy child, because of the immaturity of the ribs and flexibility of the rib cage. It is normal for the abdomen to rise with inhalation and the abdomen to fall with exhalation.
- The chest muscles are underdeveloped and used more as accessory muscles in infants and young children. This leads to early retractions in respiratory distress. Intercostal muscle retractions (between the ribs) will be seen in mild respiratory distress. Suprasternal (above the sternum), supraclavicular (above the clavicles), and sternal retractions would indicate a more severe respiratory distress.

The combination of the compliant chest wall, smaller airways, and diaphragm dependence means that infants’ lungs are prone to collapse. Since infections can cause both airway swelling and increased secretions in the airways and lungs, infants typically “grunt” to try to keep their airways and lung units open. They do this by closing off their vocal cords (“laryngeal braking”) and bearing down abdominally at the end of inspiration to try to restore or maintain a positive pressure in their lungs to prevent collapse. Try it and see how long you can do it yourself; it’s exhausting.

**Respiratory System**

- The breathing is inadequate once the respiratory rate reaches 60 breaths per minute or greater in children. If the respiratory rate begins to decrease, it may be an indication of respiratory failure. Infants may have episodes of apnea in response to stress. Parents may report that their infant stopped breathing for a short period of time and turned blue. This is a very concerning sign and should prompt a rapid transport.
- Infants and children less than 5 years of age will breathe at a rate two to three times faster than the adult patient. The breaths are also shallower than in the adult, since less volume and pressure are required to ventilate the lungs.

The muscles of the diaphragm in the infant are prone to fatigue. Since this is the primary muscle of respiration, working to breathe is very costly. The oxygen consumed by the infant who is working to breathe may not be there to supply other organ function. Typically this infant is too lethargic or tired to respond appropriately. This lack of “attitude” or normal behavior signifies a very ill infant who needs advanced care immediately.

**Cardiovascular System**

- The heart rate increases in response to fear, fever, anxiety, hypoxia, activity, and hypovolemia.
- In infants and children, bradycardia is a late response to hypoxia. In newborns, bradycardia is the initial response to hypoxia.
- Infants and children have a smaller circulating blood volume than adults because of their smaller size. This means you must stop any bleeding as quickly as possible, since what would be a comparatively small blood loss in an adult would be a major hemorrhage for a child.
- Hypotension will not usually develop in infants and children until greater than 30 percent of the blood volume has been lost. The onset of hypotension is sudden once the compensation fails.
- Infants and young children have a limited ability to increase the strength of cardiac contraction. When adults experience cardiovascular compromise, they compensate by increasing the heart rate and the strength of the cardiac contraction as well as through vasoconstriction. The infant or child does not have the ability to compensate by increasing the strength of cardiac contraction. The pediatric patient’s cardiac compensation primarily consists of changes in the heart rate and an increase in the degree of peripheral vasoconstriction—increasing systemic vascular resistance—as evidenced by mottling of the skin and cool extremities. As with the adult patient, the pediatric patient’s blood pressure is based on cardiac output and systemic vascular resistance (BP = CO × SVR).

**Abdomen**

- The child’s abdominal musculature is less well developed than the adult’s, increasing the likelihood
of internal organ damage with blunt trauma to the abdomen.

- Until the child reaches puberty, the liver and spleen are more exposed and less protected by the ribs in the abdominal cavity. This offers less protection to the organs against injury.

**Extremities**

- The bones of the extremities in a child fracture more often by bending and splintering (referred to as a greenstick fracture).
- The infant and young child’s motor development occurs from the head to the toes. The head is one of the first things the infant can control. The lack of coordination leads to frequent injury from falls.

**Metabolic Rate**

- Infants and children have a much faster metabolic rate, even at rest. The cells in their bodies use oxygen and glucose from the bloodstream two to three times faster than in adults, and periods of apnea (absence of breathing), hypoventilation (depressed breathing), or poor oxygenation can be more dangerous. Central nervous system damage can occur more quickly, with more serious injuries affecting respiratory function, resulting in poor ventilation and/or oxygenation. The higher metabolic rate and oxygen requirements explain why the pediatric patient exhibits signs and symptoms of carbon monoxide poisoning earlier than the adult patient.
- Pediatric patients are at a significant risk for the development of acute hypoglycemia because of any of these: (1) poor glucose stores, (2) inability to stimulate the release of glucose stores from an immature liver, (3) an increased metabolic rate, resulting in the utilization of large quantities of glucose, or (4) a known history of diabetes. Indications of hypoglycemia in the pediatric patient may include twitching, seizures, limpness, eye rolling, apnea, or irregular respirations. The onset of the signs and symptoms of hypoglycemia is rapid and, as a result, requires rapid intervention to prevent cerebral injury.

**Skin and Body Surface Area**

- A child’s skin surface is large compared to his body mass, making children more susceptible to hypothermia in cold environments. You should take great care in protecting the young patient from extremes in the environment.
- The skin is thinner and much more delicate than in an adult. There is much less subcutaneous tissue. Less subcutaneous tissue along with a poorly developed hypothalamus leads to temperature regulation problems and hypothermia in newborns. The lack of subcutaneous tissue also leads to a higher incidence of hypothermia in infants and young children.

---

**ASSESSMENT-BASED APPROACH TO PEDIATRIC EMERGENCIES**

**Scene Size-up**

The first component of the assessment process is the scene size-up. As with the adult patient, take the necessary Standard Precautions prior to assessment. The scene size-up can provide many clues to the nature of the emergency, the initial status of the infant or child, and obstacles that may hamper extrication to the ambulance. Determine if the pediatric patient is a medical or trauma patient, if there is only one patient, and if any additional resources are needed at the scene.

Determine if the scene is safe for you to enter. The EMT may believe that because the call involves a child there will be no threat to EMS providers (as compared to a bar fight, auto accident, or unknown medical emergency). Never get a false sense of security that the scene will be safe. The child may be a victim of violence that is ongoing or can erupt again, adults at the scene may be prone to hysterical or violent responses because of the stress of the emergency, or the child may have fallen victim to a poison or hazardous substance that can also affect EMS workers and others at the scene. Keep in mind that safety is a dynamic condition that must be constantly considered while you are at the scene.

**Primary Assessment**

The key to pediatric assessment is the quick identification and management of immediate life threats. This is even more true for pediatric than for adult patients, because children can deteriorate very quickly.

The components and flow of the primary assessment for the pediatric patient are:

- Forming a general impression using the Pediatric Assessment Triangle (PAT), developed by the American Academy of Pediatrics, or the American Heart Association’s Pediatric Advanced Life Support (PALS) initial impression assessment criteria (Figure 38-6).
- Assessing the level of consciousness (AVPU)
- Airway assessment
- Breathing assessment
- Circulatory assessment
- Priority determination

**Pediatric Assessment Triangle (PAT)**

Remember that infants and young children may not have the mental capabilities to recognize or understand why someone unknown to them (the EMT) is coming toward them intently. You may scare them to a point
where they become agitated, cry, and resist your assessment efforts. Therefore, your primary assessment should begin “at the doorway.” You should gather as much information about the young patient as possible as you observe him from across the room, while he is interacting with his caregiver and environment and has possibly not yet noticed or reacted to your presence. This assessment of the patient’s general condition, done in only a few moments as you scan the environment, should be guided by the parameters of the Pediatric Assessment Triangle.

The Pediatric Assessment Triangle (PAT), which was developed by the American Academy of Pediatrics, is integrated into the general impression portion of the primary assessment for the pediatric patient. The PAT evaluation tool is used to quickly identify a “sick” child in order to provide immediate intervention during the primary assessment. The PAT is a visual assessment that you make as you approach the child and without using any palpation or auscultation.

This tool can quickly provide valuable information about the child’s condition while exhausting little time and with minimal contact that might upset the child and alter vital signs and other critical findings. Time is critical with pediatric patients, and the PAT is effective in identifying, *at the start of the assessment process*, a child who requires immediate intervention. (Naturally, if you see signs of impending respiratory arrest or other life-threatening conditions, you will begin treatment immediately.) Further assessment will be done as you progress through the primary assessment of the airway, ventilation, oxygenation, and circulation status.

The three sides of the Pediatric Assessment Triangle (PAT) represent the three most critical parameters of the general impression:

- **Appearance**
- **Work of breathing**
- **Circulation to skin**

Review Figure 38-6, and see Table 38-2, which contrasts the PAT approach (at left) with the PALS approach (at right). The PALS approach will be discussed in the next section.
The following are characteristics to assess under each PAT category:

**Appearance**
- **Tone.** Assess for muscle tone, movement of child, resistance to examination, limpness, listlessness, and flaccidity.
- **Interactivity and irritability.** Assess for alertness; reactivity to an object, sound, or person; grasp and play with a toy or exam equipment; and disinterest in the environment and people at the scene.
- **Consolability.** Assess for the child’s ability to be consoled by the parent or primary caregiver.
- **Look or gaze.** Assess for a fix or gaze on a face, a glassy-eyed stare, or the look as if “nobody is home.”
- **Speech or cry.** Assess for the strength of crying, sound of the crying, or speech pattern and content in older children.

These characteristics to assess for on the appearance side of the triangle can be remembered by using the mnemonic TICLS (pronounced “tickles”). If the child has good muscle tone, is interacting appropriately with the environment, is not irritable, can be consoled, responds to stimuli and people, and has a normal cry, he can be assumed to have a “normal” appearance. This typically indicates an adequate airway, ventilation, oxygenation, and brain perfusion.

Irritability is typically one of the first signs of poor brain perfusion. The irritability will often lead to lethargy and then unresponsiveness. If the child is sleeping and wakes to a stimulus, becomes irritable and shakes, and reverts immediately to sleep when the stimulus is removed, you should suspect poor brain perfusion. A high-pitched cry is associated with brain injury. The glassy-eyed look is often seen in brain injury or infection.

**Work of Breathing**
- Abnormal sounds—stridor, grunting, snoring, wheezing, hoarseness
- Abnormal posture or position—sniffing, tripod position, refusal to lie down
- Retractions
- Nasal flaring
- Head bobbing

Listen for abnormal airway sounds without a stethoscope and from a distance. Once the child begins to cry, the assessment of breathing becomes more difficult. Grunting typically indicates collapsing bronchioles or fluid-filled alveoli. Stridor is indicative of upper airway edema or partial obstruction. Muffled speech or hoarseness also typically indicates swelling to the laryngeal tissue. Listen to determine if wheezing is occurring in both the inspiratory and expiratory phases of breathing. In an airway obstruction the child typically assume a sniffing position. The tripod position is assumed by the child in order to fully use the accessory muscles in respiratory distress or failure. Retractions indicate accessory muscle use and an increase in the work of breathing. Remember, abdominal breathing in young infants is typically normal; however, seesaw breathing (in which extreme respiratory effort draws the chest inward and forces the abdomen outward) is always abnormal. Nasal flaring with head bobbing indicates a significant increase in work of breathing. Rapid breathing with no increase in work of breathing may be an indication of compensatory or decompensatory shock. Irregular respirations are often associated with an increase in intracranial pressure.

When the child transitions from respiratory distress to respiratory failure, you might find that the work of breathing and the respiratory rate both decrease. If the decrease in work of breathing and respiratory rate is due to effective emergency care, you would expect to see an improvement in the appearance side of the triangle. However, if the decrease in work of breathing and respiratory rate is due to exhaustion and respiratory failure, you would expect to see a deterioration in the appearance side of the triangle.

**Circulation to Skin**
- **Pallor—**Assess skin and mucous membranes
- **Mottling**
- **Cyanosis**
- **Petechiae—**Assess for small pinpoint hemorrhages to the skin

Assess the skin visually. Pale skin with tachycardia indicates compensated shock. As the perfusion further deteriorates (shock develops), the skin will become mottled, which is an ominous sign. Cyanosis usually indicates respiratory failure or decompensated shock. Cyanosis may be seen in children with congenital heart defects and chronic cardiac or pulmonary disease.

**Pediatric Assessment Triangle Application and Interpretation.** Use the PAT—your observations of the overall appearance, work of breathing, and circulation to skin—to form a general impression as to whether this is a “well” versus a “sick” child. Does the patient:

- Display normal behavior for his age (as discussed earlier)?
- Move about spontaneously? (or) seem lethargic?
- Appear attentive and recognize the parents or caregivers?
• Maintain any eye contact (appropriate for the patient’s age)?
• Seem easily consoled by the parents or caregiver? (or) seem inconsolable?
• Respond to the parent or caregiver calling him? (or) respond inappropriately? (or) not respond at all?

A relatively “well” baby will be interactive with both the caregiver and the environment, be actively moving, have good color, and have a good, strong cry. Although noisy and upsetting at times, a crying baby is (at least) a breathing baby. A “sick” baby at first sight will be limp or flaccid, have a weak or absent cry, not interact with the environment or parents, possibly have poor skin color, and not seem to notice your approach.

The following conditions will present with these normal and abnormal PAT findings:

• **Respiratory distress.** Normal appearance, abnormal work of breathing, and normal circulation to skin
• **Respiratory failure.** Abnormal appearance, abnormal work of breathing, and normal or abnormal circulation to skin
• **Compensated shock.** Normal appearance, normal work of breathing, and abnormal circulation to skin
• **Decompensated shock.** Abnormal appearance, normal to abnormal work of breathing, and abnormal circulation to skin
• **Poor brain perfusion or brain injury.** Abnormal appearance, abnormal work of breathing, and abnormal circulation to skin
• **Cardiopulmonary failure.** Abnormal appearance, abnormal to absent work of breathing, and abnormal circulation to skin

---

**Pediatric Advanced Life Support (PALS) Initial Impression**

An alternative to using the PAT to form a general impression is the PALS initial impression (review Figure 38-6 and Table 38-2). It can be used to establish the general impression from the “doorway” as you approach the pediatric patient. The assessment criteria are very similar to the PAT and collect similar information. To perform an initial impression using the PALS criteria, you would assess:

- **Consciousness**—What is the level of consciousness? Unresponsive? Irritable? Alert?
- **Breathing**—What is the work of breathing? Absent? Decreased? Abnormal sounds? Use of accessory muscles? Abnormal breathing pattern?
- **Color**—What is the skin color? Cyanotic? Pale? Flushed? Mottled?

If the breathing is adequate during the initial impression, proceed to the primary assessment. If the patient is unresponsive and breathing is absent or gasping, begin positive pressure ventilation at 12 to 20/minute and assess the pulse. If the pulse is present, continue with ventilation and proceed with your assessment. If no pulse is present, immediately begin chest compressions and proceed with your cardiac arrest protocol. If a pulse is present, but signs of poor perfusion are present and the heart rate remains less than 60/minute despite adequate oxygenation and ventilation, begin chest compressions and proceed to your pediatric cardiac arrest protocol. If a pulse is present, and the heart rate is greater than 60/minute, continue to the primary assessment.

After forming the general impression using the PAT or PALS system, proceed with the remainder of the primary assessment by assessing level of consciousness, airway, breathing, and circulation.

---

### Assessing the Level of Consciousness (AVPU)

Following the general impression using the PAT, you must assess the child's level of consciousness (EMT Skills 38-1A). The simplest method for determining the level of consciousness in a pediatric patient is the AVPU scale (Table 38-3). It is a variation of the adult AVPU scale.

#### Airway Assessment

The number one cause of death in children is hypoxia. One cause of hypoxia is an obstructed airway. When opening and assessing the airway, keep the pediatric anatomical and physiological differences in mind (EMT Skills 38-1B).

#### Breathing Assessment

In adults, we often evaluate respiratory rates for 15 seconds and multiply those rates by 4. However, normal respirations in an infant can be irregular. The variability of respiration rates in infants may not produce an accurate rate when only observed for 15 seconds. For this reason, respiratory rates should be assessed over a minimum of 30 seconds but ideally over 60 seconds.

It is also important to note that the normal variable rate of respiration in infants may include cessation
in breathing for up to a maximum of 20 seconds. Any cessation in breathing for greater than 10 seconds, however, should be considered abnormal and require intervention. True apnea is defined as cessation of breathing for 15 seconds or longer, but many pediatric experts will not wait for that duration to diagnose respiratory failure in the very young infant. 

As with the adult, tidal volume must also be assessed to determine if the breathing is adequate. Inspect for chest rise and listen for air movement. If the respiratory rate or tidal volume is inadequate, begin positive pressure ventilation with supplemental oxygen connected to the ventilation device.

During your primary assessment, you should be acutely aware of alterations in the respiratory effort (EMT Skills 38-1C). Respiration can be counted by watching the chest rise and fall or by placing your hand on the patient’s abdomen. Adequate breathing can be assessed by watching for rise and fall of the chest at the child’s clavicles. Assess the abdomen for rise and fall, since young children use the abdominal muscles to breathe. Because the clavicles are the highest point of the chest (and the last to fill with air), movement there signifies good expansion of the lung.

Because of the importance of the respiratory system in successful management of the infant or child, be alert for the following as clues to the infant or child’s airway and respiratory status: rapid breathing, noisy breathing, and diminished breathing.

- **Rapid breathing.** As a general rule, children breathe faster than adults. The key to recognizing rapid breathing is to be familiar with normal ranges of respirations (25–30 per minute in an infant; 15–30 per minute in a child) and to repeat assessment of respiratory rate frequently, each time counting the rate over a complete minute. In cases of rapid breathing (tachypnea) look for breathing through the mouth, flaring of the nostrils, retractions, and/or the use of accessory muscles. Also check for cyanosis around the mouth and changes in mental status. Possible causes of rapid breathing are:
  - Oxygen deficiency (hypoxia)
  - Head injury
  - Lung infection
  - Fever, which raises the metabolic rate, increasing the need for oxygen
  - Diabetes, when glucose levels get very high
  - Aspirin overdoses and other forms of poisoning
  - Stress, pain, or fear
  - Shock

- **Noisy breathing.** Children may breathe more loudly than adults through the nose and, occasionally, through the mouth because of anatomical differences. Check with a caregiver if you hear an unusual sound to determine whether it is normal. When assessing breath sounds with a stethoscope, listen along both midaxillary lines (below the armpits).

This is necessary since breath sounds typically transmit easily from one side of the child’s small chest to the other. Listening midaxillary or down the back will reduce the amount of sound you are hearing that is transmitted from the opposite side. The following is a checklist of sounds characteristically produced by certain problems:

- **Coughing, gagging, or gasping** will be violent when the child breathes in a foreign body or body secretions, creating a partial blockage of the airway. (If blockage is complete, however, there will be no cough or gasp.)
- **Crackles** (sometimes called rales), sounds that resemble the noise of rolling a few strands of hair near the ear, are commonly heard on listening to chest sounds when certain respiratory diseases have caused fluid to accumulate in and around the alveoli.
- **Wheezing** is caused by air moving at a high rate through narrowed bronchioles during exhalation, is more “musical” than crackles, and may sometimes be a whistle. Wheezing sounds are caused by medical emergencies that cause narrowing of the lower airway (or bronchospasm) and can also be caused by aspiration of blood, vomitus, or foreign objects. Wheezing is usually only heard on exhalation.

**ASSESSMENT TIPS**

If wheezing in a sick child diminishes without any medication administration, this should concern you. It often implies that the child, instead of getting better, has actually worsened and is no longer moving enough air to create the wheezing sound.

- **Stridor** (as discussed earlier) is a harsh, high-pitched sound that occurs typically during inspiration. It results from severe obstruction in the upper airway, as in the case of swelling to the larynx. Because stridor occurs only with upper airway problems, if it is absent, the cause is more likely to be an emergency involving the lower portions of the airway.
- **Diminished breathing.** When something (blood, fluid, or air) prevents the lungs from inflating, there is a loss of breath sounds. The causes of diminished breathing can include obstruction, medical problems, or traumatic injuries like a pneumothorax (air in the chest cavity, collapsing one or both lungs). Consider providing positive pressure ventilation to the infant or child if breath sounds are not obvious.

**Circulatory Assessment**

Like pediatric respiratory rates, pediatric heart rates are variable. Pulse points are the same in children as they are in adults, but there are some differences in the way
these pulses are evaluated. In small children, it is recommended that peripheral pulses be obtained at the brachial artery (inside of the bicep) (EMT Skills 38-1D). Central pulses may be obtained at either the carotid or the femoral artery (EMT Skills 38-1E). In the older child, check the radial pulse (EMT Skills 38-1F). Compare the strength of the central (carotid or femoral) pulse to the strength of the peripheral pulse (EMT Skills 38-1G). If no pulses can be palpated, the EMS provider should consider auscultating the heart with a stethoscope. If a heartbeat can be heard, the child likely has a pulse, but the presence of a pulse does not mean that there is adequate perfusion.

Capillary refill time is typically quite an accurate measurement in children and is considered to be reliable in most cases. Healthy children do not have the vascular disease that many adults do, so the child’s capillary blood flow is very responsive. However, just as in the adult patient, environmental factors such as cold ambient temperatures can influence pediatric capillary refill times. For this reason, capillary refill time should be assessed closer to the core in areas like the kneecap or forearm (EMT Skills 38-2A and B). Normal capillary refill time is under 1–2 seconds. You must evaluate the pulses, skin, blood pressure, urine output, and mental status to determine if hypoperfusion and shock exist. Capillary refill alone cannot provide conclusive evidence of hypoperfusion and shock, but it is one of the best measures we have available.

Other circulation assessment parameters include the following:

- **Pulse rate and strength**—Infants and children maintain cardiac output by adjusting the heart rate. Although there can be many reasons for tachycardia in the child (e.g., fever, pain, hypoxia, anxiety), you cannot exclude a compensated shock state and must assume there is potential for decompensation when tachycardia is present.

- **Strength of peripheral versus central pulses**—Weak or absent peripheral pulses typically indicate poor perfusion status, a decrease in cardiac output, and shock.

**ASSESSMENT TIPS**

- Warmth and color of the hands and feet.
- Urinary output—A sign of the adequacy of kidney perfusion (ask if there have been more or fewer diaper changes than normal).
- Mental status—Poor mental status may indicate poor cerebral perfusion and may be another indication of shock.

**Priority Determination**

From the information you have gathered thus far, you need to make a determination based on your scene size-up and primary assessment, including your general impression using the Pediatric Assessment Triangle, whether the patient should be a priority for immediate transport. *Any patient with signs and symptoms of early respiratory distress, decompensated respiratory failure, respiratory arrest, or poor perfusion should be considered a priority patient.*

**Secondary Assessment**

For the secondary assessment, follow the guidelines from the earlier section “Dealing with the Child” as well as the tips for examining infants and children listed in Table 38-4, adapting them to the patient’s age and condition. If it is a medical emergency, gather the history first, then perform the physical exam including baseline vital signs. If it is a trauma emergency, perform the physical exam and gather vital signs before obtaining the history. If two EMTs are working together, some of these steps can be performed simultaneously.

Complete the history, using the OPQRST mnemonic if pain is identified during your assessment. If the developmental age of the patient allows, the EMT should gather this history from the patient and confirm it with the bystanders or caretaker; if not, question the family or bystanders. While gathering the history, find out if any care or treatment has been rendered already and, if so, whether it was effective. Remember to ask if all shots and immunizations are up to date.

When performing the physical exam on an infant or young child, you should follow a toe-to-head or trunk-to-head approach. This means you will assess the extremities and core of the patient’s body prior to the head. Although this is age- and situation-dependent, it allows you to gather the most physical exam information while, at the same time, increasing the infant’s or child’s anxiety level as little as possible. If the child is older or is unresponsive, you can follow the traditional head-to-toe assessment format performed in the adult patient to identify any life threats as early as possible (EMT Skills 38-3A to 38-3M). If this is a medical problem and the patient is responsive, you may perform a focused medical assessment, concentrating on the areas related to the problem. If trauma is suspected or the patient is unresponsive or unable to communicate clearly, perform a complete rapid secondary assessment. Since injuries present the same in adults and children, you will be looking for the same indicators of injury. Assess each anatomical area and body system.

**Special Considerations for the Physical Exam**

The same anatomical regions and body systems are assessed in the secondary assessment of the pediatric
patient as in the adult. However, the steps may be altered, depending on the age of the child and his condition. Some of these accommodations were previously mentioned, such as doing a toe-to-head assessment on the pediatric patient. Other special pediatric considerations are discussed in the next sections.

**Pediatric Glasgow Coma Scale (PGCS)**

The standard Glasgow Coma Scale (GCS), used to determine and quantify the level of consciousness in adults, must be modified for the noncommunicative child. For this purpose, the Pediatric Glasgow Coma Scale (PGCS) has been developed (see Table 38-5).

**Assessing Lung Sounds**

One of the most common techniques for assessing the lungs is auscultation. Auscultating lung sounds in a child should ideally be conducted in a relatively quiet environment and should take into consideration that the child has a small and thin chest wall. Lung sounds should be auscultated in the midaxillary region (below the armpits) to ensure that referred breath sounds are not heard. Referred breath sounds are sounds that can be transmitted from one side of the chest to another. Hearing referred breath sounds in children is possible because the child’s thin chest wall is capable of transmitting sounds easily.

**Pulse Oximetry**

The use of pulse oximetry in children is highly recommended and often very reliable. Just as with vital signs, pulse oximetry readings can be monitored over time to detect worsening or improvement of the patient’s condition after interventions. Be cautious about using pulse oximetry for anything other than noting trends in the patient’s condition. Rely on the entire patient presentation and not just a single SpO2 reading when doing your assessment.

According to the AHA 2010 Guidelines, a pulse oximetry reading of greater than 94% is generally adequate. If a child cannot maintain a saturation above 94% on room air, the child will require supplemental oxygen. If the child’s saturation remains below 94% on a nonrebreather mask, this is an indication that the child is experiencing consistent hypoxia and probably a ventilation or oxygenation compromise. If the child were removed from the nonrebreather mask, it is likely that the SpO2 reading would deteriorate further. Closely and continuously assess the child’s mental status as well as the respiratory effort, rate, and depth.
If the child deteriorates to respiratory failure, immediately begin positive pressure ventilation with supplemental oxygen connected to the ventilation device. A child may still be sick despite an adequate pulse oximetry reading. Treat the patient, not the SpO₂ reading, especially in children with congenital heart problems. If the child looks sick, he likely is sick and requires intervention. Pulse oximetry has limitations. As a result of shock or hypothermia, peripheral perfusion may be diminished, resulting in low or absent saturation readings. Movement, a constant issue with children, ambient light, and nail polish can also lead to poor readings.

**Other Physical Exam Considerations**

Other special considerations for the physical exam include the following:

- Infants and many children are unable to cough “productively,” especially when they are quite sick or tired from an increased work of breathing.
- Look at the interest of the child in the situation to determine the mental status and level of orientation. The greater the interest, the better the mental status. When an infant is very irritable and cannot be comforted by the parent or caregiver, it may be an indication of an altered mental status. Rely on the parent or caregiver to provide information about the child’s normal alertness and activity level.
- Hoarseness can indicate a partial upper airway obstruction. Moaning may indicate shock or a decreased mental status. An increase in intracranial pressure may produce a high-pitched cry in the infant.
- An anxious child with nasal flaring who is very focused on his breathing is probably in respiratory distress.
- Grunting may indicate severe respiratory distress. By grunting, the infant or child prematurely closes the epiglottis over the glottic opening. This traps air inside the terminal bronchioles and alveoli, not allowing the structures to collapse. If the airways did collapse after each exhalation, the next inhalation—which must move air through the bronchioles and into the alveoli—would require much more effort and the infant or child would fatigue rapidly from the increased work of breathing. Thus grunting is an attempt to keep the airway structures open and make the next breath the infant or child takes less work. Grunting is typically seen with labored breathing. A child in respiratory distress who is no longer grunting

is in impending respiratory failure and must be transported immediately.

- Obtain the respiratory rate prior to examining the child, since your touching the child will cause anxiety and an increase in the respiratory rate.
- The heart rate normally increases when the child takes a breath and decreases with exhalation.
- The blood pressure cuff must cover at least two-thirds the circumference of the arm and two-thirds the width (length of the bone). The blood pressure can be taken at the upper arm, lower arm, or thigh. Use the blood pressure cuff where it fits. In children less than 3 years of age, the blood pressure is difficult to assess and is often not accurate. Rely on the quality and rate of the pulses, comparison of the strength of the central and peripheral pulses, and skin temperature, color, and condition as well as mental status and capillary refill to assess cardiovascular status in children less than 3 years of age.
- To estimate the normal systolic blood pressure in a child who is 1 to 10 years of age, take 80 + (2 × age in years) for the median average systolic blood pressure limit. The diastolic pressure should be approximately two-thirds of the systolic pressure.
- Hypotension (low blood pressure) indicating shock would be a systolic blood pressure less than 60 mmHg in a newborn (neonate 0–28 days), less than 70 mmHg in an infant (1–12 months), less than 70 + (2 × age in years) in a 1- to 10-year-old child, and less than 90 mmHg in a child older than 10 years.
- To estimate the upper limit of a normal systolic blood pressure for a child between 1 and 10 years of age, you would take 90 + (2 × years in age). See Table 38-6.
- Children 3 years of age and older will obey your commands to move fingers, squeeze fingers, wiggle toes, or push up against your hands when you are doing the neurological exam. It is easiest to make the assessment into a game to gain the most cooperation from the child.

If the child is not cooperating and is crying, look at the quality (strong and full or weak and shallow) of the cry; inspect for the presence of tears in the eyes (no tears may indicate severe dehydration); assess the color, temperature, and condition of the skin; auscultate the breath sounds in between the cries when the child gasps for a breath; and inspect the face for symmetry (equality on both sides).

### Special Considerations for Assisting the Vital Signs

As you go on to assess the baseline vital signs in infants and children, you should be aware that, outside of heart and respiratory rates, vital signs play only a limited role in your determination of the patient’s overall status. Instead, pay more attention to the general impression you developed of the child’s appearance of “sickness” or “wellness.” Infants and children have excellent compensatory mechanisms that delay deterioration. It is only after the exhaustion of these mechanisms that you may see indicative changes in the vital signs. By then, the changes may occur very quickly, and the child’s condition typically deteriorates rapidly. Here are some special considerations for assessing the vitals:

- **Respirations.** Obtain the respiratory rate at regular intervals, based on techniques and normal ranges discussed earlier.
- **Pulse.** It is very difficult to feel a carotid pulse in infants and toddlers. To assess circulation, use the radial pulse in a child and the brachial pulse in an infant. (Review EMT Skills 38-1D.) Still another alternative is the femoral pulse near the crease between the pelvis and thigh in an infant. (Review EMT Skills 38-1E.) Another means of assessing heart rate is by auscultation of the apical pulse (at the apex of the heart). To locate it, place your hand over the fourth or fifth intercostal space on the left midclavicular line. Place your stethoscope here and count each “lub-dub” as one beat. This method will provide you with a heart rate, but it is not a measure of perfusion.

To evaluate circulation status you will want to compare central or core pulses with peripheral pulses. The farther away from the heart the peripheral pulse can be detected, the better the perfusion status. Another technique is to manually compare core and peripheral skin temperatures at the time of the pulse check. As overall perfusion decreases, the peripheral extremities will be significantly cooler than the central areas.

- **Skin.** Check skin color (e.g., pink, blue, flushed, yellow), relative temperature (the back of your hand

on the patient’s forehead or abdomen), and condition (dry or sweaty). Capillary refill can also be assessed.

- **Pupils.** Check for size, equality, and reactivity of pupils by shining your penlight into the eyes, especially if trauma is suspected or the patient is unresponsive. Note the extraocular movements of the eyes; they should be symmetric and smooth.

- **Blood Pressure.** Do not attempt to take the blood pressure of a child under the age of 3 years. Instead, rely on other indicators of perfusion discussed earlier. In children over age 3, be sure that you check the blood pressure with a correct-size cuff; it should cover about two-thirds of the upper arm. Do not take a blood pressure if the appropriate equipment is not available.

### Special Considerations for Taking a History

History taking requires a different approach in the child than in the adult. Some valuable information may be learned from the child who provides his own history information. Additional valuable information may be gained by watching the child’s reactions and activities. A history should be sought from the parent or primary caregiver until the child reaches 4 years of age. At this point, the child should be able to provide the history information relevant to the complaint or injury (Figure 38-7 ■). The following are special considerations when obtaining a history in a child:

- Children usually seek out the parent or caregiver for reassurance. If the child has a normal mental status but appears to not seek out the parents or caregiver when injured, consider the possibility of child abuse.
- If no life threats are present, try to gain the child’s trust by allowing the child to become more familiar with you. You may use a teddy bear or doll to gain the child’s trust. If the child has critical injuries or is seriously ill, however, do not waste time trying to gain trust.
- Use a reassuring and calm voice when speaking to the child. Include the child in the conversation with the parent or caregiver, especially if the child is 4 years of age or older.
- Get down to the eye level of the child. This will reduce the “authoritarian” posture you may present when you are so much bigger than the child and make the child more comfortable and willing to provide information. Smile frequently and do not stare. Staring will threaten the child.
- Avoid rapid-fire “yes” and “no” questions. Ask the following types of open-ended questions: What happened? Are you feeling any pain? What does the pain feel like?
- Avoid certain words that increase the anxiety of the child such as **cut** (cutting implies pain, as in cutting off an arm); **take** (implies that you are taking something away, as in taking a blood pressure; say “measure” instead of “take”); or **bleeding** (children think that they will lose all of their blood).
- Keep the child with the parent during the assessment, if at all possible. This will typically reduce apprehension and may prevent the child from crying during the exam.
- Perform the secondary assessment from the feet to the head. Usually, once you start assessing the head and face the child becomes frightened and cries.
- Do not explain things too far in advance. This will cause confusion and will not be understood by the child. Explain things one step at a time.
- Let the child handle the stethoscope, penlight, blood pressure cuff, or other equipment before you use it. This will reduce the child’s fear and anxiety of what the device is used for and if it will hurt.

### Reassessment

The reassessment must be performed on all patients to continuously monitor for changes in mental status, airway, breathing, and circulation status (watch any patient with respiratory distress for the development of respiratory failure; remember that compensatory mechanisms fail rapidly and without warning). Also assess and record the vital signs and check interventions. Repeat the reassessment at least every 3–5 minutes or as frequently as possible for the pediatric patient with any airway or cardiopulmonary compromise. Communicate your findings and treatment to the receiving medical facility.

### AIRWAY AND RESPIRATORY PROBLEMS IN PEDIATRIC PATIENTS

If anything should be emphasized when dealing with the assessment and treatment of infants or children, it is the assessment, establishment, and maintenance of...
the airway and respiratory function. The primary goal in treating any infant or child patient is the anticipation and recognition of respiratory problems, and to support any function that is compromised or lost. Failure to properly assess, establish, and maintain the airway, ventilatory, or oxygenation status will defeat any other or subsequent treatment, without exception! Make no mistakes regarding this aspect of prehospital care.

The respiratory system is responsible for providing the body with fresh oxygen for the blood as well as removing carbon dioxide and other wastes. Unfortunately, failure of this system is relatively common in pediatric patients. Failure of respiratory function can rapidly lead to cardiac arrest. In fact, while cardiovascular disease is the leading medical cause of cardiac arrest in the adult, the leading medical cause of cardiac arrest in the infant or child patient is failure of the respiratory system.

Compensatory mechanisms, which attempt to maintain normal physiological functioning, often run at maximum in infants and children until total exhaustion occurs, leading to rapid respiratory deterioration and cardiac arrest. Even when the primary assessment of the respiratory status appears normal, you should maintain a high index of suspicion regarding the patency of the airway and adequacy of respiratory function. Even if it seems obvious that the patient is suffering from some other form of life threat (e.g., severe hemorrhage, head injury), do not drop your guard concerning proper airway management and oxygenation.

Determining the origin of the respiratory dysfunction may not be possible in the prehospital setting, but such a determination is not necessary to initiate appropriate treatment. Focus your attention on the presenting signs and symptoms of respiratory dysfunction (the indications that there is respiratory dysfunction, without regard to what may have caused it) and provide emergency care.

It is important to recognize the difference between upper airway obstruction (from a foreign body) and obstruction caused by a respiratory infection. The methods for removing a foreign body from a pediatric patient’s airway could be deadly if applied to a patient with a condition such as epiglottitis. Any attempt to put an object, such as your fingers or suction equipment, into the throat of a child with epiglottitis can cause fatal swelling or spasm. As a result of national immunization programs, the incidence of epiglottitis is now relatively low, but the fact remains that many conditions affect children differently from the way they affect adults—and the child’s inability to compensate is directly related to his anatomical and physiological immaturity.

**Early Respiratory Distress**

If the infant or child displays the signs in the following list, but still maintains an adequate respiratory depth and rate, the patient is said to be in **early respiratory distress**, otherwise known as **compensated respiratory distress** (Figure 38-8 ■). The patient in early respiratory distress is still in serious trouble. The patient can progress from early (compensated) respiratory distress to decompensated respiratory failure and respiratory arrest in minutes. As the name implies, the infant or child is in distress but is able to compensate and his breathing has not yet failed. His respiratory rate and tidal volume are still adequate to meet his requirements. Therefore, the patient could be placed on a high concentration of oxygen, but assisted ventilations are not necessary because the breathing rate and tidal volume remain adequate. The following are signs of early respiratory distress (Figure 38-9 ■):

- An increase in respiratory rate above the normal rate for the child’s age
- Nasal flaring
- Intercostal retractions on inspiration (retractions of the tissues and muscle between the ribs)
- Supraclavicular and subcostal retractions on inspiration (retractions of the tissues above the clavicles and beneath the margin of the ribs)
- Neck muscle use
- Audible breathing noises such as stridor, wheezing, or grunting
- Seesaw respirations
- An alert or easily arousable child demonstrating behavior that reflects some energy reserve, or “attitude”

If these signs are present, provide oxygen (by methods that will be described in the “Emergency Care” sections of this chapter) and prompt transport to the hospital (Figure 38-10 ■). If at any time the respiratory rate or the tidal volume becomes inadequate, the patient has progressed from compensated respiratory distress to decompensated respiratory failure. This patient requires immediate ventilation with a bag-valve-mask device or other acceptable ventilation device and supplemental oxygen as tolerated.

** Decompensated Respiratory Failure**

The EMT may also encounter an infant or child in **decompensated respiratory failure** (Figure 38-11 ■). As the name implies, the infant or child is failing to compensate for the impaired respiratory condition and is unable to maintain adequate breathing. Either the respiratory rate or the tidal volume is inadequate and the infant or child requires immediate intervention, which may include suctioning the upper airway, repositioning, high-concentration oxygen, delivery of nebulized therapies, or even ventilation with a bag-valve-mask or other ventilation device. Supplemental oxygen must be delivered via the ventilation device. Decompensated respiratory failure is characterized by
SIGNS OF EARLY RESPIRATORY DISTRESS

Flared nostrils
Neck muscle retractions
Supraventricular retractions
Intercostal retractions
"Seesaw" respirations

Stridor
Grunting
Audible wheezing
Subcostal retractions
Suprasternal retractions

If signs of early respiratory distress are present, provide oxygen and prompt transport to the hospital.

FIGURE 38-9 Signs of early respiratory distress.

FIGURE 38-10 If signs of early respiratory distress are present, provide oxygen and prompt transport to the hospital.
the signs of early respiratory distress (compensated respiratory failure) that were previously listed, plus any of the following:

- Respiratory rate over 60 per minute
- Cyanosis (blue color)
- Decreased muscle tone
- Severe use of accessory muscles to aid in respirations
- Poor peripheral perfusion
- Altered mental status (in relation to the patient’s developmental stage)
- Grunting (may also be present in early respiratory distress)
- Head bobbing

If these signs are present, provide positive pressure ventilation with a bag-valve-mask device or other acceptable ventilation device and supplemental oxygen and immediately transport to the hospital.

**Respiratory Arrest**

Respiratory arrest (Figure 38-12) occurs when the compensatory mechanisms designed to maintain oxygenation of the blood have failed. Indications of respiratory arrest include the following:

- Respiratory rate less than 10 per minute (or absent breathing)
- Irregular or gasping respirations
- Limp muscle tone
- Unresponsiveness
- Slower than normal or absent heart rate
- Weak or absent peripheral pulses
- Hypotension (low blood pressure) in patients over 3 years of age

Remember, cardiopulmonary arrest in children is usually preceded by the progressive failure of the respiratory system. If any of the conditions listed here are present, the patient should be treated aggressively with oxygenation and positive pressure ventilation, and transported immediately to the hospital.

**Airway Obstruction**

The patient may also present with some type of airway obstruction, since children often place things in their mouths.
If the patient displays the signs just listed and still maintains an adequate respiratory volume, general treatment principles include allowing the patient to assume a position of comfort (except do not lay the patient down). Enlist the help of the parents or caregivers while you administer oxygen. Encourage the patient to cough if a tangible obstruction is present. Limit your exam so as not to further agitate the patient, and transport immediately.

Indications of a complete airway obstruction include:

- No crying or talking
- Ineffective or absent cough
- Altered mental status, including possible loss of responsiveness
- Cyanosis probable

**ASSESSMENT TIPS**

If a child becomes cyanotic, he has experienced profound hypoxia and is in significant trouble.

If the patient is displaying the signs just listed and is not maintaining an adequate respiratory volume, and if there are no indications of a medical condition that might be causing the obstruction, general treatment procedures include:

- No crying or talking
- Ineffective or absent cough
- Altered mental status, including possible loss of responsiveness
- Cyanosis probable

**ASSESSMENT TIPS**

If a child becomes cyanotic, he has experienced profound hypoxia and is in significant trouble.
should be based on foreign body airway obstruction procedures for an infant or child. These will be discussed later under “Emergency Medical Care—Foreign Body Airway Obstruction.” Treatment for specific medical conditions, some of which may cause airway obstruction, will be discussed in the next sections.

Signs and Symptoms

Signs and symptoms of a respiratory emergency require your immediate intervention, whether or not you know the exact cause of the condition. The next two sections discuss emergency medical care for respiratory emergencies in general and emergency medical care for foreign body airway obstruction.

Emergency Medical Care—Respiratory Emergencies

When any of the signs of a respiratory emergency are present, provide care as described next. For more detail on these techniques, including adaptations for infants and children, review Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

1. Establish and maintain a patent airway. If no cervical spine injury is suspected, perform the head-tilt, chin-lift maneuver, but with caution. Since the infant’s airway is much smaller and more flexible, excessive hyperextension of the head can result in the airway “kinking” (like a garden hose), actually resulting in airway occlusion. Extend the head only enough to ensure a patent airway; once that point is reached, stop (Figure 38-13). When performing a chin lift, little or no pressure should be applied to the soft tissue under the chin, which will occlude, rather than open, the airway. In pediatric patients with possible spine injury, you should perform a manual jaw-thrust technique to help establish the airway (Figure 38-14).

2. Suction any secretions, vomitus, or blood. The suctioning process temporarily prevents air from being breathed into the lungs. When suctioning an infant or child, do not suction any longer than 3 to 5 seconds at a time, so as not to promote hypoxia. Use appropriately sized equipment (Figure 38-15). Be careful not to damage tissues while inserting and moving the suctioning device in the mouth. If the patient is responsive and has a gag reflex, be careful not to suction deeply enough to cause the patient to vomit.

3. If you need to assist ventilations, maintain a patent airway with an oropharyngeal or nasopharyngeal airway. Use an oropharyngeal airway (EMT Skills 38-4A to 38-4D) if the child is unresponsive and there is no gag reflex. Use a nasopharyngeal airway (EMT Skills 38-5A to 38-5C) if the patient cannot tolerate an oral airway. However, nasopharyngeal airways should be avoided in patients with possible head trauma. Since children are prone to having adenoidal...
hypertrophy, nasopharyngeal airways can “core out” adenoidal tissue resulting in significant upper airway bleeding that is very difficult to control. In general, nasopharyngeal airways should be avoided in children and especially in infants whose nares are so small in diameter that the airway resistance created by the very small diameter of the nasopharyngeal airway is too great to make breathing through it effective.

4. **Initiate positive pressure ventilation.** If the infant or child is in decompensated respiratory failure or respiratory arrest—that is, with inadequate breathing or not breathing—you should start positive pressure ventilation using a bag-valve-mask device or a pocket mask. Supplemental oxygen must be attached to the ventilation device as soon as possible.

When using a mouth-to-mask device, use a one-way valve to prevent disease transmission. If using a bag-valve-mask device, be sure to use an appropriately-sized bag. Infants and children need a respiratory tidal volume of approximately 6–8 mL/kg. Therefore, bag-valve-mask devices for a full-term newborn, infant, or child should have a minimum volume of 450–500 mL. The bag-valve mask should be no larger than 250 mL for a neonate. Select an appropriately-sized mask that fits over the bridge of the nose and into the cleft above the chin (Figure 38-16 ■). Ensure a good mask seal by using one or two hands to hold the mask to the face (Figure 38-17 ■). A two-handed
seal is preferred to ensure delivery of an adequate tidal volume. Although this might require a second rescuer, it is truly a lifesaving skill that depends on a good seal and just enough manual compression of the bag to make the chest rise.

The infant or child patient should be ventilated at a rate of 20–25 per minute. Breathe into the pocket mask or squeeze the bag-valve-mask device slowly and evenly to ensure adequate chest rise. If regurgitation is a problem, applying cricoid pressure may help prevent it.

5. **Maintain oxygen therapy.** If the patient is breathing adequately but has other signs of early respiratory distress, administer oxygen to maintain an SpO₂ reading of 94% or greater (Figure 38-18a). If the patient will not tolerate the nasal cannula or mask, try a “blow-by” method. Push the oxygen tubing through a hole created in the bottom of a disposable cup (not Styrofoam, which flakes), and hold it near the patient’s mouth. This may be less frightening to younger patients, who may be curious and interested in the cup (Figure 38-18b). You may also hold the end of the oxygen tubing close to the patient’s face to administer the oxygen. The child may feel less anxious if the parent, other relative, or caregiver holds the tubing near his face. In general, you can use the following guidelines for ventilation and oxygenation:

![Figure 38-18](image-url)

To administer oxygen (a) a nonrebreather mask is appropriate for a child; (b) the blow-by method, using oxygen tubing and a paper cup, is appropriate for an infant or for a child who will not tolerate a mask.
Provide supplemental oxygen to all infants and children who:

- Have indications of early respiratory distress but still have an adequate respiratory effort

Provide bag-valve-mask ventilation with supplemental oxygen attached to the device for all infants and children who:

- Have respiratory distress and altered mental status
- Have cyanosis present despite oxygen via a non-rebreather mask
- Display respiratory distress with poor muscle tone
- Are in respiratory failure or in respiratory arrest

6. **Position the patient.** Patients who are in mild respiratory distress will probably prefer to be sitting in the lap of the caregiver. If the patient is unresponsive, place him in a lateral recumbent position to help prevent aspiration, and have suction available. If the patient requires ventilation, he must be kept in a supine position.

   It may be necessary to immobilize the infant or child to prevent possible aggravation of an existing spine injury. Any pediatric patient with an altered mental status, and no caregiver who is able to give you a history that would rule out trauma, should be immobilized as well. The key in immobilizing the infant or child patient is to place a folded towel (or similar item) beneath the shoulder blades to keep the head from flexing forward. More information about immobilizing an infant or child is provided later in the chapter.

7. **Transport.** Any pediatric patient with a respiratory complaint, or with evidence of respiratory distress, needs to be transported to an appropriate medical facility for further evaluation, preferably a children’s hospital or a hospital with specialized pediatric practitioners.

**Emergency Medical Care—Foreign Body Airway Obstruction**

If you notice a high resistance to airflow after initiating positive pressure ventilation on a patient with respiratory failure or respiratory arrest, attempt to reposition the airway and reventilate. If, after repositioning, the airway is still not patent, and there are no indications that the child is suffering from an illness, assume the infant or child has an airway obstructed by a foreign body—especially if the child was observed to be eating or playing with small objects and then suddenly began to choke or stopped breathing. The most common cause of airway obstruction in infants is liquids, whereas children commonly choke on small objects, food, toys, and balloons.

Perform the next steps immediately, but only if you are sure that the obstruction is not caused by a respiratory disease. Remember that putting anything in the mouth of a pediatric patient with respiratory disease can cause fatal swelling or spasms of the airway.

**Infant or Child with a Mild Foreign Body Airway Obstruction**

In a mild foreign body airway obstruction, the infant (less than 1 year of age) or child (over 1 year of age) will still be able to cough and make sounds. He will be moving air. In this case, you should allow the infant or child to continue to cough in an attempt to remove the obstruction on his own. **Do not** perform any intervention in mild foreign body airway obstruction. However, if the infant or child can no longer make any sounds or cough, indicating a severe obstruction, you must react quickly in an attempt to remove the obstruction, as described in the next section. You must constantly and closely assess the infant or child with a mild obstruction for signs of a developing severe obstruction. You can provide blow-by oxygen to the infant or supplemental oxygen to the child with a mild obstruction to maintain an SpO₂ reading of 94% or greater.

**Infant with a Severe Foreign Body Airway Obstruction**

If the infant (less than 1 year of age) is unable to cough or make any sounds, a severe foreign body airway obstruction is suspected. You must intervene immediately in an attempt to remove the obstruction. Perform the following steps.

1. Position the patient prone (belly down, back up) on your forearm in a head-down position, supporting the infant's head with your hand and supporting your arm on your thigh (Figure 38-19).
2. Deliver five sharp back slaps (blows) between the shoulder blades.
3. Transfer the patient to a supine, head-down position on your other forearm, and deliver five chest thrusts using two fingertips positioned one finger width beneath the nipple line.
4. Continue to repeat the steps en route until the obstruction is dislodged, the infant becomes unresponsive, or you arrive at the medical facility. Consider
ALS backup. If the infant becomes unresponsive, go to the steps on relieving an airway obstruction in an unresponsive infant.

**Unresponsive Infant with a Foreign Body Airway Obstruction**

If the infant (less than 1 year of age) is unresponsive and a foreign body airway obstruction is suspected, or if the infant with a mild or severe foreign body airway obstruction becomes unresponsive during your treatment, immediately perform the following steps.

1. Open the airway, using a head-tilt, chin-lift maneuver.
2. Open the mouth and look for the foreign body. If the foreign body is seen in the oropharynx, attempt to remove it (Figure 38-20 ▼). Do not perform blind finger sweeps. Doing so may push the obstruction farther down the pharynx or may damage the oropharynx.
3. Provide two ventilations over a 1-second period.
4. Using the same landmarks and techniques as for CPR, provide 30 chest compressions at a rate of 100 per minute (Figure 38-21 ▼).
5. After the chest compressions, look in the mouth for the obstruction. If it can be seen in the oropharynx, attempt to remove it.
6. Provide two ventilations followed by another set of 30 compressions.
7. Continue this sequence until the foreign body is removed. The patient should be transported without delay. Connect oxygen to the bag-valve-mask device via a reservoir to deliver the highest possible concentration of oxygen.
8. If the foreign body cannot be visualized and/or removed, continue chest compressions and attempted ventilations.

**Child with a Severe Foreign Body Airway Obstruction**

If the patient is older than 1 year of age, has a severe foreign body airway obstruction, and is no longer able to cough or make sounds, perform subdiaphragmatic abdominal thrusts (the Heimlich maneuver) as follows:

1. Assure the patient that you are there to help.
2. Position yourself behind the child, and reach your arms around his abdomen (Figure 38-22 ▼).
3. Locate the navel and place the thumb side of one clenched fist midway between the navel and the xiphoid process (cartilage below the sternum).

-Figure 38-20 Use the finger sweep only when the foreign body is visible.

-Figure 38-21 Position the infant to deliver chest thrusts.

-Figure 38-22 Abdominal thrusts on a choking but responsive child.
4. Wrap the other hand over the clenched hand.
5. Delver five abdominal thrusts inward and upward, at a 45-degree angle toward the head.
6. Continue to deliver sequential series of five abdominal thrusts until the object is dislodged, you arrive at the medical facility, or the patient becomes unresponsive.

**Unresponsive Child with a Foreign Body Airway Obstruction**

If the child (over 1 year of age) is unresponsive and a foreign body airway obstruction is suspected, or if the child with a mild or severe foreign body airway obstruction becomes unresponsive during your treatment, immediately perform the following steps:

1. Open the airway, using a head-tilt, chin-lift maneuver.
2. Open the mouth and look for the foreign body. If the foreign body is seen in the oropharynx, attempt to remove it. Do not perform blind finger sweeps. Doing so may push the obstruction farther down the pharynx or may damage the oropharynx.
3. Provide two ventilations over a 1-second period.
4. Using the same landmarks and techniques as for CPR, provide 30 chest compressions at a rate of 100 per minute (Figure 38-23).  
5. After the chest compressions, look in the mouth for the obstruction. If it can be seen in the oropharynx, attempt to remove it.
6. Provide two ventilations followed by another set of 30 compressions.
7. Continue this sequence until the foreign body is removed. The patient should be transported without delay. Be sure to connect oxygen to the bag-valve-mask device via a reservoir to deliver the highest possible concentration of oxygen.
8. If the foreign body cannot be visualized and/or removed, continue chest compressions and attempted ventilations.

**Croup**

Croup is a common infection of the upper airway, usually caused by a virus but sometimes by bacteria. It has a slow onset of symptoms, is accompanied by a low-grade fever, and is most common in children between 6 months and 4 years of age.

The infection causes swelling beneath the glottis and progressively narrows the airway (Figure 38-24). The child is typically hoarse, coughs with a harsh “seal bark,” and produces stridor with inhalation. High-pitched squeaking sounds may also be present. As the condition worsens, further obstructing the airway, you will see the classic signs of respiratory distress: nasal flaring, tugging at the throat, retraction of muscles around the rib cage, restlessness, tachycardia, and cyanosis. Severe attacks can be dangerous, and you should treat as follows.

**Emergency Medical Care**

1. Administer oxygen, humidified is preferred, to maintain an SpO2 reading of 94% or greater.
2. Keep the patient in a position of comfort, either propped up or in a caregiver’s arms.
3. Transport the patient to the hospital with as little disturbance as possible. In severe cases, consider ALS.
4. Be aware that cool night air may reduce the swelling in the airway, bringing relief. You may need to explain the original signs to emergency department personnel if the patient appears much better after transport.

---

**Figure 38-23** Chest compressions on a child who is unresponsive.  
(a) For an older child, place one hand on top of the other. (b) For a younger child, delivering the compressions with one hand may be safer.
Epiglottitis

A condition that resembles croup, epiglottitis is caused by a bacterial infection that inflames and causes swelling of the epiglottis (review Figure 38-24). Epiglottitis is life threatening if left untreated. The onset is usually rapid and is accompanied by a high temperature.

Epiglottitis has been traditionally referred to as a disease of children between the ages of 2 and 7 years; however, this is no longer the case. In fact, epiglottitis in adults has become more prevalent than in those children. There has been vast progress in the reduction of epiglottitis in children since the mid-1980s, and this is primarily attributed to the introduction of the Hib (Haemophilus influenzae type B) vaccine. The majority of epiglottitis cases were previously caused by Hib. As a result of the Hib vaccine, epiglottitis is currently being seen more in young adults than in children. The exception to this rule is in those areas where immunizations are not commonplace and where agents causing the disease are different—for example, strep.

Signs and symptoms are:

- Pain on swallowing
- High fever (102°F–104°F) and a “toxic” ill-appearing child
- Drooling (because it is painful to swallow)
- Mouth breathing
- Changes in voice quality and pain upon speaking
- Sitting up and leaning forward (tripod position)
- Chin and neck thrust outward
- Inspiratory stridor
- Respiratory distress
- A strikingly still appearance as the attack worsens

Emergency Medical Care

1. Do not place anything in the child’s mouth since this can increase swelling of the epiglottis and cause laryngospasm that can completely block the airway. Nothing in the mouth means no oropharyngeal airway, no suctioning equipment, and no fingers—unless the patient becomes completely unresponsive and is not moving any air.
2. Allow the child to assume a position of comfort (usually sitting upright, leaning forward).
3. Provide oxygen at 15 lpm by a nonrebreather mask. Provide blow-by oxygen if the child does not tolerate the mask. Be careful that it does not cause irritation or coughing. If the child’s airway is completely obstructed, provide bag-valve-mask ventilations with supplemental oxygen, forcing oxygen past the swollen epiglottis and spasmed larynx.
4. Consider ALS backup if it does not delay transport. Patients with epiglottitis may need endotracheal intubation or a surgical airway, and this should be done in a controlled setting such as an emergency department or operating room by skilled personnel.
5. Transport.

Asthma

Some of the pulmonary diseases that affect the pediatric population have begun to decrease in incidence. Unfortunately, other diseases have begun to increase substantially, leading to more pediatric illness and death.

Asthma is a long-term inflammatory process that targets the lower airways. This inflammation is characterized by increased production of mucus and an acute narrowing of the airways through inflammation of airway tissue, leading to edema (swelling) within the airways (Figure 38-25).

The narrowing of the airway diameter increases airway resistance in the bronchioles. As the bronchiolar smooth muscle contracts and the airways are narrowed,
Get the patient's history from the caregivers by asking the following questions:

- How long has the child been wheezing?
- How much fluid has he taken during this period?
- Has he had a recent cold or other infection, particularly one involving the respiratory tract?
- Has he had any medication for this attack? What is it? When? How much? (It is especially important to ask

### Pathophysiology of Asthma

**Normal**

- Bronchiole (airway)
- Smooth muscle
- Mucus glands
- Open clear airway

**Inflammation**

- Swelling inside the bronchiole
- Increased mucus production

**Bronchoconstriction**

- Contraction of bronchiole smooth muscle

**Figure 38-26** Pathophysiology of asthma. Inflammation inside the bronchiole, an increase in the production of thick, sticky mucus, and bronchiole smooth muscle contraction (bronchoconstriction) lead to a reduced bronchiole internal diameter and a higher airway resistance.

**Table 38-25** Effects of edema on airway resistance in the infant compared to the adult.

Air moves forcefully through the tiny passages, which produces the wheezing that is heard upon auscultation (Figure 38-26). Common symptoms of asthma include shortness of breath, chest tightness, wheezing, and nonproductive, “tight” coughing. For a more detailed discussion of asthma signs, symptoms, and emergency medical care, see Chapter 16, "Respiratory Emergencies."
about metered-dose inhalers.) Does he take steroids? When was the last dose of these medications?
- Does he have any known allergies to drugs, foods, pollens, or other inhalants?
- Has he visited an emergency department recently? Has he ever been hospitalized for an acute asthmatic attack? Was the child in an intensive care unit? How recently and how often? Has the patient ever required a mechanical ventilator during an attack?

During the secondary assessment of the patient, pay particular attention to:

- **Position.** Children with mild attacks of asthma often appear agitated and prefer to sit, but will lie still. Children with severe attacks seem exhausted and unable to move. Frequently they prefer to lean forward, bracing themselves on their elbows (tripod position). Children under the age of 2 often show no agitation and will lie on their backs, even when this increases their difficulty in breathing.

- **Mental status.** Sleepiness and changes in mental status are progressively more serious signs of hypoxia, acidosis, and retention of carbon dioxide.

- **Vital signs.** As an attack worsens, the pulse grows faster and weaker. Blood pressure may fall. Bradycardia (slower-than-normal heart rate) is an ominous sign of impending respiratory and potential cardiac arrest.

- **Skin color and condition.** Pinch the skin to look for evidence of dehydration (“tenting”). Check for cyanosis of the tongue and mucous membranes, suggesting hypoxia. Usually these children have some degree of dehydration from poor oral intake, severe coughing that might stimulate vomiting, and increased insensible losses from rapid respirations.

- **Respirations.** A mild to moderate attack of asthma is characterized by loud breathing sounds, loud wheezes, and occasional crackles. As the attack worsens, the breath sounds become less audible and are completely absent in a severe attack. Auscultate the entire chest, since localized wheezes suggest a foreign body obstruction, whereas asthma causes generalized wheezes.

### Emergency Medical Care

Because of the emotional component of asthma (stress makes it worse), try to be as calm and reassuring as possible and follow these treatment steps (but move somewhat quickly because definitive treatment is available at the hospital).

1. Administer oxygen, humidified if possible, to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation.
2. Allow the child to assume a position of comfort.
3. If the child has a prescribed inhaler, follow the same emergency care procedures for administration of the medication via metered-dose inhaler as for the adult. (Review Chapter 16, “Respiratory Emergencies,” for information on prescribed inhalers.) Consult medical direction for permission to administer it.
4. Usually, you will need to transport the patient for further care.

**Note:** A severe attack that cannot be managed with medication is called status asthmaticus and is extremely serious. Consider ALS backup, if available.

### Bronchiolitis

Bronchiolitis, which is easily confused with asthma, is caused when the mucosal layer within the bronchiolites in the lungs becomes inflamed by a viral infection (Figure 38–27). During exhalation, the child will wheeze loudly. He will also have other signs similar to those of asthma. Bronchiolitis typically occurs in children less than 2 years of age. The younger the age, the more severe the symptoms such that infants with the disease typically require hospitalization and, often, mechanical ventilation. To prehospital care providers, the best known infectious form of bronchiolitis is respiratory syncytial virus (RSV). Symptoms of bronchiolitis include a low-grade fever, tachycardia and/or tachypnea (rapid heart rate and rapid breathing), shortness of breath, chest tightness, wheezing, and coughing. Hypoxia can be seen in severe cases.

Collect the same history and perform the same assessment as you would for asthma.

### Emergency Medical Care

Generally speaking, management of bronchiolitis is almost identical to that for other types of respiratory distress:

1. Administer oxygen, humidified if possible, to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation.
2. Let the child assume a position of comfort or place him in a Fowler's position with his neck slightly extended if this position is more comfortable.
3. Monitor the pulse rate and mental status while you transport the child to the hospital.

### Pneumonia

Pneumonia is estimated to cause approximately 4 million deaths among children worldwide. In the United States from 1939–1996, mortality caused by pneumonia in children declined by 97 percent. This decline is most likely attributable to the introduction of antibiotics, vaccines, improvements in medical care, and the expansion of medical insurance coverage for children. Pneumonia may involve a bacterial, viral, mycoplasmal, and fungal infection of the lung. It accounts for an extremely high amount of morbidity and is the sixth leading cause of death in the United States.

Viral pneumonia usually results from spread of infection along the airways resulting in airway obstruction from swelling, abnormal secretions, and cellular debris...
bacteria. The end result, however, is typically the same: cellular destruction and an inflammatory response in the airways. As the infection progresses, cellular debris, inflammatory cells, and mucus cause airway obstruction and ultimately respiratory compromise.

Common symptoms of pneumonia include shortness of breath, chest tightness, diminished breath sounds, (Figure 38-28). The small diameter of airways in young infants makes them particularly susceptible to severe infection. Viral infection of the respiratory tract can also predispose to secondary bacterial infection by disturbing normal immune system response mechanisms.

When bacterial infection is established in the lung, the extent of injury is dependent on the particular bacteria. The end result, however, is typically the same: cellular destruction and an inflammatory response in the airways. As the infection progresses, cellular debris, inflammatory cells, and mucus cause airway obstruction and ultimately respiratory compromise.

Pathophysiology of Pneumonia

(Figure 38-27) Pathophysiology of bronchiolitis. Inflammation inside the bronchiole and an increase in the production of thick, sticky mucus from an infection lead to a reduced bronchiole internal diameter and a higher airway resistance.
and dry, hacking, productive-sounding cough. A finding in pneumonia that is specific to the pediatric population is a tendency for the child to lie on his side with his knees drawn up to the chest to minimize pleuritic pain and improve ventilation. For a more detailed discussion of pneumonia signs, symptoms, and emergency medical care, see Chapter 16, “Respiratory Emergencies.”

Obtain the history from the caregivers by asking:

- How long has the child been ill?
- How much fluid has he taken during this period?
- Has he had a recent cold or other infection, particularly one involving the respiratory tract?
- Has he had any treatment for this current illness? What is it? When?
- Has he had a fever?

During the physical exam of the patient, pay particular attention to:

- **Position.** Children with pneumonia may lie on their side with their knees drawn up to the chest. Children with severe respiratory distress seem exhausted and unable to move. Frequently they prefer to lean forward, bracing themselves on their elbows (tripod position). Children under the age of 2 often show no agitation and will lie on their backs, even when this increases their difficulty in breathing.

- **Mental status.** Drowsiness and intermittent periods of restlessness are commonly associated with pneumonia.

- **Vital signs.** As the disease progresses, the pulse grows faster and weaker. Blood pressure may fall. Bradycardia (slower-than-normal heart rate) is an ominous sign of impending respiratory and potential cardiac arrest. Children with bacterial pneumonia are at high risk for developing sepsis and septic shock. Monitor the SpO2 very carefully.

- **Skin color and condition.** Pinch the skin to look for evidence of dehydration (“tenting”). Check for cyanosis of the tongue and mucous membranes, suggesting hypoxia.

- **Respirations.** A mild to moderate exacerbation is characterized by diminished breathing sounds, and may occasionally include wheezes and/or crackles.

**Emergency Medical Care**

1. **Establish and maintain an open airway.** Administer oxygen to maintain an SpO2 of 94% or greater.
2. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
3. **Support the cardiovascular system as necessary. Consider ALS support.**

**Shock**

Severe shock in children is unusual because their blood vessels constrict efficiently, which helps to maintain blood pressure but only for so long. When adverse conditions are not corrected in a timely fashion and the conditions leading to shock continue, the blood pressure will eventually drop. It will usually drop rapidly and eventually precipitate cardiac arrest. Remember that cardiopulmonary arrest is typically due to either respiratory failure or shock.

Newborns have been known to go into shock from loss of body heat. They have immature thermoregulatory systems and cannot shiver or warm themselves through muscular activity. Their skin surface area is large in relation to their body weight, which increases their rate of heat loss.

Shock can also be precipitated by certain medical problems that can cause the same response in adults. Hypovolemic, obstructive, distributive, and cardiogenic causes of shock are also experienced by the pediatric patient. Common findings include diarrhea and dehydration, trauma, vomiting, blood loss, infection, and abdominal injuries. Less common causes of shock are allergic reactions, poisoning, or cardiac events. Refer to Chapter 15, “Shock and Resuscitation,” for a review of shock.

The goal of treatment is to correct any abnormalities that may compound the hypoperfusion state (e.g., hypoxia, continued blood loss).

Signs of shock include rapid respiratory rate; pale, cool, clammy skin; mottling; decreased mental status; prolonged capillary refill; and weak or absent peripheral pulses (see Figure 38-29 and Table 38-7). The onset of these signs in children may be sudden, occurring quickly as their compensatory mechanisms become

**Congenital Heart Disease (CHD)**

Congenital heart defects are responsible for more deaths in the first year of life than any other birth defects, according to the National Institutes of Health. The initial presentation of the infant with CHD can be inconsistent, looking like respiratory distress, infection, failure to thrive, and shock. The presenting symptoms of CHD in the infant or child are (1) inadequate pulmonary blood flow resulting in cyanosis and hypoxia; (2) excessive pulmonary blood flow resulting in congestive heart failure, hypoperfusion, and systemic shock; or (3) respiratory distress with or without cyanosis or shock. Since the defect can be due to abnormal valves, vessels, or chambers, diagnosing the defect is less important than recognizing the abnormality on assessment, initiating emergency care, and transporting rapidly to an appropriate medical facility.
To review emergency care for hypoperfusion in the infant or child, see Figure 38-30.

### Cardiac Arrest

Although cardiac arrest is not a respiratory problem per se, it is a very real concern if the patient’s respiratory status deteriorates. Almost all cardiac arrests in children result from airway obstruction or respiratory distress leading to respiratory arrest; most of the remaining are caused by shock (hypoperfusion). It is extremely important to aggressively manage both respiratory problems and shock before they progress to cardiac arrest. Provide positive pressure ventilations if breathing is inadequate or signs of respiratory failure are present. Chest compressions should be started if the heart rate drops below 60 beats per minute and signs of poor perfusion are evident.

Signs of cardiac arrest in a child are:
- Unresponsiveness
- Gasping or no respiratory sounds
- No audible heart sounds

### Emergency Medical Care

1. Establish and maintain an open airway. Administer oxygen to maintain an SpO2 of 94% or greater.
2. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
3. Control any bleeding if present.
4. Place the patient in a supine position.
5. Keep the patient warm and as calm as possible. If the patient is a newborn, preheat an isotherme or your ambulance to at least 98°F (36.5°C) for full-term babies. If you do not have an isotherme, wrap the baby in warm blankets (prewarmed, if possible), then aluminum foil, to preserve body heat. Be sure that the baby’s head (but not the baby’s face) is covered.
6. Transport to the emergency department quickly.
Emergency Care Protocol

PEDIATRIC SHOCK

1. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
2. Suction secretions.
3. Provide positive pressure ventilation with supplemental oxygen connected to the ventilation device at a rate of 12–20 ventilations/minute if breathing is inadequate.
4. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.

5. If shock is due to blood loss, control any external bleeding with direct pressure. If internal bleeding is suspected, transport immediately and expeditiously.
6. Keep the patient warm. If hypothermia is suspected, wrap the patient in warm blankets and place the ambulance heater on high. Cover the infant or child’s head. (Note: All patients in shock should be kept warm.)
7. Consider calling advanced life support.
8. Expedite transport.
9. Perform a reassessment every 5 minutes.

Emergency Medical Care

Key components of management include the following steps:
1. Provide positive pressure ventilation with supplemental oxygen.
2. Perform CPR effectively with minimal interruption. The automated external defibrillator (AED) should be applied. AEDs may be applied to children less than 1 year of age (Figure 38-31). Follow your local protocol. An AED that is capable of delivering an energy level suitable for children up to 8 years of age through a dose-attenuating system, typically pediatric pads and cables, should be used. If a dose-attenuating system is not available, an adult AED should be applied, regardless of the child’s age. An adult AED is used for children older than 8 years of age. If an AED is applied, the protocol for use should only employ a single shock followed by 2 minutes of CPR prior to reanalysis of the rhythm.
3. Call for ALS backup.
4. Transport rapidly to the closest medical facility capable of handling a patient in cardiac arrest.

Summary: Pediatric Respiratory and Cardiopulmonary Emergencies

To review possible assessment findings and emergency care for respiratory or cardiopulmonary emergencies in the infant or child, see Figures 38-32 and 38-33.

- Chest that is not moving
- Pallor or cyanosis
- Absent pulse (assess the brachial pulse in the infant, the carotid pulse in the child over 1 year of age)

Your goal is to keep the brain viable. Standing orders that provide you with orderly direction of treatment, easy access to paramedic backup, and continuous assessment are important. Unless too much time has elapsed between the arrest and initiation of artificial ventilation, the child may recover with minimal or no neurological deficit—even following comparatively long periods of arrest.
Assessment Summary

**RESPIRATORY OR CARDIOPULMONARY EMERGENCY IN THE PEDIATRIC PATIENT**

The following findings may be associated with an airway or cardiopulmonary emergency in the infant or child.

**Scene Size-up**

Ensure your own safety. Look for:
- Mechanism of injury; toxic inhalation or hazardous materials; patient in a confined space; evidence of poisoning; metered-dose inhalers or nebulizers

**Primary Assessment**

### General Impression

**Pediatric Assessment Triangle:**
- Appearance
- Work of breathing
- Circulation to skin

Is the child “sick” or “well”? Displaying normal behavior for his age? Moving spontaneously or lethargic or flaccid? Maintaining eye contact?
If older than 2 months, does he recognize his parents?
Respond when the parent calls his name?
Is he sitting up, leaning forward, neck jutting out, drooling?

**Mental Status (depending on age of patient)**

Alert to unresponsive; decreasing mental status; increased anxiety; disorientation; restlessness
Seizure activity; weak or absent cry
Does not react with environment
Does not seem to notice your presence
Cannot be consoled by parent

**Airway**

Occluded by tongue, secretions, blood, or vomitus
Signs of laryngeal edema (stridor, crowing)
Swollen tongue; drooling
Harsh cough that sounds like a “barking seal”

**Breathing**

Tachypnea (>50 respirations/minute in an infant and >30 respirations/minute in a child)
Inadequate ventilation
Wheeze; crackles
Mouth breathing; accessory muscle use; nasal flaring
Coughing, gagging, or gasping

**Circulation**

Weak central or peripheral pulses; tachycardia; bradycardia
Red, warm, and dry skin
Pale, cool, clammy skin; cyanosis
Capillary refill that is delayed >2 seconds with other findings of hypoperfusion

**Status:** Priority patient if showing signs and symptoms of respiratory arrest, respiratory failure, or respiratory distress

**Secondary Assessment**

**Physical Exam**

**Head, neck, and face:**
- Edema to face, hands, neck, and lips
- Hives; itching
- Warm, tingling feeling
- Difficulty in swallowing
- Itchy and watery eyes
- Runny or stuffy nose
- Coughed-up mucus
- Headache
- Stiff neck
- Bulging anterior fontanelle (infants <1 year)
- Neck jutted out and drooling
- Evidence of trauma to the head, neck, or face

**Chest:**
- Retractions; accessory muscle use
- Wheezing in all lung lobes; crackles
- Evidence of trauma to the chest

**Abdomen:**
- Nausea/vomiting
- Abdominal cramping
- Diarrhea; loss of bowel control
- Excessive abdominal muscle use
- Evidence of trauma to abdomen

**Extremities:**
- Warm, tingling feeling in hands and feet
- Itching, especially hands and feet
- Edema to hands and feet
- Cool, pale, cyanotic hands and feet
- Red, warm, dry skin
- Weak or absent peripheral pulses
- Poor skin turgor
- Rashes, petechiae, bruising

**History**

**Signs/symptoms of early respiratory distress:**
- Tachypnea
- Nasal flaring
- Retractions
- Stridor, wheezing, or grunting
- “Seesaw” respirations

**Signs/symptoms of decompensated respiratory failure:**
- Tachypnea >60/minute
- Cyanosis
- Decreased muscle tone
- Poor peripheral perfusion
- Altered mental status
- Grunting
- Head-bobbing

**Signs of respiratory arrest:**
- Respiratory rate less than 10/minute
- Irregular respirations

*continued*
Emergency Care Protocol

RESPIRATORY OR CARDIOPULMONARY EMERGENCY IN THE PEDIATRIC PATIENT

1. Establish and maintain an open airway, extending head only enough to allow an open airway and avoid hyperextension.
2. If severe (not coughing or not making sounds) or foreign body airway obstruction is suspected, perform the following:
   - Infant (<1 year of age):
     a. Position supine.
     b. Deliver five back slaps (blows).
     c. Deliver five chest thrusts.
     d. Assess inside mouth; finger sweep only if object is visualized.
     e. Begin immediate transport if airway is not cleared.
     f. Continue until obstruction is dislodged.
   - Responsive child with severe foreign body airway obstruction:
     a. Deliver five abdominal thrusts.
     b. Repeat twice until obstruction is dislodged or child becomes unresponsive.
     c. Begin immediate transport; continue abdominal thrusts en route.
   - Unresponsive infant or child with severe foreign body airway obstruction:
     a. Open the mouth and inspect for an obstruction. If at any time it is seen in the oropharynx, remove it. Do not perform blind finger sweeps.
     b. Deliver two ventilations.
     c. Perform 30 chest compressions.
     d. Inspect inside the mouth prior to delivering the next two ventilations. If the obstruction is seen in the oropharynx, remove it.

3. If the infant or child has a mild foreign body airway obstruction, apply a nonrebreather mask, allow the patient to assume a position of comfort, and encourage the patient to cough forcefully; do not delay transport; continue en route.
4. Suction secretions.
5. Provide positive pressure ventilation with supplemental oxygen via reservoir at a rate of 12–20 ventilations/minute if:
   - Respiratory failure
   - Respiratory arrest
   - Inadequate breathing
   - Respiratory distress and altered mental status
   - Cyanosis is present despite oxygen delivery by non-rebreather mask
   - Respiratory distress with poor muscle tone
6. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.
7. If signs and symptoms of allergic reaction and respiratory distress and/or hypotension, and with permission from medical direction, administer epinephrine by patient-prescribed auto-injector: epinephrine pediatric dose: 0.15 mg up to 66 lb. If the child’s weight is greater than 66 lb, an adult (0.30 mg) auto-injector should be used.
8. If signs and symptoms of respiratory distress and wheezing and if the patient has a prescribed metered-dose inhaler, and with permission from medical direction, administer the MDI.
9. Consider calling advanced life support.
10. Expedite transport.
11. Perform a reassessment every 5 minutes.
Emergency Care Algorithm

Rapid secondary assessment

Consider manual in-line stabilization

Assess mental status

Alert or crying vigorously

Consider oxygen administration

Assess circulation

Evidence of trauma?

Yes

Secondary assessment

Signs of asthma or wheezing?

Yes

Administer prescribed metered-dose inhaler

No

Foreign body airway obstruction suspected?

Yes

Conscious: Severe foreign body airway obstruction

Infant

Child

Unresponsive: Severe foreign body airway obstruction—adult, child, or infant

Perform CPR

No

Administer oxygen

5 back slaps
5 chest thrusts

Place in position of comfort (e.g., on parent’s lap, but not lying down) and offer oxygen

5 abdominal thrusts

Inspect inside of mouth for obstruction

Decompensated respiratory failure

Respiratory arrest

Inadequate breathing

Respiratory distress with altered mental status

Cyanosis despite oxygen delivery

Respiratory distress with poor muscle tone

Adequate

Administer oxygen

Assess circulation

Secondary assessment

Signs of allergic reaction?

Yes

Administer prescribed 0.15 mg (<66 lbs) or 0.30 mg (>66 lbs) epinephrine by auto-injector

No

PPV with O₂

Signs of anaphylactic reaction

Yes

Transport

Reassessment

No

PPV = positive pressure ventilation

Cream = assessment

Green = key decision points

Blue = interventions

CHAPTER 38 • Pediatrics
OTHER PEDIATRIC MEDICAL CONDITIONS AND EMERGENCIES

The previous section dealt primarily with respiratory and cardiac emergencies in infants and children. In particular, airway and respiratory emergencies can be life threatening and are associated with many other emergencies in the pediatric patient. Regardless of the type of medical emergency, maintaining an airway and adequate breathing and oxygenation are the primary goals. The general principles and steps of assessment—scene size-up, primary assessment, secondary assessment, and reassessment—are the same no matter what medical emergency precipitates the call.

On the following pages, additional pediatric medical emergencies are discussed with general principles of assessment and care with special application to each type of emergency.

Seizures

Seizures in infants and children may be caused by any condition that would also produce seizures in adults: epilepsy, head injury, meningitis, oxygen deficiency, drug overdose, electrolyte abnormalities, brain tumors, and low blood sugar (hypoglycemia). However, adults seldom have febrile seizures (seizures caused by fever), but children may. The risk of seizures is high among children up to age 2, and approximately 3 to 5 percent of all children in the United States will have experienced a febrile seizure by the time they reach their 5th birthday. Although these childhood seizures may be frightening, they generally have no permanent adverse effects and usually do not predict the development of epilepsy in the child unless there is a family history of epilepsy and the seizure is particularly prolonged or difficult to control.

Assessment Considerations

During the “generalized, tonic-clonic” seizure, the child’s arms and legs may become rigid, the back arches, the muscles may twitch or jerk in spasm, the eyes roll up and become fixed, the pupils dilate, and the breathing is often irregular or ineffective. The patient may lose bladder and bowel control and will be completely unresponsive. If the seizure lasts long enough, the skin can turn cyanotic from ineffective respirations. The muscle spasms may prevent the child from swallowing effectively. Hence, excessive saliva coming from the mouth is a common finding (saliva production is also more copious during the seizure). If saliva is trapped in the throat, the child will make a gurgling sound with respirations.

EMS providers may have difficulty differentiating a syncopal episode from a seizure in the pediatric population. The key difference between a seizure and another loss of consciousness is that the activity in a seizure will not alter or cease in response to your (or the parent’s) interventions. Remembering AVPU, the actively seizing patient will have no response to painful stimuli, whereas many other conditions causing an alteration in consciousness will have some, albeit a nonspecific, response to painful stimuli. As an EMS provider, you may find yourself responding to the scene of an unresponsive child. Given the high stress associated with pediatric medical emergencies, a good history of events can be difficult to obtain.

Incontinence is an uncommon finding in the patient who experienced a syncopal episode, whereas incontinence is common in seizure activity. This finding is not reliable in a diaper-dependent child since it is difficult to determine the time the diaper was soiled in relationship to the physiological event. Syncope does not present with any history of tonic-clonic activity and typically occurs with generalized symptomatology. In contrast, a seizure patient will often have a recent history of generalized tonic-clonic activity or localized, focal motor activity. However, some patients with syncope may have activity during the event that is described as seizure-like.

Determining the duration of loss of consciousness may help to establish if the etiology is related to syncope or seizures. In a syncopal event, the child generally has a relatively short duration (less than 5 minutes) of unconsciousness in contrast to a relatively longer duration (greater than 5 minutes) in a seizure.

While obtaining the history, ascertain whether the child has had prior seizures and, if so, find out whether this is the child’s normal seizure pattern. Determine whether the child has taken his antiseizure medications, if any have been prescribed.

Emergency Medical Care

A single seizure is usually self-limiting, ends within minutes, is generalized in nature (all muscles involved), and does not recur. If the child has a single seizure, maintain an airway and be sure that he does not injure himself. Transport as soon as possible after the single seizure.

1. Establish and maintain an open airway. Administer oxygen to maintain an SpO2 of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
2. Position the patient on his side if there is no possibility of spine trauma, and make sure he cannot strike any nearby objects and injure himself.
3. Be prepared to suction. Do not insert a hard suction catheter into the oropharynx of an actively seizing patient.
4. Transport. Although brief seizures are generally not harmful, there may be a more dangerous underlying condition.

If seizures last longer than 5 minutes or recur without a recovery period, this is a condition called status epilepticus, which is a true medical emergency. Provide positive pressure ventilation with supplemental oxygen.
during a prolonged seizure, if possible. After the seizure has ended, it may still be necessary to provide positive pressure ventilation. Provide rapid transport to the hospital, paying particular attention to maintaining the airway and protecting the patient from injury.

To review emergency care for seizures in the infant or child, see Figure 38-34.

**Emergency Care Protocol**

**PEDIATRIC SEIZURES**

1. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
2. Protect the infant or child from injuring himself; place him on his left side.
4. Provide positive pressure ventilation with supplemental oxygen via reservoir at a rate of 12–20 ventilations/minute if breathing is inadequate.
5. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.
6. Check the blood glucose level, if your protocol permits.
7. Expedite transport in any of the following situations:
   a. Epileptic seizures lasting >5 minutes
   b. Two or more epileptic seizures without a period of consciousness between them
   c. Febrile seizures lasting >15 minutes
   d. Seizure from any other cause (e.g., hypoxia, head injury)
8. Consider calling advanced life support.
10. Perform a reassessment every 5 minutes.

**Altered Mental Status**

An altered mental status can be the reason for the emergency call (mother informs you the baby “just isn’t acting right”) or a sign or a result of the initial reason for the emergency call (a patient with a diabetic condition who becomes unresponsive) (Figure 38-35). It is most

**FIGURE 38-34** Emergency care protocol: pediatric seizures.

**FIGURE 38-35** Findings in the pediatric patient with altered mental status.
important to assess and treat any life threat to the airway, breathing, oxygenation, or circulation associated with the altered mental status. Your pediatric patient could have an altered mental status for the same reason an adult patient would, such as hypoglycemia, poisoning, post seizure, or severe blood infection. If your protocol permits, assess the blood glucose in any patient presenting with an altered mental status. Note that if the altered mental status is associated with poor brain perfusion or brain injury, all three PAT findings—appearance, work of breathing, and circulation to skin—may be abnormal.

Assessment Considerations
The child’s level of maturity will greatly influence the format of your assessment of mental status. If using AVPU or the Glasgow Coma Scale, you will need to modify them for a child. Review Table 38-5 for the Pediatric Glasgow Coma Scale (PGCS). Ask the child simple questions. If the child appears to be lethargic, inconsolable, or agitated, ask the caregivers if this is a typical or an unusual response.

To assess the unresponsive infant or child, shout to elicit a response to verbal stimulus. Inflict a pinch to see if the child will respond to pain. Never shake an infant or child for any reason.

Emergency Medical Care
Treatment of a pediatric patient with an altered mental status is aimed at managing life threats such as airway compromise. Treatment procedures include the following:

1. Establish and maintain an open airway. Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
2. Position the patient on his side if there is no possibility of spine trauma.
3. Be prepared to suction.
4. Expedite transport. A pediatric patient with an altered mental status is always a high priority.

To review emergency care for an altered mental status in the infant or child, see Figure 38-36.

Drowning
Drowning can occur in any amount of water—from the ocean, to the bathtub, to a bucket. The main cause of death in infants or children who are submerged is not the aspiration of fluid (although it can occur in some patients). Rather, it is the hypoxia that occurs secondary to glottic closure reflex, which occurs when the water comes in contact with the glottic opening. After an initial period of glottis closure, the victim becomes hypoxic and ultimately gasps, leading to aspiration of water into the lungs.

Assessment Considerations
When confronted with a drowning emergency, you need to be aware of the possibility of trauma and/or hypothermia. Infants and children are especially prone to hypothermia. In any drowning emergency, you should also be alert for secondary drowning syndrome, a deterioration that takes place after normal breathing is restored—from minutes to hours after the event. For a more detailed discussion of drowning and other water emergencies, see Chapter 25 "Submersion Incidents: Drowning and Diving Emergencies."

Emergency Medical Care
In the case of a cold-water drowning, you should be particularly aggressive and persistent about resuscitating a pediatric patient. In response to the cold water, the mammalian dive reflex, which is pronounced in children, may slow blood perfusion and metabolism. This means that the residual oxygen in the blood would last longer. Therefore, the patient would not be expected to breathe at the surface for the same reason an adult patient would not be expected to breathe at the surface. Focus on managing the patient’s respiratory arrest and circulatory arrest.

longer for the brain to consume. Numerous cases of “saves” have been reported even after prolonged submersion in cold water (30 minutes or more). It is controversial whether these saves are made possible by the mammalian dive reflex or the cold water. If you are unclear about the length of time under water, always give the patient the benefit of the doubt and initiate resuscitation.

1. **Remove the patient from the water:** Be sure that the person who rescues the patient is properly trained and equipped for water rescue. Remove clothing and provide passive warming with blankets and a warm environment in the ambulance.
2. **Assume that a spinal injury has occurred and provide full immobilization** while establishing an airway.
3. **Establish and maintain an open airway:** Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
4. **Position the patient on his side** if there is no possibility of spine trauma.
5. **Be prepared to suction.**
6. **Check circulation. Provide CPR as needed. Attach the AED.**
7. **Maintain the treatment en route, and monitor the airway closely for regurgitation and aspiration. Have suction readily available.**

To review emergency care for drowning in the infant or child, see Figure 38-37.

### Fever

Fever in children of 104°F–105°F are concerning. Causes of high temperature include infection (such as meningitis) and heat exposure (from being left in a hot car, for instance).

### Assessment Considerations

The degree of temperature is not always of the greatest concern, but how quickly the temperature “spikes.” If the temperature rises rapidly, a febrile seizure (a seizure caused by a high body temperature) may result. Not all high temperatures produce seizures.

In addition to seizures, another common result of fever is dehydration caused by the increased insensible (evaporative) loss of fluids and electrolytes, especially if fever has been present for some time. Signs and symptoms include nausea, loss of appetite, vomiting, and possible fainting. A dehydrated child's pulse will be weak and rapid, the skin pale, the eyes sunken, and the mucous membranes dry and parched. When you pinch the skin, it might stay “tented.” Dehydration in the infant may also result in a sunken fontanelle. The caregiver may indicate a decrease in frequency of urination by reporting fewer diaper changes than usual.

### Emergency Medical Care

Lower the body temperature based only on local protocol, administer supplemental oxygen to maintain an SpO₂ reading of 94% or greater, and remove excess layers of clothing.

If the elevated core body temperature is a result of exposure to a hot environment, conduct cooling if the core temperature is excessive. Remove the child from the hot environment and avoid extreme cooling and shivering while cooling. Sponge the child’s skin with tepid water. Transport the patient and remain alert for seizures. If cooling is done, it should be performed in

---

**Emergency Care Protocol**

**PEDIATRIC DROWNING**

1. Remove the infant or child from the water. If diving was involved in children or adolescents, consider in-line spinal stabilization and complete spinal immobilization.
2. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
4. Provide positive pressure ventilation with supplemental oxygen connected to the ventilation device at a rate of 12–20 ventilations/minute if breathing is inadequate.
5. Perform chest compressions if no pulse is present. Apply the AED. Contact medical direction otherwise for orders. If hypothermia is suspected, deliver only one defibrillation.
6. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.
7. If hypothermia is suspected, remove wet clothing, wrap the patient in warm blankets, and place the ambulance heater on high. Cover the infant or child's head.
8. Consider calling advanced life support.
10. Perform a reassessment every 5 minutes.

---

**FIGURE 38-37** Emergency care protocol: pediatric drowning.
Meningitis

In meningitis, the lining of the brain and spinal cord (the meninges) are infected by either bacteria or viruses (Figure 38-39). These infections can be rapidly fatal, so they must be assessed promptly and treated in a slow, controlled manner unless the child has a temperature over 106.9°F. If a child with an elevated core body temperature is cooled too quickly, the brain will be overstimulated and the child may seize.

To review emergency care for fever in the infant or child, see Figure 38-38.

**Emergency Care Protocol**

**PEDIATRIC FEVER**

1. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
2. Suction secretions.
3. Provide positive pressure ventilation with supplemental oxygen via reservoir at 12–20 ventilations/minute if breathing is inadequate.
4. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.
5. Febrile seizures > 15 minutes are a dire emergency and require expeditious transport and consideration for advanced life support.
6. Consider calling advanced life support.
7. Transport.
8. Perform a reassessment every 5 minutes.

**Pathophysiology of Bacterial Meningitis**

In meningitis, the meningeal tissue swells inside the skull and around the spinal cord, causing an increase in pressure inside the skull and compression of the brain.
in a timely and appropriate manner. Fever in a child younger than 3 months should be considered meningitis until proven otherwise.

**Assessment Considerations**

Signs and symptoms of meningitis in children include recent ear or respiratory tract infection, high fever, lethargy, irritability, or vomiting. They generally do not have headaches or stiff necks but are lethargic and will not eat. The fontanelle may be bulging unless the child is dehydrated. Movement is painful so the caretakers may report that “he cries every time we pick him up.” Rash may or may not be present.

**Emergency Medical Care**

If you suspect meningitis, you should wear a mask, gloves, and possibly a gown. Complete the assessment rapidly and transport to the hospital. If the child is in shock (hypoperfusion), establish and maintain an open airway. Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.

**Gastrointestinal Disorders**

Diarrhea, which is characterized by frequent and watery bowel movements, is often caused by gastrointestinal infections, although it can also come from other illnesses or changes in diet. The most common cause of diarrhea in children is an infection of the gastrointestinal tract, also known as gastroenteritis, and is a leading cause of dehydration in young children.

Appendicitis is an inflammation of the vermiform appendix, most commonly seen in young adults. Acute appendicitis is the most common surgical emergency you will encounter in the field, mostly in older children and young adults. In the majority of cases, acute appendicitis is caused by an obstruction of the appendix by fecal material. Once the appendix becomes obstructed, it becomes inflamed and can lose its blood supply. The loss of blood flow to the appendix results in tissue hypoxia and, eventually, tissue death. As the appendix dies, its walls weaken and may rupture, spilling infectious contents into the peritoneal cavity.

**Assessment Considerations**

Appendicitis commonly presents early in its course with diffuse, crampy pain surrounding the umbilicus. Other symptoms may include nausea and vomiting and sometimes a low-grade fever. As the infection worsens, the pain may become localized to the right lower quadrant, but not always. Once the appendix actually ruptures, the pain again becomes diffuse and the patient can become critically ill with septic shock and signs of hypoperfusion.

**Emergency Medical Care**

For acute abdominal pain where appendicitis is suspected, provide supplemental oxygen to maintain an SpO₂ of 94% or greater. Place the patient in a position of comfort, usually with knees flexed. If the patient is vomiting, place him on his side. Transport without delay.

**Poisoning**

Poisonings constitute a large number of emergency runs for pediatric patients. Because of children’s inquisitive nature, they are always moving about and getting into things. Recent scientific studies have suggested that the greatest incidence of poisonings occurs in children between 1 and 2 years of age. Poisonings in children less than 4 years of age account for approximately 46 percent of all poison exposures.

**Assessment Considerations**

For these patients, a thorough secondary assessment is critically important. Because poisons can enter the body through numerous routes (ingestion, inhalation, absorption, injection), it is important to gather as much information as possible about the type of overdose prior to transporting the patient to the hospital.

For specifics on assessment and management, see Chapter 22, “Toxicologic Emergencies.”

**Emergency Medical Care**

Emergency treatment of poisoned patients is geared toward the effects of the poisoning on the patient, rather than treating the specific type of poisoning. General emergency care for a pediatric patient suffering from a poisoning is as follows.

**If the Patient Is Alert**

1. **Contact medical direction or the local poison control center.** You may be instructed to administer activated charcoal if a poison was ingested; however, activated charcoal is not effective in most situations, so it is unlikely that you will ever administer it. The dose of activated charcoal given is 1 gram/kg of body weight. Follow your local protocol, on-line medical direction, or the poison control center’s advice on the use of activated charcoal.

2. **Maintain an open airway and adequate ventilation and oxygenation.** Administer oxygen to maintain an SpO₂ of 94% or greater. If the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.
3. **Transport** any patient who was poisoned. Conduct a reassessment en route, closely monitoring for a change in mental status or for airway or breathing compromise. If possible, transport any medication or substance of the type that was ingested along with the patient.

**If the Patient Is Initially Unresponsive or Becomes Unresponsive en Route**

1. Establish and maintain an open airway and adequate ventilation and oxygenation. Administer oxygen to maintain an SpO\textsubscript{2} of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device.

2. **Expedite transport.**

3. **Perform a rapid secondary assessment** to identify or rule out trauma as a cause of the altered mental status. Check blood glucose level, if your protocol permits.

To review emergency care for poisoning in the infant or child, see Figure 38-40 ■.

**Apparent Life-Threatening Events**

In 1986 the National Institutes of Health and Consensus Development Conference on Infantile Apnea and Home Monitoring defined an apparent life-threatening event (ALTE) as: “an episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change, or becomes unresponsive en route.”

**Emergency Medical Care**

If called for an infant exhibiting any of these transient signs, establish and maintain an open airway and adequate ventilation and oxygenation. Administer oxygen to maintain an SpO\textsubscript{2} of 94% or greater. If the breathing is or becomes inadequate, begin positive pressure ventilation with supplemental oxygen delivered through the ventilation device and immediately transport to a medical facility for further evaluation.

**Sudden Infant Death Syndrome**

*Sudden infant death syndrome* (SIDS), commonly known as “crib death,” is defined as the sudden and unexpected death of a previously healthy infant. This diagnosis is established when no cause of death is determined after an appropriate postmortem examination. The postmortem examination includes toxicologic testing, complete autopsy, and forensic evaluation. The incidence of this syndrome varies considerably around the world, with higher rates reported in industrialized countries with predominantly low birth weight infants. The etiology of SIDS is unknown. It is characterized by sudden death without apparent cause and is more common among infants under 6 months of age. There are several potential contributing factors, including viral or bacterial respiratory infections, gassy infant colic, lung hypoplasia, and genetic factors. The incidence of SIDS decreases with increasing socioeconomic status, suggesting that social and economic factors may play an important role in its causation.

**Emergency Care Protocol**

**PEDIATRIC POISONING**

1. **Extend** the head only enough to allow an open airway; avoid hyperextension.

2. **Suction** secretions.

3. **Provide** positive pressure ventilation with supplemental oxygen at a rate of 12–20 ventilations/minute if breathing is inadequate.

4. **If** breathing is adequate, administer oxygen via nonrebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.

5. **Treat** the specific poisoning:

   **Ingestion**
   
   If you are instructed to administer activated charcoal and the patient is alert and able to swallow, give at 1 g/kg (12.5–25 grams). Activated charcoal is contraindicated in the following:
   
   - Altered mental status
   - Ingestion of acids or alkalis
   - Patient who is unable to swallow

**Inhalation**

Remove from toxic environment. Maximize oxygenation by nonrebreather mask at 15 lpm if breathing adequately or by positive pressure ventilation if breathing inadequately.

**Absorption**

Flush with water for 20 minutes at the scene. If eyes are involved, continue to flush en route.

**Injection**

Carefully monitor airway and breathing. If allergic reaction, and with order from medical direction, consider administration of epinephrine by auto-injector at 0.15 mg if the child weighs less than 66 lb. If the child’s weight is greater than 66 lb, an adult (0.3 mg) auto-injector should be used. Apply a constricting band proximal to site of bite or injection.

6. **Consider** calling advanced life support.

7. **Expedite** transport.

8. **Perform** a reassessment every 5 minutes.

**FIGURE 38-40** Emergency care protocol: pediatric poisoning.
unexpected death of an infant (under 1 year of age) in which an autopsy fails to identify the cause of death. It is the leading cause of death among infants between 1 month and 1 year of age, with a peak incidence at 2 to 4 months. SIDS is a postmortem diagnosis, not one that can be made in the field. While the facts behind SIDS will be outlined here, do not make a firm diagnosis to a family member.

To date, no reliable ways to predict or prevent SIDS are known. The etiology of SIDS remains unknown. It almost always occurs while the baby is sleeping. The typical SIDS case involves an apparently healthy infant, frequently with a history of having been born premature, who suddenly dies during a sleep period in his crib. No illness need be present, though the baby may have had recent cold symptoms. There is usually no indication of struggle. Sometimes, though, the child has obviously changed position near the time of death. Risk factors include sleeping in a prone (belly down) position, sleeping on a soft surface, and secondhand smoke.

There is much confusion about SIDS among both the general public and the medical profession. Not until recently has serious medical research on SIDS been conducted. However, its exact cause is still unknown.

Assessment Considerations

SIDS cannot be diagnosed in the field. When you arrive in response to the emergency call, you will find the patient in cardiac arrest and you will proceed with care as you would for any patient in this condition. Do not delay resuscitation (as described in the next section) but, as practical, obtain a brief history of the infant and observe the surroundings, including:

- Physical appearance of the infant
- Position of the infant in the crib
- Physical appearance of the crib
- Presence of objects in the crib
- Unusual or dangerous items in the room (such as plastic bags)
- Appearance of the room/house
- Presence of medication, even if it is for adults
- Circumstances concerning discovery of the unresponsive child
- Time the infant was put to bed or fell asleep
- Problems at birth
- General health
- Any recent illnesses
- Date and result of last physical exam

Since this may be a potential crime scene rather than a medical case of SIDS, be very careful not to convey by the wording of your questions or your manner any suspicion that the parents or caretakers may be responsible for the child’s condition.

Emergency Medical Care

When you find an infant in respiratory and cardiac arrest—a condition for which SIDS is only one of many possible causes—proceed as follows:

1. Immediately try to resuscitate. Attempt aggressive resuscitation of the infant. The exceptions are rigor mortis (when joints become rigid) and dependent lividity (discoloration created by gravity causing the blood to pool in the lowest body areas). If the patient displays rigor mortis or lividity, he should be left in the position found and local authorities should be called according to local protocol.
2. Encourage the caregivers to talk and tell their story.
3. Do not provide false reassurances.
4. Transport the infant to the hospital. Tell the caregivers where you are taking the child and provide clear directions about how to get there. Encourage them to have someone else drive them, and remind them to arrange for care of any siblings.
5. Deliver the infant into the hands of the emergency department staff. Be careful of what you say to your colleagues at the hospital. Casual comments such as “smothered” or “injured” may be overheard by the family and cause unnecessary emotional distress. Never say anything that the family may overhear that makes them feel they are to blame or are being blamed for the infant’s death.

To review emergency care for sudden infant death syndrome, see Figure 38-41 in the textbook.

Aiding Family Members in SIDS Emergencies

The reactions of family members to the SIDS incident will be varied. One of the most common immediate reactions of caregivers to SIDS is shock and disbelief. This may cause family members to become immobilized—in capable of making decisions. Or it may cause them to act as if they are cold and unfeeling. It is not that they do not care, just that they are having a hard time facing reality.

It may be difficult for you to deal with extreme reactions. Some caregivers may physically act out their emotions, resulting in hysteria, crying, or wailing. Caregivers may be confused and overwhelmed with guilt feelings, unfairly venting their anger and frustration on each other—or on you.

Do not dismiss the caregivers because they are not the patients in the traditional sense of the word. The tendency is to ignore the mother’s barrage of questions concerning her child, and to tell her politely to go away. While you are there to give medical care and not to become personally “involved,” you must understand that these caregivers and family members need your care also. Small, often nonverbal, gestures on your part are
Emergency Care Protocol

SUDDEN INFANT DEATH SYNDROME

1. If rigor mortis and dependent lividity are present, do not attempt to resuscitate. Turn your attention to supporting the parents.
2. Attempt resuscitation if any chance of survival exists:
   a. Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension.
   b. Suction secretions.
   c. Provide positive pressure ventilation with supplemental oxygen connected to the ventilation device at 12–20 ventilations/minute and chest compressions at a rate of at least 100/minute.
   d. Consider calling advanced life support.
   e. Expedite transport.
   f. Perform a reassessment every 5 minutes.
3. Care for the caregivers or parents.
   a. Encourage them to talk and tell their story.
   b. Do not provide false reassurances.
   c. Avoid any statements that might place blame on the caregiver or parents.
4. If resuscitation is not attempted, contact the coroner or follow your local protocol regarding moving the infant for transport.

Presence of Parents During Pediatric Resuscitation

Several scientific studies conducted within the recent past suggest that the presence of parents during resuscitation is beneficial to both children and the parents. When a child died during resuscitation, parents in one study stated that they felt more accepting of the death if they were able to be with the child at the time of death. Children who survived appeared to be more cooperative and accepting of procedures when their parents were present. The studies also found that there were minimal negative effects on the success rates of clinicians who performed the interventions.

PEDIATRIC TRAUMA

Trauma is the leading cause of death in children from ages 1 to 14. Each year, thousands of children die from unintentional injury and more are permanently disabled. Fifty percent of deaths from trauma occur within the first hour after an injury. The primary killer of American children is the automobile; however, children may experience trauma while riding bicycles, all-terrain vehicles, and motorcycles; while climbing trees; as pedestrians; during recreational activities; and even from homicide and suicide.

Despite highly effective injury prevention strategies (car seats and other child passenger restraint systems, seat belts, helmets, and educational programs for children and caretakers alike), these preventable injuries and deaths still occur at alarmingly high rates. To quote the former U.S. Surgeon General C. Everett Koop, MD, himself a pediatric surgeon, “If a disease were killing our children in the proportions that injuries are, people would be outraged and demand that this killer be stopped.”

Blunt trauma is the most common injury in children. Quite frequently, a child will be severely injured but display no early, obvious signs. (Review Chapter 27, “Trauma Overview: The Trauma Patient and the Trauma System.”) At the scene, try to reconstruct the incident and understand the mechanism of injury.

When assessing mechanism of injury during the scene size-up, look at not only the vehicle (or other object) that caused the trauma, but also the size of the patient in relation to what he came into contact with. The following are mechanisms of injury and the common patterns of injury to expect in infants and children:

- Unrestrained children in cars will probably suffer head and neck injuries because the child’s head is proportionally larger than the adult’s, and it is likely to come into contact with the interior of the car (e.g., the dashboard). Child passengers in the front seat may suffer face, neck, or chest injuries from deployment of a passenger-side air bag.
- Restrained passengers will probably suffer abdominal and/or lumbar injuries from the stress applied by the seat belt during the accident. This is especially true if the child was improperly restrained in the automobile.
If the child was struck while riding a bike, he is likely to sustain head injuries, spinal injuries, and abdominal injuries because these areas of the body are typically near the same height as the bumper and hood of a car.

If the young patient was struck by a car while walking, one should suspect the high likelihood of some or all of the three elements of the Waddell triad: head injuries, chest/abdominal injuries, and lower extremity injuries. A quick estimation of the patient’s pain site as well as the height of the bumper and hood on the car can help localize where the patient suffered trauma.

If the patient was diving into water or fell from a height, suspect head and spinal injuries.

If the mechanism of injury involved burns, be aware that the burns may be more severe to the infant or child because his skin is not as thick or durable as an adult’s. The inhalation of smoke, toxic fumes, or superheated air during a fire can cause airway swelling more rapidly and severely than in adults.

Sports injuries typically involve injuries to the head and neck.

Unfortunately, child abuse is another cause of trauma. Child abuse is discussed later in the chapter.

**Trauma and the Pediatric Anatomy**

A full discussion of trauma is presented in Chapters 27 to 36; the following is a brief overview of injuries as they relate to the infant or child patient. Remember that the treatment emphasis (regardless of injury) will always be airway, breathing, and circulatory management and consideration of spinal immobilization.

**Assessment Considerations**

Because of differences in infant and child anatomy, as compared to adult anatomy, there are some special considerations for the assessment of the infant or child trauma patient. Some of these considerations for injuries to the head, chest, abdomen, and extremities are discussed next.

**Head.** Head injuries are common in children because of the relatively larger size of the child’s head compared to the body (Figure 38-42). The weight of the head will carry it forward in advance of the body. Often in trauma the head is the first thing to strike an object. Common findings of head injury include:

- Nausea and vomiting; altered mental status
- Respiratory arrest (common to serious head injuries)
- Facial and scalp injuries (in infants and children, blood loss can be profound enough to cause hypoperfusion)

The most common cause of hypoxia in the unresponsive patient with a head injury is the tongue obstructing the airway. Therefore, an important consideration in the primary assessment is the airway.

Shock is not typically one of the signs of a closed head injury. If signs of shock are present with a closed head injury, you should suspect that other injuries (e.g., internal injuries) are more likely causing the shock.

**Chest.** Infants and children have ribs that are more pliable than adult ribs. This means that the young patient is less likely to suffer rib fractures, but is more likely to sustain internal damage (lung injury, heart wall injury) because the ribs do not protect these structures very well from forces applied to the chest. Even when you see minimal signs of external trauma, still suspect serious intrathoracic injuries.

**Abdomen.** The abdominal muscles are not as developed in the child as in the adult, so they cannot offer as much protection from blunt trauma. If you have a patient who is deteriorating rapidly without external signs of injury, suspect hidden injuries of the abdomen. Consider any trauma to the abdomen as a serious injury, and transport the patient immediately.

**Extremities.** The presentation of injuries to the extremities is the same for infants, children, and adults, and assessment and treatment of them is essentially the same. However, you should be sure to use the appropriately sized immobilization equipment rather than trying to “makeshift” an adult device to fit an infant or child.
**Burns.** Infants and children under the age of 5 years suffer more severe consequences from burns than do older children and adults. They are more at risk for hypothermia, fluid loss, and other effects, partly because of their greater skin surface in relation to body mass. In a trauma emergency that involves burns, remember to cover the burn with a dry, sterile burn dressing and keep the patient warm. If the burns meet the criteria for burn center admission in your area, transport to that facility. Review the special segments on infants and children in Chapter 29, “Burns.”

**Emergency Medical Care—Pediatric Trauma**

As with an adult, the priorities in treating an infant or child trauma patient center around airway management (Figure 38-43 ■), breathing, oxygenation, and circulatory support as follows:

1. **Establish and maintain in-line spine stabilization and the airway,** using a jaw thrust.
2. **Suction as necessary.** Constantly reassess for hemorrhage into the mouth.
3. **Provide oxygen at 15 lpm by nonrebreather mask if ventilations are adequate and any signs of poor perfusion are present,** or initiate positive pressure ventilation with supplemental oxygen connected to the ventilation device if breathing is inadequate.
4. **Provide complete spinal immobilization** (a discussion of infant/child immobilization is given later in this chapter). Never use sandbags as a means to secure the head to a long spinal board. If it ever becomes necessary to roll the backboard with the patient secured (for vomiting), the heavy sandbags will put unnecessary pressure on the head.
5. **Transport** to a hospital. See Figure 38-44 ■ for criteria that may require transport to a trauma center. It is preferred that the pediatric patient be transported to a trauma center that specializes in pediatric trauma. Pediatric emergencies often involve charged emotions. Remember that the safety of everyone is crucial during transport. All passengers should be properly restrained, the use of lights and sirens should be limited, and safe driving practices should be adhered to.

**Infant and Child Car Seats in Trauma**

Because of child-restraint laws, you will encounter most children involved in motor vehicle crashes who are in child safety seats. These seats, if properly installed, are designed to hold a child in place during impact, particularly from head-on or rear-end collisions. Their effectiveness in broadside or rotating crashes is not yet clear. A survey of caretakers by the National SafeKids Campaign found that more than half of all children are either buckled incorrectly into child safety seats or don’t use restraints at all. The most common mistakes caregivers make include choosing an inappropriate seat size for the child, improperly threading the safety belt through the seat, and failing to make the safety strap fit snugly enough.

**Removing the Infant or Child from a Car Seat**

According to the National Highway Traffic Safety Administration (NHTSA), if the car seat the child was in was involved in a moderate to severe motor vehicle crash, do not use it to transport the child. Once a car seat has been involved in a moderate to severe crash, the structural integrity is in question. If the crash was minor, the car seat the child is in can be used to transport the child only if the following NHTSA “minor crash” criteria are met:

- The vehicle was able to be driven away from the crash site;
- The vehicle door nearest the safety seat was undamaged;
- There were no injuries to any of the vehicle occupants;
- The air bags (if present) did not deploy; and
- There is no visible damage to the safety seat.
2011 Guidelines for Field Triage of Injured Patients

1. Measure vital signs and level of consciousness
   - Glasgow Coma Scale <13
   - Systolic Blood Pressure (mmHg) <90
   - Respiratory Rate <10 or >29 breaths per minute, or need for ventilatory support (20 in infant aged <1 year)

   Assess anatomy of injury
   - All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee
   - Chest wall instability or deformity (e.g., flail chest)
   - Two or more proximal long-bone fractures
   - Crushed, degloved, mangled, or pulseless extremity
   - Amputation proximal to wrist or ankle
   - Pelvic fractures
   - Open or depressed skull fracture
   - Paralysis

   Transport to a trauma center, Steps 1 and 2 attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the defined trauma system.

2. Assess mechanism of injury and evidence of high-energy impact
   - Falls
     - Adults: >20 feet (one story is equal to 10 feet)
     - Children: >10 feet or two or three times the height of the child
   - High-risk auto crash
     - Imposition, including roof: >12 inches occupant seat:
     - >18 inches any site
     - Ejection (partial or complete) from automobile
     - Death in same passenger compartment
     - Vehicle telemetry data consistent with a high risk of injury
   - Auto vs. pedestrian/bicyclist throw, run over, or with significant (>20 mph) impact
   - Motorcycle crash >20 mph

   Transport to a trauma center, which, depending upon the defined trauma system, need not be the highest level trauma center.

3. Assess special patient or system considerations
   - Older Adults
     - Risk of injury/death increases after age 55 years
     - EBSP <15 may represent shock after age 55
     - Low impact mechanisms (e.g., ground level falls) may result in severe injury
   - Children
     - Should be triaged preferentially to pediatric capable trauma centers
   - Anticoagulants and bleeding disorders
     - Patients with head injury are at high risk for rapid deterioration
   - Burns
     - Without other trauma mechanism: triage to burn facility
     - With trauma mechanism: triage to trauma center
   - Pregnancy >20 weeks
   - EMS provider judgment

   Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.

4. When in doubt, transport to a trauma center.
   - Find the plan to save lives, at www.cdc.gov/fieldtriage

National Center for Injury Prevention and Control
Division of Injury Response

FIGURE 38-44 Guidelines for Field Triage of Injured Patients.
If the child must be removed from the car seat and immobilized on a backboard, follow these guidelines:

1. Establish cervical spine stabilization manually, while your partner cuts the restraining straps and lifts the front guard of the car seat.
2. Apply a cervical spine immobilization collar (appropriately sized for the child—see item 8), or similar device, to offer mechanical support to continued manual in-line stabilization.
3. Position the entire car seat in the center of the backboard to which the patient will ultimately be secured. With a coordinated effort, tilt the car seat backward until resting on the backboard. Take care not to let the patient slide out.
4. The EMT at the head calls for a coordinated movement of the patient, following the long axis of the body, sliding the patient out head first onto the backboard, maintaining in-line stabilization, and supporting the head, neck, and trunk.
5. Remember that the back of the infant’s or child’s head is large and can cause the head and neck to flex forward. If necessary, place a small, folded towel beneath the shoulders of the patient to prevent flexion of the head and neck.
6. While you maintain manual in-line spinal stabilization, have your partner place rolled-up towels on both sides of the patient to help pad spaces prior to securing the patient with straps.
7. Secure the patient to the board using straps or wide tape. Position the securing straps across the chest, hips, and legs.
8. Finish the immobilization by placing a cervical immobilization device (CID), or other such device (you can use rolled towels), on each side of the patient’s head. Finally, secure the head to the backboard using tape across the forehead and cervical collar. (Avoid taping across the chin.)

Almost any child under age 5 will resist being restrained. Sometimes laying a hand gently on the forehead will keep the patient from fighting against the straps. You may have to manually stabilize the cervical spine until you arrive at the emergency department and hospital personnel take over. To minimize the emotional stress for the child, have a caregiver close enough to maintain eye contact with, talk to, and touch the child.

There are a number of pediatric immobilization devices on the market today. The “baby size” cervical collars are designed to fit a child at or about 24 months of age. Don’t try to force a larger collar on a small child. If you do not have a cervical collar of the correct size, improvise one by rolling up a towel, taping it, laying it in a horseshoe shape over the neck, and taping down the ends. In addition you may find specialized child-size immobilizers. Each manufacturer produces a slightly different product and it is up to your system to decide which type to use.

Safe Transport of Children in Emergency Ground Ambulances

The transportation of children in a safe manner in ground ambulances has been an issue for EMS for many years. Because of the varying guidelines at the state and local levels, there is no uniformity to the requirements for the transport of children in an ambulance. In 1999, the National Highway Traffic Safety Administration (NHTSA) published The Dos and Don’ts of Transporting Children in an Ambulance, which included the following recommendations that are still applicable to transportation of children:

- Do tightly secure all monitoring devices and equipment.
- Do ensure that available restraint systems are used by EMTs and other occupants, including the patient.
- Do transport children who are not patients properly restrained in an alternate passenger vehicle whenever possible.
- Do not leave monitoring devices and other equipment unsecured in moving EMS vehicles.
- Do not allow parents, caregivers, EMTs, or other passengers to be unrestrained during transport.
- Do not have the child/infant held in the parent, caregiver, or EMT’s arms or lap during transport.
- Do not allow emergency vehicles to be operated by persons who have not completed the DOT NHTSA Emergency Vehicle Operating Course (EVOC), national Standard Curriculum, or its equivalent.

Because of the lack of uniform implementation and unanswered questions, the National Highway Traffic Safety Administration (NHTSA) published in September 2012 the Working Group Best-Practice Recommendations for the Safe Transportation of Children in Emergency Ground Ambulances. This document makes the most current recommendations for the safe transportation of children in an ambulance. The goal of the recommendations is to “prevent forward motion/ejection, secure the torso, and protect the head, neck, and spine of all children transported in emergency ground ambulances.” It is also the consensus of the group that “it is not appropriate to transport children, even in a child restraint system, on the multi-occupant squad bench located in the rear of the ground ambulance.”

It is necessary that EMS services pre-plan for situations that might involve the transport of children. One such situation might involve an infant or child at the scene of an injured or ill adult who must be transported with the patient because no other caregiver is at the scene who is able to care for the child. Another situation may involve multiple patients who might require transport, such as a mother and one or more newborns.

The NHTSA 2012 recommendations for safe transport address five situations involving children at the scene of an emergency. Ideal recommendations are provided, with other practical recommendations provided in case the ideal recommendations cannot be achieved.
**Situation 1—An uninjured or not ill child at the scene of an injured or ill patient.**

**Ideal Recommendation:**

Transport the child in a vehicle other than the ground ambulance, using a size-appropriate child restraint system that complies with the Federal Motor Vehicle Safety Standard (FMVSS) Number 213.

**Practical Recommendation if Ideal Is Not Available:**

1. Transport the child in a size-appropriate child restraint system that complies with FMVSS #213 that is appropriately installed in the front passenger seat with the air bags turned off; or
2. In a forward-facing EMS provider’s seat/captain’s chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with FMVSS #213; or
3. In a rear-facing EMS provider’s seat/captain’s chair in a size-appropriate child restraint system that complies with FMVSS #213. The system can be a convertible or combination seat using a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider’s seat. You can also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213; or
4. Transport the ill or injured patient in the original emergency ground ambulance and leave the non-ill, non-injured child under appropriate adult supervision on the scene. Transport the non-ill, non-injured child in a size-appropriate child restraint system that complies with FMVSS #213 to hospital, residence, or other location in another appropriate vehicle.

**Situation 2—A child who is ill or injured and whose condition does not require continuous and/or intensive medical monitoring and/or intervention.**

**Ideal Recommendation:**

Transport the child in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 and secured appropriately on the cot.

**Practical Recommendation if Ideal Is Not Available:**

1. Transport in the forward-facing EMS provider’s seat/captain’s chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213; or
2. In the rear-facing EMS provider’s seat/captain’s chair in a size-appropriate child restraint system that complies with FMVSS #213. The system can be a convertible or combination seat using a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider’s seat. You can also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213; or
3. Secure the child to the cot, head first, using three horizontal restraints across the torso (chest, waist, and knees) and one vertical restraint across each of the child’s shoulders.

The cot should be positioned (follow manufacturer’s specifications) to provide for the child’s comfort based on the child’s injuries and/or illness and to allow for appropriate medical care.

**Situation 3—A child whose condition requires continuous and/or intensive medical monitoring and/or interventions.**

**Ideal Recommendation:**

Transport the child in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 and secured appropriately on the cot.

**Practical Recommendation if Ideal Is Not Available:**

Secure the child to the cot, head first, using three horizontal restraints across the torso (chest, waist, and knees) and one vertical restraint across each of the child’s shoulders. If the child’s condition requires medical interventions, which requires the removal of some restraints, the restraints should be resecured as quickly as possible as soon as the interventions are completed and it is medical feasible to do so. In the best interest of the child and the EMS personnel, the emergency ground ambulance operator is urged to consider stopping the ambulance during the interventions. If spinal immobilization of the child is required, follow the recommendations for Situation 4.

**Situation 4—A child whose condition requires spinal immobilization and/or lying flat.**

**Ideal Recommendation:**

Secure the child to a size-appropriate spine board and secure the spine board to the cot, head first, with a tether at the foot (if possible) to prevent forward movement. Secure the spine board to the cot with three horizontal restraints across the torso (chest, waist, and knees) and a vertical restraint across each shoulder.

**Practical Recommendation if Ideal Is Not Available:**

Secure the child to a standard spine board with padding added, as needed to make the device fit the child, and secure the spine board to the cot, head first, with a tether at the foot (if possible) to prevent forward movement. Secure the spine board to the cot with three horizontal restraints across the torso (chest, waist, and knees) and a vertical restraint across each shoulder.

**Situation 5—A child or children requiring transport as part of a multiple patient transport.**

**Ideal Recommendation:**

1. If possible, for multiple patients, transport each as a single patient according to the recommendations in Situations 1 through 4.
2. Transport in the forward-facing EMS provider’s seat/captain’s chair (which is currently rare in the industry) in a size-appropriate child restraint system that complies with the injury criteria of FMVSS #213.
3. For mother and newborn, transport the newborn in an approved size-appropriate child restraint system that complies with the injury criteria of FMVSS #213 in the rear-facing EMS provider seat/captain’s chair that prevents both lateral and forward movement, leaving the cot for the mother. Use a convertible seat with a forward-facing belt path. Do not use a rear-facing only seat in the rear-facing EMS provider’s seat. You may also use an integrated child restraint system certified by the manufacturer to meet the injury criteria of FMVSS #213.

NOTE: A child passenger, especially a newborn, must never be transported on an adult’s lap. Newborns must always be transported in an appropriate child restraint system. Never allow anyone to hold a newborn during transport.

Practical Recommendation if Ideal Is Not Available:
When available resources prevent meeting the criteria shown for the previous Situations 1 through 5 for all child patients, including mother and newborn, transport using space available in a nonemergency mode, exercising extreme caution and driving at reduced (below the legal limit) speeds.

Four-Point Immobilization of an Infant or Child

If an appropriate child restraint is not available and the child must be transported, adult equipment (such as a KED—Kendrick Extrication Device—or like product) can be modified to immobilize the child (Figure 38-45 ■). When you must secure an infant or child to a stretcher, be aware that most straps attached to stretchers are designed to accommodate an adult. One way to accommodate children and infants is to use a four-point safety harness, as shown in EMT Skills 38-6A to 38-6E.

Injury Prevention

Because injury is the leading cause of death and disability in children and adolescents, there must be an intentional process for identifying and preventing pediatric injuries. The term injury is not synonymous with accident. Unlike an accident, a childhood injury is an understandable, predictable, and preventable occurrence.

Pediatric injury prevention is one of the most important and challenging aspects of child health care. Young children inherently lack mature decision-making skills to protect themselves from injury, while some older children and adolescents engage in risky behaviors. No child is immune to all dangers that pose a threat to his health and safety. Statistics show that preventable childhood injuries account for 44 percent of all deaths in individuals between the ages of 1 and 19 years. In 2002, unintentional injury resulted in the death of 20,000 children, adolescents, and young adults. Rates and statistics cited here are mainly from the American Academy of Pediatrics (AAP) Policy Statements, pediatric medical journals, and the AAP publication *Injury Prevention and Control for Children and Youth*.

Injury prevention must be of paramount concern to EMS providers. Common injury prevention strategies currently employed by EMS providers across the United States include child safety seat education and inspections, fire safety programs, and community CPR training, among others. As an EMS provider, you should identify and engage in injury prevention programs within your local jurisdiction.

To review emergency care for trauma in the infant or child, see Figure 38-46 ■.

CHILD ABUSE AND NEGLECT

The estimated number of children who are abused or neglected in the United States is staggering. Six million child abuse cases were reported in 2010. Abuse results in five child deaths each day. In fact, child abuse is the only major cause of infant and child death that has increased in the last 30 years. The United States has the worst record among industrialized nations.

Physical abuse takes place when improper or excessive action is taken so as to injure or cause harm. Sexual abuse is the involvement of a child in sexual activities for the gratification of an older or more
Emergency Care Protocol

PEDIATRIC TRAUMA

1. Establish and maintain in-line spine stabilization and open the airway, using a jaw-thrust maneuver.
2. Suction secretions no longer than 3–5 seconds each time.
3. Provide positive pressure ventilation with supplemental oxygen connected to the ventilation device at a rate of 12–20 ventilations/minute if breathing is inadequate.
4. If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.
5. Occlude any open wounds to the chest with a nonporous dressing taped on three sides.
6. Manage abdominal evisceration by applying a moist sterile dressing to exposed organs, covered by a nonporous dressing secured in place.
7. If spinal injury is suspected, completely immobilize the patient to a long board.
8. Consider calling advanced life support.
9. If a pelvic injury is suspected and the patient has abdominal pain, apply the pneumatic antishock garment according to local protocol.
10. Expedite transport.
11. Splint fractures and dress wounds.
12. Perform a reassessment every 5 minutes.

Emergency Medical Care Guidelines for Child Abuse

You should be familiar with several important guidelines when called to a possible child abuse situation. While the following care steps assume that a caregiver is the abuser, remember that a child may also be abused by a relative, sibling, or neighbor.

- **Gaining entry.** If the call came from outside the family, the caregivers may resist, and entry should be handled by the police. If you are asked to help the child, calm the caregivers and indicate that you are there to help and render emergency care to the child. Speak in a low, firm voice. If the scene is, or becomes, dangerous, request law enforcement to be dispatched.

- **Dealing with the child.** Speak softly and call the child by his first name. Do not ask the child to tell what happened while he is in the crisis environment, with the possible abuser present. If the child makes a spontaneous statement about abuse, it should be recorded as a quotation.

- **Examining the child.** If you have reason to suspect abuse, perform a head-to-toe (toe-to-head or trunk-to-head for an infant or toddler) rapid trauma assessment.

- **Malnourishment and unsafe living environment**
- **Delay in reporting injuries**
- **Implausible explanations based on the child’s developmental level** (e.g., 6-month-old infant pulled boiling water onto himself)

Accidental bruises are usually found on the bumper areas; lower arms, knees, shins, iliac crests, forehead, and under the chin. “Suspicious” bruises are found on the non-bumper areas; buttocks, genitalia, thighs, ears, side of face, trunk, and upper arms. Any bruises in a nonmobile infant are suspicious.

Powerful person. Neglect is the provision of inadequate attention or respect to someone who has a claim to that attention. Emotional abuse takes place when one person shames, ridicules, embarrasses, or insults another so as to damage the child victim’s self-esteem.

The adult (usually a caregiver) who abuses a child often behaves in an evasive manner, volunteering limited, inconsistent, and contradictory information in describing what happened to the child. The caregiver may show outright hostility toward the child or another caregiver and rarely shows any guilt. An abused child usually shows fear and reluctance when asked to describe how the injury occurred.

A child will often be the victim of a combination of neglect, physical, emotional, and sexual abuse. General indicators of abuse and neglect include (EMT Skills 38-7A to 38-7D):

- Multiple abrasions, lacerations, incisions, bruises, or broken bones
- Multiple injuries or bruises in various stages of healing
- Injuries on multiple planes of the body (both the front and back or on both sides)
- Unusual wounds and pattern injuries (such as cigarette burns or bruises from a belt buckle)
- A fearful child
- Injuries to non-bumper areas (see text following the bulleted list) such as the genitals, abdomen, back, buttocks, ears, neck.
- Injuries, often lethal, to the brain or spinal cord that occur when the infant or child is violently shaken (known as “shaken baby syndrome”)
- Situations in which the injuries do not match the mechanism of injury described by the caregivers or the patient
- Lack of adult supervision
- Untreated chronic illnesses (e.g., no medication for a child with asthma)
for evidence of and clues to internal injury. Look carefully for signs of head trauma, closely examining the ears and nose for blood or cerebrospinal fluid and the eyes for pupillary changes. Conduct the examination in a matter-of-fact fashion, and keep your suspicions to yourself. Since this is likely a crime scene, also note all that you observe at the scene (e.g., condition of the home and objects such as a belt or straps that might have been used to hurt the child).

- **Dealing with the caregivers.** After administering emergency care, tell the caregivers that the child should be taken to the hospital for further care. In a separate room from the child, ask the caregivers to describe how the injury occurred. (This permits hospital staff, social service workers, police officers, and others to compare the child’s account with the caregivers’ report.) Do not question the caregivers about abuse, or act accusatory in any way. This is inappropriate and will only delay transport. Simply gather information concerning the injuries as you would for any other problem.

- **Transporting the child.** Do not allow the child to be alone with the suspected abuser. This may provide the opportunity for further abuse or intimidation.

- **Providing documentation.** When you reach the hospital, privately convey your suspicions and findings to the health care provider on duty. Know your state’s reporting laws for child abuse. Federally, you are a mandated reporter of any suspected child abuse. You need not be able to prove it, only suspect it. Failure to report is punishable by law. Document everything, but be objective, not subjective. It is not your role to write “The patient was abused,” which is a judgment. Rather, by your accurate, objective, and detailed description of the injuries and history, the person reading the run report will come to this conclusion. Record all of your findings regarding the assessment, the conditions of the home, the behavior of the caregivers, and so on. Make drawings of injury patterns or locations of injuries. Maintain total confidentiality regarding the incident; do not share it with your family or friends.

It is critical that you be aware of the reporting laws in your state and the reporting protocols for your EMS system. Aspects of the law to know are:

- Who must report suspected abuse
- What types of abuse and neglect must be reported
- To whom the reports are to be made
- What information a reporter must give
- What immunity the reporter is granted
- Criminal penalties for failing to report

Child abuse cases are particularly painful for EMS providers. Be sure you talk out your feelings with someone you can trust (making sure not to divulge particulars of the case). Feelings of anger, revulsion, frustration, and helplessness are normal. In most instances, there is no perfect solution, whether the child remains in the home or is placed elsewhere. An EMT’s skillful interview and well-written report can make a positive difference, even in bad situations.

To review emergency care for abuse and neglect in the infant or child, see Figure 38-47.

---

**PEDIATRIC ABUSE AND NEGLECT**

**1.** Consider calling law enforcement to gain entry or if the scene becomes unstable or dangerous.

**2.** Establish and maintain an open airway, extending the head only enough to allow an open airway and avoid hyperextension. If spinal injury is suspected, provide in-line spine stabilization and perform a jaw-thrust maneuver.

**3.** Suction secretions.

**4.** Provide positive pressure ventilation with supplemental oxygen connected to the ventilation device at a rate of 12–20 ventilations/minute if breathing is inadequate.

**5.** If breathing is adequate, administer oxygen via non-rebreather mask at 15 lpm; consider blow-by oxygen in infants and very young children.

**6.** Manage immediately life-threatening wounds.

**7.** If spinal injury is suspected, completely immobilize the patient to a long board.

**8.** Consider calling advanced life support if a priority patient.

**9.** Expedite transport.

**10.** Splint fractures and dress wounds.

**11.** Perform a reassessment every 5 minutes.

**12.** Special considerations when dealing with child abuse and neglect:

   a. Speak softly and call the child by his first name.
   b. Do not ask the child to re-create the situation or answer questions while still in the abusive environment.
   c. Your main goal is to conduct an assessment and treat the injured infant or child. You are not there to investigate a crime; however, note and report objectively what was observed at the scene.
   d. Do not question the caregivers about the abuse, but ask what happened.
   e. Do not let the child be left alone with the suspected or possible abuser.
   f. Provide accurate and objective documentation in the EMS report.
   g. Report your suspicions to receiving staff.

---

**FIGURE 38-47** Emergency care protocol: pediatric abuse and neglect.
Taking Care of Yourself

Taking care of a critically ill or injured child is one of the most challenging facets of an EMS career. The death of a child has a profound effect on every one of us. Almost half of the children in the United States who die from unintentional injuries are pronounced dead either at the scene or in the emergency department. EMTs who treat infants or children commonly experience stress and anxiety from:

- Lack of experience in treating children (from the relative infrequency of treating children)
- Fear of failure
- Identifying patients with their own children (e.g., “This could be my daughter . . .”)

To help alleviate stress:

- Understand that much of what you learned about adults does apply to children; typically it is not what you do but how you do it that varies when your patient is an infant or child.
- Learn skills and practice using equipment with and examining children; the best defense against anxiety is preparation, practice, and more practice.
- Focus on the task at hand while treating infants and children. In other words, temporarily separate how you feel from what you must do.

As a professional EMT, you will need to control your emotions so that you can render the best possible assistance to your patient and be supportive of other victims. But after the incident is over, you still need to deal with those feelings. Most EMS systems have ready access to mental health services that can help defuse the stress that certain events can create. Use them. If not, find a trusted friend who will listen to you and allow you to talk about the EMS field.
EMT SKILLS
38-1

Pediatric Primary Assessment

■ 38-1A Assess mental status using the AVPU method.

■ 38-1B Ensure an open airway. Listen for abnormal sounds that may indicate a need for suctioning.

■ 38-1C Assess breathing. Listen for noisy breathing. Assess for diminished breathing.

■ 38-1D Assess the strength of the peripheral pulse. In an infant, check the brachial pulse.
Assess the strength of the central pulse. In an infant, check the femoral pulse. Locate this pulse by identifying the midpoint of an imaginary line extending from the anterior superior iliac spine to the symphysis pubis, then moving your fingertip about one to two finger breadths inferior.

In a child, check the radial pulse.

To assess the strength of the central pulse in an older child, check the carotid pulse. Compare the strength of the central pulse to the previously determined strength of the peripheral pulse.

Press the top of the patient’s hand or foot.

Release and note how long before normal color returns.
The Pediatric Physical Exam

■ **38-3A** Examine the head. Look for bruising or blood or clear fluid draining from the nose or ears. Palpate gently for soft or spongy areas, skull irregularities, or crepitus (feeling of grinding bone fragments). In infants, check the fontanelle.

■ **38-3B** Check the eyes. The pupils should be equal in size and reactive to light.

■ **38-3C** Examine the neck. Check for the position of the trachea, swollen neck veins, stiffness, tenderness, or crepitus.

■ **38-3D** Examine the chest. Check for bruising, crepitus, and equal chest rise and fall. Watch for signs of breathing difficulty.
While examining the chest, be aware of the contents of the thorax.

Auscultate for breath sounds over all lung fields.

Examine the abdomen. Check for bruising, tenderness, or guarding. Look for swelling that may indicate swallowed air.

continued
Divide the abdomen into quadrants and examine each one while remembering which organs are located in each quadrant.

- Examine the pelvis for tenderness, swelling, bruising, or crepitus.
- If there is unequal movement in the extremities, immobilize the spine and the affected extremity. Check capillary refill and peripheral pulses and compare with the other arm or leg, both before and after immobilizing an extremity.
- Examine the back. Assess for tenderness, bruising, and crepitus. If the child requires immobilization, the back can be checked while the child is being log rolled onto the spine board.
**EMT SKILLS 38-4**

**Oropharyngeal Airway**

- **38-4A** A variety of oropharyngeal airways.
- **38-4B** Sizing an oropharyngeal airway.
- **38-4C** Inserting an oropharyngeal airway, using a tongue depressor for insertion in a pediatric patient.
- **38-4D** An oropharyngeal airway in place.

**EMT SKILLS 38-5**

**Nasopharyngeal Airway**

- **38-5A** Nasopharyngeal airways in a variety of pediatric and adult sizes.
- **38-5B** Retract the tip of the nose prior to inserting the nasopharyngeal airway into the nare.

---

*continued*
A Pediatric Immobilization System

38-6A While maintaining manual in-line stabilization, attach the three-point safety harness and adjust it for proper length.

38-6C Secure the arms and legs, using the extremity straps. Place straps across the forehead and chin to securely affix the patient’s head to the pediatric sleeve.

38-6D The patient is now completely immobilized to the device. Secure the patient’s legs to the backboard, using a backboard strap.

Note: The air pressure control bulb shown in photo D inflates a bladder within the device that pads voids between the patient and the pediatric sleeve. In younger patients with larger heads, the bladder should be inflated as needed to maintain the spine and the airway in a neutral position.
The completely immobilized patient secured to the cot.

Note: Always follow local protocols when performing this, or any, procedure.

EMT SKILLS 38-7

Child Abuse and Neglect

- **38-7A**  Bruise on a child’s thigh.  (© Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children’s Hospital)

- **38-7B**  Bruises on buttocks of a preschool child.  (© Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children’s Hospital)

- **38-7C**  Marks from a switch on the thigh of a school-age child.  (© Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children’s Hospital)

- **38-7D**  A loop mark on a school-age child from being whipped with an electric cord.  (© Janet M. Gorsuch, RN, MS, CRNP. Courtesy of Akron Children’s Hospital)
SUMMARY

There are two major differences between caring for an adult patient and caring for an infant or child: (1) With pediatric patients you must usually also deal with their parents or other caregivers, and (2) you must consider the developmental characteristics of pediatric patients and their anatomical and physiological differences from adults. A rapid general impression of the pediatric patient can be made “from the doorway” by using the pediatric assessment triangle to evaluate the infant or child’s appearance, work of breathing, and circulation.

The primary goal in treating any infant or child is to anticipate and recognize respiratory problems and to immediately support any respiratory function that is compromised or lost. Failure to do so will defeat any other or subsequent treatment.

You must also be prepared to assess and provide emergency medical care for other medical problems common to infants and children, including seizures, altered mental status, poisonings, fever, shock (hypoperfusion), and drowning. A particularly difficult situation is SIDS, or the sudden death of an infant from an unidentified cause. SIDS cannot be diagnosed in the field, and you must immediately attempt resuscitation and transport the infant to the emergency department.

Trauma is the leading cause of death in children ages 1 to 14. Differences in the pediatric anatomy must be considered, especially with head, chest, abdominal, and extremity injuries. In cases where you suspect child abuse, your job is to treat the child’s injuries and transport him to the hospital, to objectively document your findings and care, and to report any suspicion of abuse to the proper authorities according to the laws of your state.

Case Study Follow-up

Scene Size-up

You have been dispatched to an 11-month-old infant with an unknown medical problem. Having parked your ambulance out of the flow of traffic, you have almost run time for further scene size-up as the parents come running out of the house and thrust an infant into your arms, exclaiming, “Oh, help! Help! Jason’s not breathing!”

Primary Assessment

As soon as you see the infant, you identify cyanosis, flaccid muscles, and an absence of any response to the environment. It is obvious that this child is terribly ill, with ominous signs of respiratory arrest. As you immediately attempt to open the airway and assess for respirations, your EMT partner takes the parents and directs the mother to the passenger side of the ambulance, with the father to follow in a private vehicle to the hospital.

With little Jason in your arms, you rapidly proceed into the back of the ambulance. Your immediate opening of the airway did not result in spontaneous respirations. The mother cries from the front of the unit, “What’s wrong with my baby!”

After confirming breathlessness, you attempt to provide positive pressure ventilation without success. You reposition Jason’s airway and attempt ventilation again. Still no success. Your partner starts the unit moving to the hospital. Jason’s color worsens.

Secondary Assessment

Since Jason is still suffering from a life threat, you have not proceeded to the secondary assessment. However, your partner quickly asks Jason’s mother if he had shown any signs of illness. She shouts back to you, “He was absolutely fine.” Because Jason’s mother says he was not ill (which tends to indicate the problem is not related to a respiratory disease), and because repositioning the airway was unsuccessful, you now assume that Jason’s airway is obstructed by a foreign body.

You lay Jason on a backboard, open his mouth, and look inside for evidence of an obstruction. Finding none, you position his airway and attempt to deliver two ventilations by bag-valve-mask device. You then deliver 30 compressions. You inspect inside the mouth prior to delivering the next two ventilations. This time, when you look into Jason’s mouth, you see what looks like a peanut in the back of his throat. You quickly turn him on his side to remove it.

Jason is still not breathing so you insert an oropharyngeal airway and continue to provide positive pressure ventilations using a bag-valve mask with oxygen attached. This time, you are able to make Jason’s chest rise with each ventilation, so you know that you have succeeded in unblocking his airway. You continue ventilations at 20 breaths per minute while assessing the pulse. The brachial pulse is currently 110/minute, and peripheral perfusion seems sluggish. His SpO₂ reading is 84% but increasing.
Case Study Follow-up continued

her tears, the mother states that Jason was alone in the living room when he pulled himself up against a coffee table that had snacks in a bowl. When she returned into the living room, she says he was “just lying on the floor, gazing up, not moving—that’s when I called.”

Reassessment
You are still about 4 minutes away from the hospital when you notice that Jason’s color has changed from blue to a normal pink. His muscle tone has returned, and he is moving around actively. You stop the ventilations and assess Jason’s spontaneous respiratory effort. You find it to be at a rate of 30 per minute and with a normal depth. Jason starts crying as you now apply oxygen at 15 lpm via a nonrebreather mask. You’ve never been so happy to hear a crying baby before! Jason’s mother starts crying all over again when she hears him—this time tears of joy. Peripheral perfusion has returned to normal by the time you arrive at the hospital.

You communicate your assessment and treatment to the receiving facility and complete the appropriate paperwork. Before leaving the hospital, you stop in Jason’s room and find him to be alert and responsive to his surroundings. Both parents start crying again when they see you. The mother hugs you and your partner and the father slaps you hard on the back as they thank you for saving their son’s life.

You and your partner give each other a couple of happy grins as you mark back in service, prepared for the next call.

IN REVIEW

1. Describe differences in anatomy and physiology of the infant and child patient as compared to the adult patient.
2. Differentiate between early (compensated) respiratory distress and decompensated respiratory failure.
3. List the signs of an obstructed airway.
4. Describe the methods of determining end organ perfusion in the infant and child patient.
5. List the common causes of seizures in the infant and child patient and describe the management of seizures for the pediatric patient.
6. Describe the patterns of injury most likely to occur when pediatric patients are victims of trauma.
7. List the indicators of possible child abuse and neglect.
8. Discuss ways the EMT can deal with the emotional consequences of a difficult infant or child transport.

CRITICAL THINKING

You arrive on the scene at a residence and are directed to the second-floor bedroom by a male who is frantic. He indicates he is the father of a 2-year-old child who is really sick. He tells you that his wife placed the child in the bathtub and left for a couple of minutes to answer the phone. When she returned, the baby was submerged in the water. As you enter the bedroom, you note that the toddler is cyanotic and is limp. You yell the child’s name and then squeeze the trapezius muscle but receive no response to either. The carotid pulse is absent and there is no ventilation evident.

1. What emergency care would you immediately provide for the toddler?
2. What special anatomical characteristics would you consider when establishing an airway and ventilating the toddler as compared to the adult?
3. How would you perform CPR on this toddler?
4. Would you apply the AED? If so, what special considerations must you contemplate when using the AED on a 2-year-old?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Special Patient Populations (Content Area: Geriatrics)

**COMPETENCY** • Applies fundamental knowledge of growth, development, aging, and assessment findings to provide basic emergency care and transportation for a patient with special needs.

**OBJECTIVES** • After reading this chapter, you should be able to:

39-1. Define key terms introduced in this chapter.
39-2. Summarize age-related anatomical and physiological changes for each of the following systems:
   a. Cardiovascular
   b. Respiratory
   c. Neurological
   d. Gastrointestinal
   e. Endocrine
   f. Musculoskeletal
   g. Renal
39-3. Discuss characteristic findings and emergency care steps for common medical emergencies in the elderly population, including:
   a. Myocardial infarction
   b. Congestive heart failure
   c. Pulmonary edema
   d. Pulmonary embolism
   e. Pneumonia
   f. Stroke
   g. Chronic obstructive pulmonary disease
   h. Stroke and transient ischemic attack
   i. Seizure
   j. Syncope
   k. Hyperosmolar hyperglycemic nonketotic syndrome (HHNS)
   l. Drug toxicity
   m. Dementia and delirium
   n. Alzheimer’s disease
   o. Trauma or shock
   p. Gastrointestinal bleeding
   q. Environmental emergencies
   r. Abuse
39-4. Describe modifications that may be necessary to effectively assess and treat geriatric patients.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- acute p. 1091
- ageism p. 1106
- Alzheimer’s disease p. 1103
- arteriosclerosis p. 1093
- aspiration pneumonia p. 1099
- cardiac hypertrophy p. 1092
- chronic p. 1091
- chronic obstructive pulmonary disease (COPD) p. 1099
- congestive heart failure (CHF) p. 1098
- delirium p. 1103
- dementia p. 1102
- drug toxicity p. 1102
- dysrhythmias p. 1093
- hyperthermia p. 1105
- hypothermia p. 1105
- intracranial pressure (ICP) p. 1101
- kyphosis p. 1095
- neuropathy p. 1094
- osteoporosis p. 1095
- pneumonia p. 1099
- pulmonary edema p. 1098
- pulmonary embolism p. 1099
- seizure p. 1101
- silent heart attack p. 1096
- stenosis p. 1091
- stroke p. 1101
- syncope p. 1101
- transient ischemic attack (TIA) p. 1101
INTRODUCTION

In the United States, people over age 65 are the fastest growing segment of the population. In fact, the majority of EMS calls involve geriatric patients. Therefore, it is important that you understand the characteristics of geriatric patients and how to tailor your assessment to their special needs.

Geriatric patients differ from their younger counterparts. The elderly are at greater risk for nearly all types of injuries and illnesses. They present with different signs and symptoms because of the changing physiology of the geriatric body system. Additionally, the geriatric patient often has one or more coexisting long-term conditions that may require multiple medications. All of these factors can mask or change the presentation of the current emergency problem.

EFFECTS OF AGING ON BODY SYSTEMS

The human body changes with age. As a person ages, there are changes in cellular, organ, and system functioning. This change in physiology—which typically starts around age 30—is a normal part of aging. Although people may try to slow the aging process by diet, exercise, health care, and so on, it cannot be stopped entirely.

One trend, however, is that people are living longer with chronic (long-term or progressing gradually) illnesses. This means that the elderly are likely to constitute a larger percentage of an EMT’s patient volume. Most elderly patients will have not one but a combination of different disease processes in varying stages of development.

The aging body has fewer reserves with which to combat diseases, and this ultimately contributes to the incidence of acute (severe, with rapid onset) medical and traumatic emergencies. However, although illness is common among the elderly, it is not an inevitable part of aging.

It is important that you understand and recognize changes in geriatric body systems so that you can provide appropriate care for elderly patients (Figure 39-1). The physiological changes discussed on the following pages result from the normal aging process, not from disease progression. However, any disease or injury the patient experiences will only worsen—or be made worse by—these changes.

The Cardiovascular System

With age, degenerative processes affect the ability of the heart to pump blood. Calcium is progressively deposited in areas of deterioration, especially around the valves of the heart. Damage to the valves of the heart from this degeneration can result in a variety of problems. One problem is stenosis (narrowing) of the valve opening. When this occurs it restricts the flow of blood through the heart. In extreme cases it may reduce blood flow through the heart to the point where the heart cannot meet the demands of the body, causing deterioration of the patient. Another problem with valve damage is regurgitation (backward flow of blood). If a valve can no longer seal correctly, blood may be forced back through it. This is more common with the bicuspid than with the tricuspid valve. When this occurs, blood regurgitates into the left atrium, which can cause a backup of blood into the lungs, resulting in pulmonary edema.

With age, fibrous tissue begins to replace muscle tissue throughout the cardiovascular system. The walls
of the heart become generally thickened without any increase in the size of the atrial or ventricular chambers. This thickening of the heart walls is known as cardiac hypertrophy. It causes a decrease in the stroke volume of the heart (because the heart is unable to hold as much blood), resulting in less blood being ejected from the heart with each contraction and a consequent decrease in cardiac output, which is defined as the amount of blood ejected from the heart over a minute’s time. This decreases the efficiency of the body’s compensatory mechanisms in the face of stress that may be brought about by illness or injury.

Although older patients generally have higher resting heart rates than younger people, necessary to meet normal demands, older hearts have less ability to raise their rate to meet an increased demand from physical activity, stress, or illness. This contributes to a decreased cardiac output in the older patient.

**PATHOPHYSIOLOGY PEARLS**

As the heart grows older, there are fewer electrical conducting cells (“pacemaker cells”) and the heart is less responsive to catecholamines in the body. This prevents the heart from increasing its rate when a greater cardiac output is required.

**ASSESSMENT TIPS**

The decrease of pacemaker cells means that, although the older patient’s resting heart rate may be faster than in a younger patient, his heart cannot achieve a maximum heart rate, even during moments of physiological stress from conditions such as infection, shock, or respiratory distress that would raise the heart rate in a younger person.

Other contributors to the deterioration of cardiac output in the geriatric patient, which can be critical or
even fatal at times, are **dysrhythmias**. Dysrhythmias are irregular contractions of the myocardium secondary to electrical disturbances in the heart.

### PATHOPHYSIOLOGY PEARLS

Just as all other muscles in the body contract in response to an electrical impulse, the heart muscle contracts in response to electrical impulses created by the conduction system of the heart. With aging, there can be a general deterioration in the heart's conduction system, resulting in the inability of the heart to initiate and propagate a normal impulse.

### ASSESSMENT TIPS

When the heart's conduction system begins to fail, causing a decreasing ability to generate a normal impulse, the result is an irregularity in the heart's rate, rhythm, or contraction force. All of these can cause the patient's pulse to feel weak, irregular, or, in the case of certain fatal dysrhythmias, absent.

Another cardiovascular change as the body ages is that the arteries lose their elasticity (their ability to constrict and dilate easily), which creates greater resistance against which the heart must pump to maintain adequate blood flow through the vascular system. Widespread hardening of the arteries, or **arteriosclerosis**, tends to occur with age, which causes the arteries to become stiff and leads to further increases in the pressure the heart must pump against. Compounding the stiffness of the arteries is a drop in baroreceptor sensitivity. (Baroreceptors are specialized "pressure sensors" in the aortic arch and the carotid bodies. Baroreceptors serve only to monitor the blood pressure. When a rise or drop in pressure occurs, baroreceptors provide this information to the brain stem so that corrective measures can be taken.) With a drop in baroreceptor sensitivity, it becomes harder for the geriatric patient to regulate his blood pressure. This often leads to orthostatic hypotension, or postural hypotension, which is defined as a drop in systolic pressure and elevation in the heart rate when the patient goes from a lying to standing position.

To summarize, the aging heart grows weaker even as it must pump against a higher resistance in the arteries, there may be abnormal heart rates or rhythms because of the degeneration of the conduction system, the systolic blood pressure may start to rise because of increased arterial resistance to blood flow, and the blood vessels will not react as fast (or as efficiently) in response to stimulation from the central nervous system, which compromises blood pressure regulation during times of stress or emergency.

### The Respiratory System

Almost every component of the respiratory system experiences some type of deterioration over time. These changes in the aging respiratory system occur mainly as a result of alterations in the respiratory muscles and in the elasticity and recoil of the thorax. Specifically, there is a decrease in the size and strength of the muscles used for respiration, and calcium deposits begin to form where the ribs join the sternum, causing the rib cage to become less pliable. The average person continues to generate new alveoli until the age of 20. In the elderly, there is a decline in diffusion of oxygen and carbon dioxide across the alveolar membrane as alveolar surfaces progressively decrease. Chemoreceptors located in the aortic arch, in the carotid bodies, and on the surface of the brainstem that monitor the levels of carbon dioxide and oxygen in the blood become less sensitive over time. This results in a relative inability to detect oxygen depletion (hypoxia) or increased carbon dioxide levels (hypercapnia) in the blood and tissues.

Another change is in the airflow in and out of the lungs. In a younger person, the smaller airways (bronchioles) are supported by smooth muscle, which allows them to keep their open shape so that oxygen is easily inhaled with each incoming breath and carbon dioxide is easily exhaled with each exiting breath. With aging, there is a decrease in both the number and strength of these smooth muscle fibers that support the smaller airways. The result is turbulent airflow, which diminishes airflow to the terminal alveoli during inspiration and may also result in air trapping during exhalation. Airflow velocity through the airways slowly starts to diminish after the age of 30, and is accentuated by pathological diseases such as chronic obstructive pulmonary disease. These factors are further exaggerated with the heightened respiratory activity needed during episodes of stress, shock, or pulmonary conditions such as pneumonia.

The ability of the lungs to inhibit or resist disease and infection is also diminished with age. The cough reflex, which helps eliminate inhaled particles from the airway, may not trigger as readily, and because of the weakening of muscles, the coughing that does occur may be less forceful. The hairlike projections (cilia) that line the airway and help remove foreign particles trapped in the mucous lining are less able to move the material up and out of the airway. The nose and breathing passages secrete less of an antibody substance into the mucus that protects the body from viruses. Thus, the elderly are more susceptible to pneumonia and other types of lung infections. Dehydration, common in the elderly, increases the tendency for respiratory infection.

The net effect of these respiratory system changes in an elderly patient is that the body is less able to detect hypoxia or hypercapnia, less air enters and exits the lungs, less gas exchange occurs, the lung tissue loses its elasticity, and many of the muscles used in breathing lose their strength and coordination.

### The Neurological System

The neurological (nervous) system also becomes impaired by the normal effects of aging. There is an actual
decrease in the mass and weight of the brain and a resulting increase in the amount of cerebrospinal fluid (CSF) that occupies the extra space in the skull. As brain neurons degenerate, waste products can collect in tissues, causing abnormal structures called plaques and tangles to form. As these changes atrophy, plaques, and tangles take place, the overall ability of the brain to operate as it did when younger becomes increasingly impaired.

Nerve cells (neurons) begin to degenerate and die as early as the mid-20s, and over time this impedes the ability of the body to adapt rapidly to changes within and outside of the body. Nerve cell degeneration is responsible for the slowing of reflexes. The elderly have a harder time perceiving or sensing their body position, resulting in their becoming less steady on their feet. The combination of neurological degeneration and changes in the musculoskeletal system make it easy to understand why falls are so prevalent and serious in the geriatric population. Sight diminishes (especially at night). Although hearing loss is not inevitable, the ability to discern higher-frequency sounds may slowly be lost. Also, the geriatric patient may have difficulty in differentiating close from background noise. The illnesses and injuries that result from neurological deterioration over time can be some of the most devastating and costly to the geriatric patient.

The ability of the elderly brain to control many of the body’s processes becomes less efficient. Because of changes that occur in the brainstem and other regulatory centers of the brain, the ability to perceive hunger and thirst is altered. The ability of the brain to monitor and regulate vital functions such as the rate and depth of breathing, heart rate, blood pressure, and core body temperature can become deranged and not operate with the same efficiency during stressful times as in the younger patient.

Sensory perception tends to diminish over time, including everyday senses such as auditory, visual, olfactory (smell), touch, pain, hot and cold sensations, and body position. For example, there is diminishment in visual acuity (the ability to see clearly) and visual accommodation (the ability to adjust the lens of the eye to maintain clear vision on objects of varying distances). The deterioration of these visual capabilities can contribute to accidental trauma from falls and contribute to the inability to see medications clearly enough to ensure proper dosage. As part of the eyesight deterioration, there is a drop in the ability to discriminate color and progressive impairment to see clearly when it is darker in a room or outside. Diminished tear production leads to eye irritation from inadequate moisture. The disease processes listed next also compromise the elderly patient’s ability to see clearly:

- **Cataracts** are a clouding of the lens of the eye. The clouding (sometimes referred to as opacity) can be slight, causing some visual disturbance, or significant, severely obstructing light from entering the eye. If sufficient light cannot pass into the eye for focusing on the retina, then it becomes difficult or impossible to see clearly.

- **Glaucoma**, which is the second leading cause of blindness in the United States, is a disease process in which increased intraocular pressure damages the optic nerve and inhibits the ability of the eye to transmit visual information properly.

- **Macular degeneration** typically occurs in older adults and affects the ability to see objects in the center of the visual field. This makes activities like reading or recognizing a person’s face difficult or impossible. Sometimes, however, there may be enough peripheral vision left intact that the person can still carry on with most activities of daily life.

- **Retinal detachment** is a condition where the retina (the light-sensitive portion of the posterior eye) becomes detached from the supportive tissue behind it. The retina converts light images to nerve impulses for transmission via the optic nerve to the brain, but when it becomes detached it can no longer do so. Retinal detachment may be local or complete, causing visual disturbances up to and including blindness.

### Neurological TIPS

Neurological changes, especially diminished vision and hearing, separately or in combination, can easily result in falls, automobile crashes, and other causes of injury.

Although many people experience hearing loss from exposure to loud noise over time, there may also be some natural degeneration of a person’s ability to hear with aging. The effect of aging on hearing is known as presbycusis, or age-related hearing loss. It is described as progressive, bilateral, and symmetrical hearing loss. The hearing loss is most marked at higher frequencies. If hearing loss becomes severe enough that it inhibits communication, the patient may need a hearing aid (or sometimes hearing aids for both ears). When communicating with a patient who needs a hearing aid, ensure that the patient is wearing it and that it is turned on. Do not talk loudly when communicating with a person with a hearing aid, as it may cause what is heard to be distorted and difficult to understand.

Another neurological disorder is neuropathy, which is any derangement or abnormal function of the motor, sensory, and autonomic nerve tracts. It could be diffuse, involving multiple neurons and nerve tracts that affect many parts of the body, or focal neurons that affect a single, specific nerve and part of the body. Generally, its findings include pain, numbness, tingling, swelling, muscle weakness, or even absent pain perception. This can further complicate the presentation of findings characteristic to a particular problem. For example, recall how diabetic patients may not experience the pain from a myocardial infarction because of...
the neuropathy that develops secondary to long-term diabetes. This patient may not realize he is having a heart attack because he doesn’t feel the characteristic pain. Many diabetics are especially prone to developing peripheral neuropathy, which affects the extremities, especially the hands and feet.

**The Gastrointestinal System**

Changes in the gastrointestinal system contribute to various medical conditions, including malnutrition. A reduction in the senses of taste and smell results in decreased food enjoyment (possibly causing the person to stop eating regularly). Deterioration of structures in the mouth and periodontal disease can cause loss of gum tissue and consequent tooth loss. There is a drop in salivary flow from degeneration of the salivary glands. The smooth muscle contractions of the esophagus decrease, and the opening between the esophagus and the stomach loses tone, which can result in chronic heartburn as gastric acid enters the esophagus from the stomach. There is also a decrease in the amount of hydrochloric acid secreted into the stomach. This contributes to less efficient breaking down of food prior to its entering the small intestine.

With age, the liver decreases in size, weight, and function, which decreases hepatic enzymes, causing a loss in the liver’s ability to aid in digestion and to metabolize certain drugs. These effects are further hampered by the reduction in blood flow that occurs over time to the liver.

Smooth muscle contractions (peristalsis) throughout the gastrointestinal tract are slowed, so it takes longer for food to move through the system. As a result of degeneration of the lining of the small intestine, nutrients are not as readily absorbed, further contributing to malnutrition. Fecal impaction and constipation are common because smooth muscle contractions of the large intestine diminish. In some, degeneration of the rectal sphincter muscle can cause loss of bowel control.

**The Endocrine System**

The progression of age-related changes to the endocrine system is unique. For most people, the changes in the endocrine system have no noticeable effect on overall health. The changes may, however, increase the risk of some health problems. For example, changes in insulin effectiveness increase the risk of type 2 diabetes.

Both hormone levels and target organ response are altered in the aging endocrine system. There can be an increase in the levels of hormones that increase blood pressure (vasopressor hormones such as norepinephrine and vasopressin), which contributes to development of hypertension (high blood pressure). The levels of certain hormones that help regulate the body’s fluid balance (such as renin and aldosterone) become deranged and contribute to fluid imbalance, which has further effects on blood pressure. A decrease in target organ response to beta (sympathetic) stimulation in the heart and vascular smooth muscle is caused by diminishment in receptor cell sensitivity. The net effects of these endocrine changes are seen in the clinical syndromes of hypertension and orthostatic hypotension that are characteristic of the elderly.

In addition, aging produces mild carbohydrate intolerance and a minimal increase in fasting blood glucose levels, caused by a drop in receptor cell responsiveness to insulin. Atrial natriuretic hormone (ANH) from atrial muscle tissue helps to regulate water, sodium, potassium, and fat. The serum level of this hormone is typically increased in the elderly and contributes to fluid imbalance. Aging also decreases the metabolism of thyroxine, a hormone that influences metabolic activity of the body. With a drop in the secretion of thyroxine, there is also a decrease in its conversion into triiodothyronine, the most powerful thyroid hormone, which affects almost every process in the body, including body temperature, growth, and heart rate.

Collectively, changes to the endocrine system may cause elevation of blood sugar levels (especially after eating a large meal), alteration of the blood pressure (resulting in high or low blood pressure), and fluid imbalance (resulting in either fluid retention or dehydration).

**The Musculoskeletal System**

The most significant musculoskeletal change resulting from aging is a loss of minerals in the bones, which is known as osteoporosis. This makes the bones more brittle and susceptible to fractures and slows the healing process. The osteoporosis itself is less a problem than the possible resulting bone injury or immobility, which can lead to illness and death.

The disks located between the vertebrae of the spine start to narrow, which causes the characteristic curvature of the spine, seen in two out of every three elderly patients, known as kyphosis. This curvature is seen along the entire spine but is usually most pronounced in the thoracic vertebrae and can complicate spinal immobilization. It may be necessary to place additional padding under the patient to fill voids and create effective immobilization (EMT Skills 39-1).

Joints begin to lose their flexibility with aging. There is a thinning of the cartilage that covers the articular surfaces where joints meet, and the synovial fluid that surrounds these joints starts to thicken. The ligaments that provide joints with stability start to weaken as well. The effects are diminished range of joint motion, possible pain with movement, and increased risk of joint injury. Complicating this is the general and progressive loss of skeletal muscle mass. The elderly are more prone to falls because of general weakness, worsening balance, and a loss in joint mobility. Because of the
changes in bone structure, these falls commonly result in skeletal fractures that take longer to heal than in younger people and that may also cause other medical emergencies.

The Renal System

The normal aging process also affects the renal system (kidneys). The kidneys become smaller in size and weight because of a loss of the functional parts of the kidney, the nephrons. The loss of nephrons can reduce the actual weight of the kidneys by about one-third of their normal weight. The effect is a decrease in the surface area of the kidney available to filter blood. The arterial system supplying the kidneys is also subject to the changes in the cardiovascular system, which results in a drop in renal blood flow. In combination, these changes result in a lesser amount of blood per minute passing through the kidneys for filtration, in addition to the decrease in available filtration surface area.

Since the kidneys play a vital role in fluid and electrolyte balance, kidney malfunction or injury typically leads to a secondary disturbance in fluid balance and electrolyte distribution. Since many drugs (including antibiotics) are filtered out by the kidneys, it is common for the elderly to suffer from drug toxicity if they take too much medication or take it too frequently. The geriatric renal system may be functional enough to meet the demands of the body on a day-to-day basis, but as a result of acute illness or injury the elderly patient’s renal system may fail.

The Integumentary System

Aging results in tremendous changes in the integumentary system (the skin). The skin becomes thinner from a deterioration of the subcutaneous layer, and there is less attachment tissue between the dermis (inner layer) and epidermis (outer layer). An elderly person’s skin is much more prone to injury than the younger person’s skin. Replacement cells are produced less rapidly, so wounds heal more slowly and skin is slow to replace itself. Less perspiration is produced, and the sense of touch is dulled. As the skin breaks down, there is a tendency for sores and tearing injuries to occur. This diminishes the effectiveness of the skin as a protective barrier in keeping microorganisms out of the body. Also, skin is the major organ of thermoregulation; therefore, hypothermia and hyperthermia are more likely in the elderly.

SPECIAL GERIATRIC ASSESSMENT FINDINGS

Because of the general decline in virtually every body system of the geriatric patient, the elderly are prone to certain traumatic and medical emergencies that can cause rapid deterioration. As stated earlier, aging may change the individual’s response to illness and injury. Pain may be diminished or absent, and consequently the patient or EMT may underestimate the severity of the patient’s condition. It is important that the EMT recognize these emergencies and provide appropriate emergency care. Having an understanding of what is occurring physiologically in these emergencies will help in recognizing and providing prompt, appropriate care. Be alert for the findings discussed on the following pages as you assess patients over the age of 65. As you read about these conditions, refer to Table 39-1 for special considerations regarding such medical conditions in the elderly.

Assessment Finding: Chest Pain or Absence of Chest Pain

Heart Attack (Myocardial Infarction)

A lack of oxygen and other nutrients to the heart typically produces chest discomfort in a younger person. In contrast, as a result of decreased pain perception, geriatric patients may experience what is known as a silent heart attack. The elderly heart attack patient may have no, or very little, chest discomfort. Instead, the geriatric patient suffering a heart attack will usually present with general complaints such as weakness, fatigue, confusion, dizziness, nausea/vomiting, abdominal pain, and syncope. Trouble breathing is also a common initial complaint. Although one-third of elderly heart attack patients never experience pain, aching shoulders and indigestion are common.

The patient who chronically experiences chest pain may take nitroglycerin for the problem, so finding nitroglycerin medication at the scene will clue you in to a patient’s history of heart problems. If the patient does take nitroglycerin, you may be able to assist in the administration of it with permission from medical direction (Figure 39-2). (Refer to Chapter 17, “Cardiovascular Emergencies,” for a thorough discussion of nitroglycerin.)

Emergency care steps for a suspected heart attack—whether or not the patient’s symptoms include chest pain—are to administer high-concentration oxygen, administer nitroglycerin as appropriate in consultation with medical direction, and transport the patient expeditiously (but cautiously) to the hospital.
Incidence of chest pain decreases with age. The most common signs or symptoms are syncope (fainting), confusion, and dyspnea (shortness of breath).

Other signs of pneumonia may be falls or a rapid decline in the patient’s ability to do normal daily activities.

More than half of patients may not have a fever (are afebrile) with the pneumonia.

Increased respiratory rate (tachypnea) is almost always present in pneumonia.

Crackles may not be heard when the chest is auscultated because the elderly patient may not cooperate and take deep breaths when requested during the physical exam.

Pneumonia

Elderly patients with pneumonia commonly do not present with classic signs and symptoms. Cough is a common complaint, except with those, often in nursing homes, who can’t complain because of an altered mental status. In those patients, altered mental status is the predominant sign.

Other signs of pneumonia may be falls or a rapid decline in the patient’s ability to do normal daily activities.

More than half of patients may not have a fever (are afebrile) with the pneumonia.

Increased respiratory rate (tachypnea) is almost always present in pneumonia.

Crackles may not be heard when the chest is auscultated because the elderly patient may not cooperate and take deep breaths when requested during the physical exam.

Pulmonary embolism

Approximately 90 percent of emboli originate from deep vein clots in the lower extremities and near vessels in the pelvis.

Elderly patients are more prone to pulmonary emboli because of immobility or reduced activity, congestive heart failure, tumors, and surgery.

The most common signs and symptoms are shortness of breath (dyspnea), chest pain, and cough. Some elderly patients will not complain of any of the three most common complaints and may only present with confusion. Also look for rapid respiratory rate (tachypnea) and rapid heart rate (tachycardia).

Stroke

Headache, including migraine, is less common in the elderly; therefore, headache may be a significant finding in the elderly.

Head pain may indicate bleeding within the brain or skull, tumors, infection, herpes zoster (skin lesions, “shingles”), or metabolic disorders.

Approximately one-third of patients over 75 years of age exhibit symptoms of coronary artery disease. Close to one-half of males and one-third of females over 74 years of age will suffer an unrecognized heart attack (myocardial infarction).
**Congestive Heart Failure**

**Congestive heart failure (CHF)** is another type of emergency seen typically in the geriatric patient (see Chapter 17, “Cardiovascular Emergencies”). It can be a chronic condition that the patient may tell you about during your history taking, or it may have an acute onset and be the cause for the elderly person summoning EMS.

Even though CHF is primarily caused by a cardiac disease, it can present differently than a heart attack. It is caused by a heart that becomes weakened over time as a result of the changes in aging, as well as hypertension, arteriosclerotic disease, dysrhythmias (abnormal heart rhythms), and heart valve damage. As a result of these changes, the heart can no longer pump as effectively, and blood begins to cause a “backup” in the peripheral blood vessels and the vessels in the lungs. This causes fluid to leak out of the vessels. Assessment findings characteristic to CHF include edema in the extremities, jugular vein distention, altered mental status, fatigue, rales or crackling upon auscultation, possible wheezing, dyspnea, orthopnea, chest pain, and anxiety. Emergency care steps for CHF include administering high-concentration oxygen, placing the patient in a Fowler’s position, and expediting transport. Be sure to watch for inadequate breathing, and be prepared to ventilate.

**Assessment Finding:**
**Shortness of Breath (Dyspnea)**

Respiratory distress can result from a number of conditions occurring in the geriatric patient. It can be the primary symptom of a pulmonary problem, or it can be a symptom secondary to failure of a different body system (CHF, for example, can cause difficulty in breathing). Difficulty breathing or “shortness of breath” (dyspnea) is one of the more common complaints noted in the elderly (see Chapter 16, “Respiratory Emergencies”). The elderly already have diminished respiratory function. Any additional burden can easily overwhelm the respiratory system and lead to inadequate breathing. The four most common causes of shortness of breath are pulmonary edema, pulmonary embolism, pneumonia, and chronic obstructive pulmonary disease (Figure 39-3).

**Pulmonary Edema**

**Pulmonary edema,** or fluid in the lungs, can have a gradual or sudden onset and can result in death if proper emergency care is not provided. Pulmonary edema typically results from the failure of the heart’s pumping function. Causes include CHF, heart attack, dysrhythmia, or valve damage. The left ventricle starts to eject less blood than the right (the ventricles should eject the same amount of blood simultaneously) resulting in excessive pressure in the vessels in the lungs. Fluid begins to “leak” into the space between the alveoli and the capillaries, causing pulmonary edema, which results in inadequate gas exchange and respiratory distress.

Assessment findings include severe respiratory distress especially when lying down (orthopnea), altered mental status, coughing with possibly blood-tinged sputum, and other signs of CHF. As with CHF, emergency care includes administering oxygen to maintain an SpO₂ of 94% or greater, placing the patient in a Fowler’s position, monitoring for inadequate breathing, and transporting expeditiously. Continuous positive airway pressure (CPAP) is often indicated in elderly patients who have chronic obstructive pulmonary disease (COPD) to maintain oxygenation.
pressure (CPAP) can be administered if the patient is in significant respiratory distress or if the SpO2 cannot be maintained at 94% or greater as long as no contraindications exist and your protocol allows you to do so. It may be necessary to perform positive pressure ventilation in severe cases.

**Pulmonary Embolism**

Pulmonary embolism, or blockage in the arteries of the lungs, is a respiratory emergency seen more frequently in elderly than in younger patients. Pulmonary embolism may present with a sudden onset of dyspnea, in conjunction with chest discomfort that is localized and does not radiate (there may also be back or shoulder pain), weakness, or possibly syncope. The patient may also be anxious. This emergency usually occurs when a blood clot (embolism) breaks free from veins of the lower extremities or pelvis and is transported back through the right side of the heart. The clot eventually lodges somewhere in the arteries of the lungs.

This results in poor oxygen and carbon dioxide gas exchange in the alveoli because the clot is preventing blood from flowing through the capillaries. The inadequate exchange of oxygen and carbon dioxide results in respiratory distress. The degree of respiratory distress depends on the changes to blood flow and gas exchange. With large clots the blood cannot make it from the right side of the heart to the left, and hypotension ensues. The EMT may also notice localized wheezing to one of the lungs, and with blockage the pulse oximeter may drop dangerously low.

*If a large embolism occludes more than half of the pulmonary circulation, it can rapidly cause death.*

Predisposing factors to a pulmonary embolism include aging, smoking, cancer, fractures of large bones, major surgery, existing cardiovascular disease, prolonged bed rest, oral contraceptives, and trauma. Emergency care includes administering oxygen to maintain an SpO2 of 94% or greater and monitoring for inadequate breathing. Provide positive pressure ventilation, if necessary, and transport the patient rapidly to the hospital with ALS intercept.

**Pneumonia**

Pneumonia is an infection of the lungs caused by a bacterium, virus, or other pathogen. It is common in the elderly because of a diminished ability of the respiratory system to fight off infections. Of special concern is aspiration pneumonia, which often results from accidental aspiration of food or vomitus into the lungs. That is why preventing aspiration of foreign material is so important in the maintenance of the geriatric airway.

Pneumonia has a tendency to strike when multiple risk factors are present. Some of these include advancing age, being bedridden at home or institutionalized, immune system compromise, a history of other pulmonary diseases (for example, chronic obstructive pulmonary disease), cancer, and a history of inhaled toxins.

The elderly pneumonia patient may be insensitive to the subtle pain from pneumonia and may not exhibit the classic signs and symptoms of pneumonia that would appear in a younger patient (high fever, chills, chest pain, coughing up bloody sputum). In the elderly, watch for increased respiration rate, progressive worsening of dyspnea, dyspnea with exertion, congestion with or without fever and chills, a cough with some sputum production, possible wheezing, and other findings of malaise (nausea, vomiting, musculoskeletal pain, weakness, and weight loss). The patient may also display an altered mental status. In severe cases of pneumonia, the patient may be found to be breathing inadequately, hypotension could occur, dehydration could be present, percussion of the chest may produce dull sounds, and increased vocal fremitus (also known as tactile fremitus) may be present.

Emergency care is primarily supportive and includes maintaining the patient’s airway, administering oxygen to maintain an SpO2 of 94% or greater, and transporting the patient in a Fowler’s position or a position of comfort. Continuous positive airway pressure (CPAP) can be administered if the patient is in significant respiratory distress or if the SpO2 cannot be maintained at 94% or greater as long as no contraindications exist and your protocol allows you to do so. If breathing becomes inadequate, provide oxygen via positive pressure ventilation.

**Chronic Obstructive Pulmonary Disease**

Chronic obstructive pulmonary disease (COPD) is actually a disease complex that includes a number of individual pulmonary disease processes (principally chronic bronchitis and emphysema) that result from the gradual deterioration of the pulmonary structures. (Refer to Chapter 16, “Respiratory Emergencies,” for a discussion of COPD.) The effects of COPD cause a disturbance in gas exchange in the lungs.

The EMT will typically encounter the elderly COPD patient complaining of respiratory distress and will observe the patient using accessory muscles when breathing. Upon arrival at the scene, the EMT may find the patient already on oxygen from a home oxygen unit (Figure 39-4 ■). Emergency care includes the administration of oxygen to maintain an SpO2 of 94% or greater. The EMT may also help relieve the respiratory distress, after consultation with medical direction, by assisting the patient with administering his prescribed metered-dose inhaler. Continuous positive airway pressure (CPAP) can be administered if the patient is in significant respiratory distress or if the SpO2 cannot be maintained at 94% or greater as long as no contraindications exist and your protocol allows you to do so.

Transport the patient in a position of comfort, which will usually be a Fowler’s (sitting) position. Since the COPD patient can become easily fatigued from the
effort of breathing, monitor the patient closely for signs of inadequate breathing. If breathing becomes inadequate, provide positive pressure ventilation with supplemental oxygen.

Assessment Finding: Altered Mental Status

You will encounter many elderly patients who are alert and who respond appropriately to you and to their environment. Some, however, will be unable to remember details, whereas others may be routinely confused or totally unresponsive. The geriatric person presenting with altered mental status may be one of the most challenging patients you will encounter. There can be a variety of causes of altered mental status (Figure 39-5). The patient may have an altered mental status from some chronic condition (such as Alzheimer’s disease), from an acute onset of the primary emergency (such as stroke), as a sign of an underlying medical illness (for example, poor perfusion of the brain when the volume of blood is depleted by severe bleeding), or even from the effect of prescription drugs.

Never assume that a patient’s altered mental status is normal for him or that it is “what happens when you get old” and risk missing an important sign of injury or illness. As you assess the patient, attempt to determine if the patient’s mental status is normal for him or if it represents a significant change. (Family members or others who know the patient may be able to supply this information.) Remember also that the noise of radios, a siren, strange voices, or a different environment may add to the patient’s confusion. Attempt to explain or reduce the noise.

While the management principles remain essentially the same regardless of the cause of the altered mental
status, an understanding of common underlying causes will assist you in knowing what to look for during scene size-up and in formulating questions to ask the patient, friends, or bystanders during history taking. Following are certain types of emergencies that can cause altered mental status in an elderly patient.

**Stroke**

*Stroke* is a common reason for altered mental status in the elderly patient (see Chapter 18, “Altered Mental Status, Stroke, and Headache”). A stroke occurs when a blood vessel in the brain becomes blocked by a clot, obstructing blood flow, or ruptures and allows blood to accumulate in the brain tissue. Since the skull does not expand, the pressure within the brain (intracranial pressure, or ICP) sharply increases, while the nerve cells in the brain start to die or malfunction from the pressure. The level of carbon dioxide in the brain increases, which causes cerebral vessels to dilate and further increases the ICP.

The extent and location of the stroke affects the severity of the altered mental status. The patient could be simply slightly disoriented or totally unresponsive. A massive stroke can lead to death within minutes. Aside from altered mental status, you may also find the following signs and symptoms:

- Inequality of pupils
- Slurred speech or abnormal speech patterns
- Headache
- Memory disorders
- Alterations in the respiratory pattern
- A rapid, or abnormally slow, heart rate
- High systolic pressure (hypertension), which gradually becomes normal or hypotensive
- Possible seizures
- Nausea or vomiting
- Muscle weakness or paralysis (usually to one side of the body)
- Sensory loss unilaterally (on one side of the body)

Key emergency care for a stroke centers around recognition, aggressive oxygenation, and ventilation. Your emergency care steps for stroke should include protecting the airway, maintaining oxygen saturation at an SpO2 reading of 94% or greater, and suctioning as necessary to prevent aspiration. You will transport the patient in a Fowler’s position, if possible, or a lateral recumbent (recovery) position if he is unresponsive and there is no suspicion of trauma.

**Transient Ischemic Attack**

*Transient ischemic attack (TIA),* or “mini stroke,” is similar in presentation to a stroke, but the signs and symptoms are completely reversed within 24 hours of onset, usually sooner. No permanent neurological dysfunction occurs with a TIA. A TIA is caused when blood supply to an area of the brain is temporarily occluded, causing a malfunction of brain tissue that is not being perfused. The malfunctioning brain tissue can cause the same signs and symptoms as stroke and is a warning sign of an impending stroke. Treatment steps are the same as those discussed for stroke.

**Seizure**

*Seizure,* a sudden and temporary alteration in the mental status caused by massive electrical discharge in a group of nerve cells in the brain, is another cause of disorientation in the elderly. (Refer to Chapter 19, “Seizures and Syncope,” for a full explanation.) You may encounter the patient while he is actively seizing, or after the seizure is over and the person is still unresponsive or slow to respond (the postictal state, or recovery period). Common causes of seizures in the elderly include cardiac arrest, low blood sugar, tumors, head trauma, stroke/TIA, infections, or electrolyte imbalance from kidney problems.

Treating an elderly seizure patient is the same as treating the younger seizure patient. Do not physically restrain the patient while he is actively seizing. Monitor the airway and suction as necessary (patients often vomit during seizures). Administer oxygen to maintain an SpO2 reading of 94% or greater if breathing is adequate, or provide positive pressure ventilation if breathing is inadequate. Place the patient in a recovery position to help prevent aspiration if he is unresponsive and if trauma is not suspected.

**Syncope**

*Syncope* (fainting) is a common emergency for the elderly patient. Syncope is a temporary loss of responsiveness that usually reverses once the patient is lying down. Caused by a reduced blood flow to the brain, it can be a sign of a number of underlying diseases as well as a side effect of medications or even a reaction to strong emotion. Emergency care steps in treating a syncopal episode include ensuring an adequate airway, maintaining adequate oxygenation at 94% or greater if the breathing is adequate, or with positive pressure ventilation if the breathing is inadequate, and placing the patient in a recovery position to prevent aspiration if he is still unresponsive. If the patient suffered a fall in conjunction with the syncopal episode, he should be fully immobilized as a precautionary measure.

**Hyperosmolal Hyperglycemic Nonketotic Syndrome**

Hyperosmolal hyperglycemic nonketotic syndrome (HHNS) is a diabetic complication that is more common to the elderly patient with diabetes mellitus (see Chapter 20, “Acute Diabetic Emergencies”). HHNS is a condition...
Drug Toxicity

Drug toxicity, or an adverse or toxic reaction to a drug or drugs, is a condition for which the elderly patient is more at risk than the younger patient (see Chapter 22, “Toxicologic Emergencies”). The geriatric population takes approximately one-third of all prescription medications. They also buy the greatest number of over-the-counter medications (Figure 39-6). Since they tend to have a number of coexisting diseases, they are at greater risk for drug interaction from prescription medications.

Certain medications (taken individually or in conjunction with others) have a tendency to alter the patient’s mental status, cause a syncopal episode, or even cause total unresponsiveness. Drug toxicity may also be caused by an error in dosing: the elderly person may take a wrong dose because of poor eyesight, confusion, forgetfulness, or a tendency to take the medication after it is no longer needed.

Treatment for a patient suffering from drug toxicity is based on figuring out how the drug is affecting the patient’s airway, breathing, and circulation status—not what drug caused the problems. Thus, key treatment includes airway maintenance, oxygenation, and prevention of aspiration. If possible, take all medications found on the patient or at the scene (prescription and non-prescription) to the hospital. A poison control center can be a good resource for additional information.

Dementia and Delirium

Dementia is a condition resulting from the malfunctioning of normal brain activity. It is a chronic, irreversible condition that can be severely worsened by infection, medication change, trauma, or another acute condition. It is normal for the mental processes to
undergo changes as a person ages, but approximately 15 percent of those over the age of 65 develop severe dementia, which results in profound disturbances in mental functioning. The characteristic results of dementia are chronic changes in cognition, including loss of short-term memory; decline in intellectual abilities; and decline in judgment, math ability, and abstract thought. The patient with dementia may present as agitated. It is important to remember that the anger is not directed at the EMT; rather it is a product of the disease process.

Dementia may be caused by medications, especially analgesics, sedatives, tranquilizers, and those taken to reduce blood pressure or ease the symptoms of Parkinson's disease. Other common causes of dementia in the elderly include Alzheimer's disease, strokes, brain trauma and tumors, visual and auditory problems, endocrine and metabolic disorders, heart disease, constipation, urinary retention, infection, depression, alcohol use, chronic pain, certain workplace exposures, and other underlying diseases such as Huntington chorea.

Management of the patient with dementia is supportive in nature, and includes maintaining adequate oxygenation at an SpO2 of 94% or greater, positioning, and transport to the hospital with reassessments to ensure patient stability. While this seems straightforward, problems may arise in the management of a patient with dementia because of the altered mental functioning. For example, the patient may be uncertain of what the actual complaint is, or may simply be a poor historian and not be able to adequately verbalize the signs or symptoms. These patients may not be able to follow your simple commands, and coupled with the anxiety they may experience as you take them out of their known home environment or as you treat them, their anger may escalate into physical aggression.

Delirium can also result in an alteration in mental status, but unlike dementia—which is a chronic condition—delirium presents with a more recent and sudden onset. Delirium is often described by family members as starting abruptly, and it may present with delusions. The patient may have a history consistent with a delirium episode that can include intoxication or withdrawal from alcohol, sedative use, infectious medical conditions, dehydration, fever, stroke, blood sugar level abnormality, a psychiatric disorder, malnutrition, hypoxia, endocrine disorders, or even environmental emergencies. During your assessment of the patient with delirium, you may note the following findings: faster onset, disjointed (nonsensical) thought processes, incoherent speech, declines in mental status, and a fluctuating course of psychomotor activity.

Delirium is not an emergency in itself; rather, it is indicative of a significant disturbance in some body system (e.g., renal failure or hepatic failure). The additional physical findings (vitals, breath sounds, pupils, motor, and so on) will reflect the underlying pathology that is causing the delirium. The best way to differentiate delirium from dementia is to ask a family member or the primary care provider about the patient's mental status an hour ago or even on the previous day. A history consistent with a recent onset signals delirium. If the change in mental status has progressed over a long period, or if the condition has been present for a number of years, it signals dementia. Management of delirium, as for dementia, is primarily supportive in nature and includes maintaining an SpO2 of 94% or greater, patient positioning, protection from injury, and transportation to the hospital. Remember though, if the delirium is caused by a reversible cause the EMT can treat (for example, low blood sugar), provide specific management for that condition.

**Alzheimer’s Disease**

Alzheimer’s disease is believed to affect more than 2 million Americans and to be responsible for more than 100,000 deaths each year in the United States. The disease does not directly cause death, but it can cause patients to stop eating, become immobile, and eventually be subject to numerous infections. It is thought to be the most common cause of dementia in the elderly. While its cause is presently unknown, it is believed to be a disease of the nerve cells in which brain cells degenerate and die. Alzheimer’s disease is both progressive and global in nature, involving the central nervous system. Although it is commonly a disease of the elderly, it can affect people as young as age 40.

The signs and symptoms of Alzheimer’s disease mimic those of many other conditions. (The presence of Alzheimer’s disease can be determined definitively only on examination of the brain during autopsy.) The disease causes confusion, emotional depression, irritability, and violence between lucid intervals. There is a progressive loss of appetite and a decreasing ability of the patient to care for his own needs. Eventually, the patient does not recognize loved ones; in late stages, the patient becomes childlike. Alzheimer’s disease patients often attempt or commit suicide.

The treatment of patients suffering from Alzheimer’s disease or any other form of dementia requires special compassion from the EMT. Naturally, you must take necessary actions to establish and maintain the airway, breathing, oxygenation, and circulatory systems. But often you will be transporting these patients in a nonemergency setting. You may find the patient very uncooperative, even combative, with biting, spitting, and punching at times. Remember that the uncooperativeness and aggression are symptoms of the disease, not conscious acts of aggression against you personally. You may also find yourself informing the patient of the same thing over and over because his mind may not be able to process, let alone remember, what you are saying. Do not take the patient’s actions or words personally.
Assessment Finding: Signs of Trauma or Shock

Trauma is one of the leading causes of death in the geriatric population. The type of trauma seen most frequently in the elderly is blunt trauma from falls, motor vehicle crashes, and pedestrians struck by automobiles. There are numerous reasons for this, including:

- Altered mental status from a variety of conditions
- Slower reflexes
- Failing eyesight and hearing
- Medication effects
- Activities that exceed physical limitations
- Arthritis
- Blood vessels that are less elastic and more subject to injury
- Fragile tissues, brittle bones, and stiffer joints
- General loss in muscle tone and strength

Falls are responsible for half of all accidental deaths in the elderly and are a common cause of head injuries. There are sometimes environmental reasons why the elderly fall. These may include stairways without handrails, slippery bathtubs, loose rugs, steep steps, or improperly fitting footwear. There are also a number of medical reasons why the elderly fall. The most common are dizziness, side effects from medications, heart rhythm problems, spinal weakness, syncope, transient ischemic attacks, low blood pressure, internal bleeding, and poor vision.

Many elderly people who fall do not develop life-threatening injuries and do not die as a result of the fall. But certain injuries are common among those who fall. Make sure you assess for a hip fracture, head injuries, chest and abdominal injuries, spinal fractures, and fractures of the hand, wrist, forearm, or shoulder (caused by falling on an outstretched hand).

Head injuries are harder to detect in the elderly. As mentioned previously, the brain shrinks in size during the aging process. Even though there is additional cerebrospinal fluid surrounding the smaller brain, there is still more space in which the brain can swell or blood can accumulate in response to injury. Signs of brain injury in an older person may take days or weeks to develop, and the patient may have forgotten the initial injury by the time the signs and symptoms develop.

Regardless of the type of injury incurred, whenever you assess an elderly fall patient, you should determine if the fall was preceded by dizziness, faintness, or palpitations, indicating a potential medical emergency, or if it resulted from slipping or tripping on something.

The effects of years of disease processes sharply diminish the ability of the geriatric body to handle the stress of trauma. Because the heart and the arteries of an elderly person don’t respond well, shock progresses much more rapidly in the elderly than in any other age group. Loss of even a small amount of blood can drive an elderly person into shock. The compensatory mechanisms do not function nearly as effectively nor last as long, and the organs cannot tolerate periods of hypoperfusion (see Chapter 15, “Shock and Resuscitation”).

Treatment of geriatric trauma must be executed expeditiously. Stabilize the spine during the primary assessment if necessary, administer high-concentration oxygen if poor perfusion is evident, and provide positive pressure ventilation if the patient is breathing inadequately. Regard any signs of poor perfusion (such as pale skin, tachycardia, disorientation, hypotension, or increased respiratory rate) as signs of serious trauma and transport the patient as rapidly as possible.

Assessment Finding: Gastrointestinal Bleeding

Gastrointestinal (GI) bleeding is a rather common and potentially life-threatening emergency in the elderly. GI bleeding may occur anywhere along the digestive tract from the mouth to the anus and may be obvious or may be occult (hidden). While GI bleeding is a sign that some disease of the gastrointestinal tract is present, it is not a disease itself. Bleeding may come from the upper GI tract or the lower GI tract as a result of an ulcerative disease, inflammation, infection, or obstruction. The most common finding with any abdominal pathology is abdominal pain. The type, location, presentation, history of the pain, and associated complaints will help isolate the type and source of bleeding.

Being able to recognize that GI bleeding is present is more important to the EMT for managing it appropriately than diagnosing exactly where along the digestive tract the bleed is originating or what is causing it. Findings that support the field impression of GI bleeding in an elderly patient include the following:

- Hematemesis (vomiting blood)
- Hematochezia (red undigested blood in bowel movement)
- Melena (dark tarry bowel movement, indicative of digested blood)
- Dyspepsia (indigestion)
- Hepatomegaly (enlarged liver)
- Jaundice (yellowing of sclera and skin, indicative of liver problems)
- Constipation or diarrhea
- Agitation
- Dizziness
- Inability to find a comfortable position

While these findings are consistent with GI disorders, a geriatric patient may also present with significant signs of shock, which can result from even a small amount of blood loss because of aging compensatory mechanisms. Since the liver is often involved in chronic disease, there may also be peripheral, sacral, and periorbital edema from venous congestion. Other findings may include a low-grade fever, respiratory distress, and vital sign changes.
Your approach and assessment should be similar to any assessment format for the geriatric patient. Focus on ensuring a patent airway, and provide manual or mechanical airway assistance if the patient is unable to protect the airway himself, possibly because of a depressed mental status. If the breathing is adequate, provide supplemental oxygen to maintain an SpO₂ reading of 94% or greater; if breathing is inadequate, the oxygen should be provided via positive pressure ventilation. Keep the patient in a recovery position if he is conscious, or supine if he is unresponsive or if you are maintaining the airway and/or breathing. In a conscious patient, if the blood pressure is 10 mmHg lower when the patient is standing as compared to lying supine, consider it a positive sign for volume depletion.

Assessment Finding: Environmental Temperature Extremes

The effects of the aging process leave the elderly at greater risk of experiencing an emergency as a result of changes in the environmental temperature. The ability of the body to create heat when cold, or to dissipate heat when hot, may be impaired not only from the aging process but from certain diseases and medications the patient may be taking. Whenever you enter the scene of a geriatric emergency, you should be acutely aware of any extremes in the ambient air temperature to which the patient has been subjected. Even a temperature that seems only moderately warm or cool to you may be intolerable to the elderly person.

A body temperature less than 35°C (95°F), or hypothermia, is of special concern in an elderly patient. A number of factors make the elderly more prone to hypothermia. These factors include a smaller insulating layer of fat, reduced muscle mass, the body’s metabolic rate slowing with age, impaired reflexes, decreasing blood flow (especially to the extremities), and a reduced shivering response. Living on a fixed income may result in being unable to keep the home adequately heated. Because of physical impairments, the elderly may not be able to move around much, so they get colder much more easily. Also, certain medications may make the elderly patient prone to hypothermia.

Treatment includes protecting the airway and maintaining normal breathing and circulatory status. Not only should you remove the patient from the cold environment, but you should also remove any wet clothes and insulate the patient in a dry blanket. Use caution when handling a severely hypothermic patient as excessive handling or moving may put the patient into a lethal heart rhythm.

Equally serious is the elderly patient suffering from a heat-related disorder or an increased body temperature (hyperthermia). The geriatric patient’s core temperature can increase more rapidly than the younger patient’s, and the length of time exposed to the environmental extreme should be taken into consideration when preparing to treat the patient. To institute prehospital cooling of a hyperthermic geriatric patient, you would follow the same guidelines as for treating a younger patient. A complete discussion of the prehospital treatment for hypothermia and hyperthermia can be found in Chapter 24, “Environmental Emergencies.”

Elder/Geriatric Abuse

Elder or geriatric abuse may occur in care centers and other medical institutions, but it also happens at home. Any elderly person is especially at risk if he is cared for by someone who is under stress from other sources. Abuse of the elderly can occur in many forms similar to pediatric abuse, and includes neglect, physical abuse, sexual abuse, financial abuse, or emotional/mental abuse. At highest risk are those elderly who are bedridden, demented, incontinent, frail, or who have disturbed sleep patterns. The most common category of elder abuse is to elderly females who live with a son.

Geriatric neglect is similar to pediatric neglect. It is the withholding by a care provider of attention or medical care that the victim is entitled to. This type of neglect could occur passively or actively, the difference being the intent of the care provider. In situations of active neglect, there is an intentional failure of the care provider to meet his obligations to the elderly victim. With passive neglect, the failure is said to occur unintentionally and is often the result of the care provider feeling overwhelmed by the needed tasks or that the care provider simply does not know or understand the care or interventions that the patient needs. Regardless of reason, this type of neglect could be manifested as failing to provide adequate nutrition or hydration, failing to provide medications or accessing medical services when warranted, failing to care for personal hygiene, or even the development of bed sores because the care provider does not turn the patient as needed to prevent the breakdown and deterioration of the skin.

Physical abuse can involve hitting, unnecessary restraining, shaking, or shoving an elderly patient. Because of the elderly person's frailty, the injuries incurred from these attacks can be significant (Figure 39-7). Sexual abuse is said to occur when there are unwanted or unwarranted advances of a sexual nature (either through body contact or exposure) that the older person does not consent to or is incapable of giving consent to. The EMT may note signs of soft tissue trauma around or near the genital region in situations of sexual abuse. Financial abuse consists of the care provider exploiting the material possessions, property, credit, or monetary assets of the elderly patient for personal gain. With emotional or mental abuse, there is an infliction of psychological distress or mental harm to the elderly patient through verbal assaults, verbal insults, ignoring the elderly patient, or threats of physical harm.
needs that should always be treated with the utmost respect and compassion.

The EMT should always consider it an honor to help care for a geriatric patient in need. The compassion and attitude shown to the geriatric patient should reflect this. Always consider approaching the geriatric patient with the same degree of concern and consideration that you would show a pediatric patient. Additionally, avoid any of the purposeful or accidental stereotyping of ageism. Ageism occurs when a person either knowingly or unknowingly discriminates against people who are old. Derogatory terms such as “old geezer” or “gomer” are extremely unprofessional. Even addressing the elderly person as “dear,” “honey,” or “pops,” or calling him by his first name without having permission to do so are forms of ageism and should be avoided. Consider for a moment the amount of the history retained by the elderly. An elderly patient nearing his 90th birthday will have lived through the Great Depression, two World Wars, numerous military conflicts (e.g., Korea and Vietnam), the Cold War with the Soviets, the Civil Rights Movement, space flight, the computer age, and more currently the turmoil in the Middle East. They have witnessed what most EMT students have only read about in school. They have earned the respect of a nation, and should receive nothing less from the EMT.

Other considerations with the geriatric population are their social issues. Probably the two greatest are isolation and marital status. With advancing age comes the loss of many friends and family near their own age. This isolates the elderly from the rest of society as their social network decreases. Contributing to this and compounding it greatly is the loss of a spouse. Pinched finances are also a common issue facing the geriatric population. Unless a great deal of financial planning was done at an earlier age, many elderly patients find themselves on a fixed income of governmental support that often does not meet their economic needs. Too often the elderly patient may have to choose between paying for rent, food, or the medications needed to treat chronic conditions.

**ASSESSMENT TIPS**

Many indications that the EMT will encounter, both physical and emotional, can point to abuse. Your primary role is to provide assessment and care for the patient. Do not try to investigate the suspicion of abuse or attempt to confront the alleged abuser. However, do report your findings to the medical staff and provide thorough and objective documentation in your prehospital care report.

Your priority is to provide emergency care for the injuries. Do not confront the family or care provider with your suspicion of abuse. Instead, you should make your suspicion known to the receiving hospital’s staff so that they may follow up with the appropriate authorities. Follow local protocols or state laws regarding reporting of suspected abuse.

**ASSESSMENT-BASED APPROACH: GERIATRIC PATIENTS**

Since geriatric patients are among the patients the EMT will encounter most frequently, you should understand some of the historical, environmental, and social factors that impact the elderly. First, the number of elderly in the United States is growing rapidly. Current statistics show that the number of people over the age of 65 has boomed over the last century and that the number of people over the age of 85 is actually growing faster than the number over age 65. Many have special health care needs that should always be treated with the utmost respect and compassion.

The EMT should always consider it an honor to help care for a geriatric patient in need. The compassion and attitude shown to the geriatric patient should reflect this. Always consider approaching the geriatric patient with the same degree of concern and consideration that you would show a pediatric patient. Additionally, avoid any of the purposeful or accidental stereotyping of ageism. Ageism occurs when a person either knowingly or unknowingly discriminates against people who are old. Derogatory terms such as “old geezer” or “gomer” are extremely unprofessional. Even addressing the elderly person as “dear,” “honey,” or “pops,” or calling him by his first name without having permission to do so are forms of ageism and should be avoided. Consider for a moment the amount of the history retained by the elderly. An elderly patient nearing his 90th birthday will have lived through the Great Depression, two World Wars, numerous military conflicts (e.g., Korea and Vietnam), the Cold War with the Soviets, the Civil Rights Movement, space flight, the computer age, and more currently the turmoil in the Middle East. They have witnessed what most EMT students have only read about in school. They have earned the respect of a nation, and should receive nothing less from the EMT.

Other considerations with the geriatric population are their social issues. Probably the two greatest are isolation and marital status. With advancing age comes the loss of many friends and family near their own age. This isolates the elderly from the rest of society as their social network decreases. Contributing to this and compounding it greatly is the loss of a spouse. Pinched finances are also a common issue facing the geriatric population. Unless a great deal of financial planning was done at an earlier age, many elderly patients find themselves on a fixed income of governmental support that often does not meet their economic needs. Too often the elderly patient may have to choose between paying for rent, food, or the medications needed to treat chronic conditions.

**ASSESSMENT TIPS**

The financial straits in which many elderly patients find themselves may be manifested by a reluctance to go to the hospital for fear of the ambulance and hospital bills that will be incurred.

Many geriatric patients may be found living in independent or dependent living arrangements. Independent living is when an elderly person lives in his own home, tending to his own needs. Independent living is also when the geriatric patient lives in a “gated” adult community, senior apartments, or independent living in congregate housing. While this type of independence is valued by most elderly people, it is not always possible. Many geriatric patients live with family members...
who care for them. Other geriatric patients have a high
degree of independence but, because of a chronic con-
dition or disability, they live in some type of assisted
living facility where there is 24-hour supervision and
access to a health care professional should a problem
arise. Living arrangements of this nature include resi-
dential care, boarding homes, or the traditional “nursing
home.” A patient with Alzheimer’s disease may reside
in an Alzheimer’s care facility. In instances of terminal
illness that can no longer be managed by medicine, the
elderly may be found at home where they receive pal-
liative care through a hospice care program.

One consistent feature of almost all these living ar-
rangements is that the EMT may be delayed in getting to
the patient’s side by the locked doors of care facilities,
privacy gates in adult communities, or simply waiting
for the patient’s primary care provider to arrive and give
the patient’s medical and physical history. Attempt to
obtain as much information as possible from the patient
himself. If this is impossible because of the patient’s
mental state, the EMT can still initiate the physical exam
while awaiting the medical history from the appropriate
primary care provider.

An important concern of many elderly is advance di-
rectives. Advance directives are designed to express the
patient’s wishes as to the care he will receive should he
experience a significant change in his health. For exam-
ple, an elderly person with incurable cancer may have
had advance directives prepared on his behalf should he
er later experience another significant health crisis. Since
the depth and breadth of advance directives vary from state
to state, it is up to the EMT to become familiar with how
they are handled in his particular state and EMS system.

The leading causes of illness and death in the ge-
eriatric population—starting with the highest-frequency
cause and listing downward from there—are heart dis-
ease, cancer, stroke, chronic obstructive pulmonary dis-
ease, pneumonia, diabetes, trauma (e.g., fractures, falls),
and misuse of drugs. The signs and symptoms of any of
these problems may be masked by, or confused with,
the physiological changes of aging. You may wonder if
a sign or symptom is the result of a present illness or
injury, or the result of the normal aging process.

Also, as a result of the normal aging process, the
response to illness is altered. Many medical problems
present with different signs and symptoms in the elderly
than in the general population. For example, a lack of
chest pain in a geriatric patient who is experiencing a
heart attack is common.

In general, the geriatric patient needs to be assessed
and treated carefully. Any delay in recognizing health
care needs and providing care may have devastating,
irreversible consequences. Especially at risk are those
elderly people who:

- Live alone
- Are incontinent
- Are immobile
- Have been recently hospitalized
- Have been recently bereaved
- Have an altered mental status

**Scene Size-up**

Begin the scene size-up by determining if there are any
safety hazards to yourself, your crew, your patient, or
bystanders. As always, you should approach the patient
with Standard Precautions taken. Since tuberculosis is
prevalent in nursing homes and other extended-care fa-
cilities, wear a HEPA mask when you encounter a pa-
tient with signs or symptoms of a respiratory disorder
(such as a cough and, perhaps, blood-tinged sputum) in
such a facility. Elderly patients often have a depressed
immune system. If the EMT has a simple cold or flu, it
would be very easy to pass this accidentally to the el-
derly patient, with potentially disastrous effects. It is al-
ways warranted that the EMT wear gloves, but it is also
advised to don a protective mask if you fear you may
have a cold or flu that could be passed to your patient.
The best advice in this situation is simply to not function
as an EMT while you are recovering from an illness.

Since many elderly live on fixed incomes, it is not
uncommon to find an elderly patient inside a house
without proper heating during the winter or cooling
in the summer. Remember to assess the environmen-
tal temperature (even if it means taking your arm out
of your jacket in the wintertime to determine room
temperature). Since the elderly patient has deteriorat-
ing compensatory mechanisms, the body’s response to
environmental extremes of temperature will be dimin-
ished, potentially leading to cold- or heat-related emer-
gencies more rapidly than in a younger person.

When the elderly patient shares living quarters, or
lives in an extended-care facility, numerous patients
may be victim to an environmental emergency (e.g.,
temperature extremes, toxic fumes). Determine if any
additional patients are present and call for additional
resources, if necessary.

Part of the scene size-up is determining whether the
patient is suffering from trauma or a medical problem.
Be alert to the fact that the cause of the emergency may
be more complex than is first apparent. For example,
since the geriatric patient may have numerous chronic
diseases, an unresponsive patient (seemingly a medical
emergency) may actually be unresponsive because he
failed to eat a meal, which caused a diabetic reaction,
which caused him to fall from a chair, which resulted in
a head injury that is now presenting with delayed symp-
toms—a combined medical and trauma emergency.

There may be reliable family members, care pro-
viders, or bystanders who witnessed or are aware of
what happened to the patient. However, while you may
make a preliminary determination of the nature of the
problem during the scene size-up, maintain a high in-
dex of suspicion. Look for clues to chronic or acute
conditions (Table 39-2).
primary assessment, keep in mind the following special considerations for the geriatric patient (Table 39-3):

- **Mental status.** The geriatric patient’s mental status may be influenced by a chronic illness, the present illness or injury, prescription drugs he is taking, or relative familiarity with his surroundings. The purpose of assessing the mental status is to determine a baseline level of consciousness and the possible need for airway protection and ventilatory assistance. It is important to ask family or caregivers to describe the patient’s normal mental status. One of the best assessment tools when determining the patient’s mental status is patience on the EMT’s part. Not only will geriatric patients normally process information more slowly than their younger counterparts, the stress and confusion of an emergency may slow them even more.

</table>

Be ready to change your focus of care as you gather additional information during the primary and secondary assessments.

### Primary Assessment

In performing the primary assessment, keep in mind the following special considerations for the geriatric patient (Table 39-3):

- **Airway, breathing, and oxygenation.** The elderly patient’s diminished gag reflex makes him vulnerable to aspiration of fluids and food or other solids, which can be fatal. Therefore, monitoring the elderly patient’s airway is especially important.

  Also pay close attention to breathing patterns. If a geriatric patient is suffering acute respiratory distress, the muscles of respiration may fatigue and fail more rapidly than in a younger person. This can cause inadequate breathing (hypoventilation), which the geriatric patient tolerates even less than a younger patient. Although it is normal for hypoxia, or oxygen deprivation, to cause an increase in respiratory rate, don’t get a false sense of security if the geriatric patient’s rate starts to slow. This may actually indicate respiratory failure rather than improved oxygenation. **Be prepared to initiate positive pressure ventilation.** Administer oxygen to maintain an SpO2 reading of 94% or greater in the patient with adequate breathing.

- **Circulation.** Assess central and peripheral pulses, noting the rate, strength, and rhythm. Your initial pulse check should include an assessment of the radial pulse. However, since the geriatric patient is predisposed to peripheral vascular diseases, the radial pulse may be markedly diminished or absent. This is not necessarily an abnormal sign; just be sure to check other pulses if the radial pulse is weak or absent.

  Although it is natural for the pulse rate of an elderly patient to be slightly higher at rest than a younger person’s, you should note any irregularity to the rhythm. This could be from the degenerative processes that affect the conduction system of the heart or from a drug (or drugs) that the patient is taking. Nonetheless, an acute onset of an irregular pulse should be considered an abnormality that necessitates emergency department evaluation.

- **Skin condition and temperature.** When assessing the skin, remember that the geriatric body does not display the same signs and symptoms of dehydration as in the younger patient. Since the geriatric patient has, overall, a lower amount of body water, and because of the changes in the skin from aging, dry-looking skin may be normal. If you suspect dehydration, the best way to assess for it is to look at the mucous membranes of the eyes and in the mouth. Normal hydration status will show them to be...
### TABLE 39-3 Special Considerations in the Primary Assessment of the Geriatric Patient

| **Chief complaint** | The elderly patient may not complain of pain because of a preexisting central nervous system condition, such as stroke. However, any complaint of pain in the elderly must be taken seriously. Some elderly patients will not experience pain when suffering a serious condition, such as a heart attack, because of a disease process that affects the nerve endings. This is common in diabetic patients. Prickling and burning-type pain is usually caused by a condition affecting the superficial structures of the body, whereas an acheing-type pain usually indicates an organ is involved in the condition. Changes in the peripheral nerves in the skin can affect the elderly patient’s ability to distinguish between hot and cold. A sudden loss of vision in one eye is not normal in the elderly and normally indicates a retinal artery occlusion or retinal detachment. Depression in the elderly is a serious complaint and must be managed properly. A depression state may cause the patient to not report or to minimize significant symptoms. There is a high rate of suicide among the elderly. Alcohol abuse is more common in the elderly. Keep a higher index of suspicion and look for evidence of alcohol abuse in the scene size-up. Side effects of medications or interactions with other medications may cause the presenting signs and symptoms. Fainting may be a serious complaint associated with conditions affecting the brain, lungs, heart, or circulatory system such as heart attack, pneumonia, blocked pulmonary artery (pulmonary embolism), shock, head injury or stroke, or congestive heart failure. |
| **Mental status** | Hypoxia causes agitation and aggression. High levels of carbon dioxide cause confusion and disorientation. A sudden onset of an altered mental status is not a normal part of aging and is not considered to be dementia. It is usually an indication of a serious illness or injury. Altered mental status may be due to inadequate perfusion to the brain, hypoxia in the brain, dehydration, electrolyte disturbances, change in the blood glucose level, infection, cold emergency (hypothermia), stroke, head injury, tumors, drugs, or alcohol intoxication. |
| **Airway** | A reduction in the patient’s reflexes may cause a high incidence of choking and aspiration of food or other substances. Cervical arthritis may make performing an effective head-tilt, chin-lift maneuver difficult because of the stiffness of the neck structures. A jaw-thrust maneuver may provide a better manual airway. Loose dentures may cause an airway obstruction. If the dentures are loose or poorly fitted, remove them. If the dentures are well fitted and snug in place, do not remove them. In a patient without dentures or teeth, it is much more difficult to get an effective mask seal if ventilation needs to be performed. |
| **Breathing** | Elderly patients have higher resting respiratory rates. A resting respiratory rate greater than 20 per minute may be completely normal. Elderly patients have lower tidal volumes. This can lead to early onset of hypoxia. Retractions are less likely to occur in the elderly because of the less elastic and compliant chest wall muscles. |
| **Circulation** | Elderly patients have higher resting heart rates, typically greater than 90 beats per minute unless they are on beta blockers. An irregularly irregular pulse (no regular rhythm or pattern) may be normal in an elderly patient. The skin will normally appear to be dry and less elastic. Assessment of skin turgor in the elderly is not a reliable test of skin hydration. Inspect the inside of the mouth or under the lower eyelid to check for hydration status. Cold skin may indicate hypothermia, even when the elderly patient is found in his or her home. This is referred to as “urban hypothermia.” A reduction in subcutaneous fat and skin vessel response may cause the body core temperature to decrease faster. Fever is less common in the elderly patient, even with serious infections. Hot skin may indicate a heat emergency, such as heat stroke. Elderly patients are more prone to heat emergencies because of their inability to dilate the vessels to assist in cooling the body. |
moist. A dehydrated patient will have a dry mouth, the tongue may be furrowed, the eyes may appear to be “sunken” into the orbits, and the membranes around the eyes will also appear dry. It is no longer advised to check for “skin tenting” as an assessment for dehydration in the geriatric patient since almost all will display tenting. This is usually secondary to skin elasticity degeneration and a loss of subcutaneous fat rather than from significant dehydration.

Equally important is skin temperature. The geriatric patient has a depressed response to infection. Whereas you may feel unusually warm skin from a fever in a young patient, you may not feel warm skin in a geriatric patient even if he does have an infection (e.g., pneumonia, upper respiratory infection). The temperature-regulating mechanism may be depressed, leading to minimal or absent fever or even hypothermia with severe infection. (Again, this contributes to the geriatric patient’s susceptibility to temperature-related emergencies.)

Like the pediatric patient, you can quickly categorize the elderly patient as “stable,” implying no life threats, or “unstable,” indicating that a life threat is present. Categorizing the patient as stable or unstable is relatively easy. The patient with an intact airway and adequate breathing, circulation, and mental status who requires minimal support during the primary assessment is considered stable. Conversely, the patient who presents with any disturbance or abnormality to the airway, breathing, circulation, and mental status is identified as unstable.

If there is any question as to whether the patient is stable or unstable, err on the side to benefit the patient and manage him as unstable. Be extremely alert to the stable patient who can deteriorate rapidly into an unstable patient. As you progress through your secondary assessment you may change the patient’s status. For example, you may have completed a primary assessment in a patient with a complaint of vomiting up blood and have not identified any abnormality. The heart rate is slightly elevated, but you think it might be attributed to anxiety associated with the situation. As you assess the abdomen you find rigidity and tenderness. This finding would cause you to change the patient’s status from stable to unstable.

The following points can help you identify which category the geriatric patient should be assigned to:

- **Stable.** An elderly patient who is alert and has an open airway, adequate breathing, signs of good peripheral perfusion, and a strong peripheral pulse is categorized as stable.

- **Unstable.** An elderly patient with an acute change in mental status, an obstructed airway, inadequate breathing, or signs of poor perfusion is categorized as unstable and is in need of immediate emergency care during the primary assessment. Note that any one of these conditions is enough to place the patient in the unstable category.

### Secondary Assessment

Gather the history and conduct your physical exam based on the patient’s mechanism of injury (if trauma) or chief complaint (if medical). When interviewing a geriatric patient, you may encounter characteristic challenges resulting from the general depression of the sensory organs (especially failing eyesight and diminished hearing). These special considerations are discussed next with suggestions on how best to communicate to ensure a reliable history:

- **Diminished sight or blindness.** You can expect increased patient anxiety because of an inability to see surroundings, coupled with an inability to exert control over the situation. You must talk calmly and be positioned so that the patient can best see you if he has any sight at all (Figure 39-8 ■). Explain your procedures carefully. If the patient has eyeglasses, make sure he is wearing them. The elderly patient may have cataracts or glaucoma and be less able to tolerate bright lights and glare. These conditions contribute to diminished sight or blindness and can easily heighten your patient’s anxiety.

- **Diminished hearing or deafness.** Many elderly people cannot hear high-frequency (or pitch) speech, especially consonants. Obtaining a history can be difficult if the patient cannot understand questions. Do not assume that the patient is deaf without first inquiring with the family or bystanders. The majority of geriatric patients still have intact hearing.

If the patient is wearing a hearing aid, make sure that it is turned on. Do not shout, as it distorts sounds if the patient has some hearing, and it does not help if the patient is deaf. However, increasing the volume of your voice (rather than the pitch) may help with the hearing-impaired patient. You may also try placing your stethoscope earpieces in the patient’s ears and speaking into the diaphragm. If the patient can lip-read, speak slowly and directly toward the patient. Note-writing may help,
too. Whenever possible, verify the history with a reliable relative or friend, or seek assistance from these individuals in communicating with the patient.

For the Geriatric Trauma Patient

Note the mechanism of injury if possible trauma is involved. Just as with younger patients, the elderly can be involved in car accidents, falls from ladders or rooftops, falls down stairs, assaults, and so on. In fact, the elderly are at a greater risk for experiencing a traumatic injury (primarily from falls) (Figure 39-9) because of a variety of factors, which we discuss later in the chapter. Situations that may be minor in other age groups may require aggressive care in the elderly.

The geriatric trauma patient, if responsive, may not indicate that the pain he is experiencing is severe. This may be a function of the aging process. The elderly patient may have a decreased sensitivity to pain; therefore, the severity of pain is unreliable as an indicator of the seriousness of the injury. You should maintain a high index of suspicion and treat any complaint of pain as a symptom of a serious injury.

Examine the head, neck, chest, abdomen, pelvis, extremities, and posterior body. Inspect and palpate for any evidence of trauma. See Chapter 36, “Multisystem Trauma and Trauma in Special Patient Populations,” for more information on trauma in the elderly.

While completing the secondary assessment, you will also assess and record baseline vital signs (Table 39-4) and obtain a history from the patient if he is responsive, or from family and bystanders. Special considerations for obtaining a history from the geriatric patient are detailed in the following section.

Remember, the elderly deteriorate much more rapidly than do young people, especially following trauma. A minor problem may become a major one in a short period of time. To properly treat the geriatric patient, you need to perform an entire physical examination.

For the Geriatric Medical Patient

While the mechanism of injury in a geriatric trauma patient may be easy to determine, discerning a chief complaint in a medical emergency may be more difficult. The geriatric patient may have one or more chronic diseases or medications, which can mask or alter the presentation of signs and symptoms; the elderly patient may not be a reliable source of information for exactly the same reasons.

Because of the aging process, the patient’s memory, hearing, sight, and orientation may be diminished. This can challenge your ability, or even the patient’s ability, to determine the chief complaint (what prompted the present emergency call). For example, a geriatric patient may report experiencing a headache or neck pain but forget that he fell yesterday. Compounding this, the geriatric patient typically does not have a single chief complaint. Rather, the EMT may find that geriatric patients present with various forms and combinations of pain, fatigue, weakness, discomfort, and so on. The EMT must diligently assess the geriatric patient so that it is possible to delineate normal findings from those caused by chronic or acute illness or injury.

Yet you should remember that not all geriatric patients are deaf or blind, or have a diminished mental status. While these problems may be more common among the elderly than among the young, they are not the rule. The best way to destroy the patient–provider relationship is to assume that the patient has diminished hearing, sight, or mental capabilities.

Approach the geriatric patient with concern and compassion and talk to the patient about the emergency (Figure 39-10) rather than talking about the patient to others, unless unavoidable. If you have some doubts about whether the patient can grasp what you are saying, you may want to make sure, subtly of course, that a family member or bystander also is hearing and noting

---

**TABLE 39-4 Special Considerations in Vital Signs of the Elderly**

- The resting respiratory rate is normally higher in the elderly.
- The resting heart rate is normally greater than 90 bpm, unless influenced by medications.
- The skin is normally dry and less elastic.
- Fever is less common in the elderly, even when a serious infectious disease is present.
- The systolic blood pressure will increase in the elderly patient, making systolic hypertension more common. The hypertension may give a false reading in the patient who has lost blood or who is dehydrated; however, the blood pressure will fall quickly since the patient cannot compensate well.
- The pupils are more sluggish to respond to light as a result of the normal aging process. The pupils may be distorted (not round) because of cataract surgery or other conditions. Eye drops that the patient may be taking for conditions such as glaucoma may cause the pupils to dilate and not react normally to light.

---

**FIGURE 39-9** Severe fracture in an 80-year-old man from a fall on the boardwalk.
the information. The bottom line is, don’t assume the elderly patient has diminished capabilities until you have evidence (through your assessment) of it.

Remember that the geriatric patient may not report everything that is wrong. One reason is that the older patient doesn’t perceive pain or discomfort as readily as the younger patient. This may lead him to delay the call for an ambulance until the situation becomes critical. Or the geriatric patient may attribute his ailment to “just old age” when, really, there is a serious emergency progressing. Sometimes patients minimize their symptoms because they fear losing their independence if admitted to the hospital. (Their perception may be that old people go to the hospital to die or, at the least, to be moved on to a nursing home instead of being allowed to come home.) The EMT should exercise extreme caution, and use thorough history and physical assessment skills to ensure that there are no other life-threatening conditions the patient is suffering from.

In obtaining the history and conducting the physical examination of the geriatric medical patient, remember the following points:

- The patient may become fatigued easily.
- You should clearly explain what you are going to do before examining the elderly patient.
- The patient may minimize or deny symptoms because he fears being bedridden or institutionalized or losing his self-sufficiency.
- Peripheral pulses may be difficult to evaluate.
- You must distinguish signs and symptoms of chronic problems or natural aging processes from the signs and symptoms of acute problems:
  - Loss of skin elasticity and mouth breathing may give the false appearance of dehydration.
  - Edema (swelling) may be caused by varicose veins, inactivity, and position rather than heart failure.

Since you should anticipate that the elderly patient may not report or fully report all complaints, elicit as much information as you can by asking questions such as these:

- Have you had any trouble breathing?
- Have you had a cough lately? (If so, have you been coughing up anything like mucus or blood?)
- Have you had any chest pain?
- Did you get dizzy? (If so, what were you doing when this occurred?)
- Have you fainted?
- Have you had any headaches lately?
- Have you been eating and drinking normally?
- Have there been any changes in your bowel or bladder habits?
- Have you fallen lately?

As discussed previously, it is best to address the elderly patient as “Mr.” or “Mrs.” or “Miss,” as appropriate. Despite current misconceptions, the geriatric patient is not “set at ease” when an unknown EMT arrives on the scene and talks to him as if they have been friends for years. It is inappropriate to address the elderly patient by his first name or a nickname and contributes to ageism stereotyping. The only exception is if the elderly patient voluntarily tells you otherwise.

As you begin the physical exam, you will notice that the geriatric patient is typically dressed in layers of clothing, since the ability of the elderly to regulate body temperature is usually impaired. This makes performing a physical exam more difficult since the manipulation necessary to remove the patient’s clothing can easily fatigue the patient. In fact, it may be tempting just to skip the physical exam rather than take the time to remove clothing. This could, however, be fatal if you miss a life-threatening injury or problem because you chose not to perform a complete physical exam.

If the patient is unresponsive or has an altered mental status because of the medical emergency, perform a physical assessment of the head, neck, chest, abdomen, pelvis, extremities, and posterior body to find and treat any life threats that may be causing the alteration in mental status. Scan the scene for any clues to the patient’s problem (medicine bottles, mechanism of injury, environmental extremes, and so on). It is important to collect and transport the patient’s medications. Finally, assess and record baseline vital signs.

As with geriatric trauma patients, you will perform a secondary exam on geriatric medical patients whether they are alert, have an altered mental status, or are unresponsive. Even the mentally competent geriatric patient may not give reliable information—for reasons discussed earlier—so the physical exam will better enable you to assess for injuries, or signs of injury, or other medical abnormalities.

**Emergency Medical Care and Reassessment**

A geriatric patient can deteriorate rapidly. It is critically important to anticipate problems and to continuously reassess the patient. In the geriatric patient, the injury or
failure of one body system can rapidly cause the failure of others. Key considerations and emergency care steps for the geriatric patient are:

1. **Maintain a patent airway.** Geriatric patients often wear dentures, and if these dentures become dislodged, they can create an airway obstruction. Look in the mouth to determine if the dentures (or any other foreign object or substance) is blocking the airway. If necessary, suction and clear the airway immediately before assessing the breathing status. If the neck is stiff and not flexible enough to perform a head-tilt, chin-lift maneuver, perform a jaw thrust to establish a patent airway.

2. **Insert an airway.** The geriatric patient’s mental status is subject to rapid deterioration. If the patient is unable to maintain his own airway as a result of injury or altered mental status, insert an oropharyngeal airway. If the patient cannot tolerate an oropharyngeal airway, insert a nasopharyngeal airway.

3. **Assess and be prepared to assist ventilations.** It is vitally important to assess the geriatric patient’s rate and depth of respirations. Because of the general decline in respiratory muscle strength, a minor chest injury or lung disorder can easily put the patient into respiratory failure unless proper care is initiated. If the rate or depth is inadequate, positive pressure ventilation should be initiated immediately. Be careful not to ventilate the patient with excessive pressure or volumes, which could cause lung injury. Although loose dentures could cause an airway obstruction, if they are still firmly seated in the elderly patient in need of positive pressure ventilation it may be advisable to leave them in place. The dentures will help support the soft tissues around the mouth on which the mask of the ventilation device will be seated.

4. **Maintain adequate oxygenation.** As with all patients, be sure to provide supplemental oxygen with positive pressure ventilation if the patient’s breathing is inadequate. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia, heart failure, poor perfusion, or respiratory distress are present, oxygen may not be necessary. If the SpO2 reading is less than 94%, the patient complains of dyspnea, or exhibits signs of respiratory distress or heart failure, apply a nasal cannula at 2 to 4 lpm. If signs of severe hypoxia or poor perfusion are present, place the patient on a nonrebreather mask at 15 lpm.

5. **Position the patient.** Exercise extreme caution when preparing the patient for transport, based on the type of emergency as outlined in the following guidelines:
   - If the emergency is medical in nature and the patient is alert and able to protect his own airway, place the patient in a position that is comfortable for him. This is typically a Fowler’s (sitting-up) position.
   - If the patient has an altered mental status and is unable to protect his own airway, he should be placed in a left lateral recumbent position (recovery position) to avoid aspiration.
   - If spinal injury is suspected, the patient needs immediate manual stabilization of the spine during primary assessment, followed by immobilization to a long backboard. One limitation, however, is the geriatric patient with severe curvature of the spine caused by kyphosis. The patient with severe kyphosis could actually be injured if forced to be immobilized in the same fashion as a younger person. You may need to be creative and construct the cervical immobilization devices out of blankets to accommodate the curvature of the spine.
   - If the patient is unresponsive, assume a possible cervical spine injury and immobilize the patient fully as a precautionary measure.

6. **Transport.** Reassess the patient en route to the hospital, remembering that the geriatric patient’s condition can rapidly deteriorate without warning.

In order to ensure appropriate care, reevaluate the geriatric patient frequently. The length of time spent with the patient or the condition of the patient will assist in establishing how often to repeat the reassessment phase. Repeat and record the assessment at least every 15 minutes for a stable patient. If the patient is unstable, repeat and record at a minimum of every 5 minutes.

Overall, successful assessment and treatment of a geriatric patient will depend in a large part on your approach, demeanor, and attitude. It can be extremely stressful to the elderly patient if you immediately start “pulling out equipment and doing things” without first gaining the patient’s cooperation. Your goal is to help lower the patient’s anxiety, not increase it. Remember, what you do as an EMT on a regular basis (assessments, treatment, and so on) becomes routine to you. In contrast, this may be the first experience with EMS and emergency care for the patient, who has no idea what to expect. You need to explain everything that you are doing.
EMT SKILLS

39-1

Immobilizing a Patient with Kyphosis

■ 39-1A Patient with kyphosis who has suffered a fall.

■ 39-1B One EMT holds manual stabilization as a second EMT applies a cervical collar.

■ 39-1C Three EMTs log roll the patient onto a backboard.

■ 39-1D EMTs apply padding to make the patient comfortable on the backboard.

■ 39-1E The patient is fully immobilized to the backboard.
SUMMARY
As people age, they experience many changes to body systems, including the cardiovascular, respiratory, musculoskeletal, neurological, gastrointestinal, renal, endocrine, and integumentary systems. Assessment findings in the elderly often associated with these body systems include chest pain (or absence of chest pain in conditions where it might be expected), shortness of breath, altered mental status, and abdominal pain. Other common findings in the elderly include trauma, environmental temperature extremes, and, sadly, geriatric abuse. In addition to understanding findings commonly associated with various body systems, it is also important to understand the social and financial considerations that many elderly persons experience. Always remember to treat elderly patients with the respect they have earned.

Case Study Follow-up

Scene Size-up
You have been dispatched to the scene of a 72-year-old female patient complaining of difficulty in breathing. While you are walking into the house, the patient’s husband, Mr. Vaughn, tells you that the patient has not been feeling well over the past few days and that yesterday she started having trouble “catching her breath.” You note no particular hazards to yourself or your partner and do not see any obstacles that would make the extrication difficult. As you enter the bedroom, you note that the patient is sitting up in bed, wearing her nightgown, and you notice a bottle of nighttime cold medicine on her nightstand.

Primary Assessment
When you introduce yourself, Mrs. Vaughn makes a motion indicating that she cannot hear you. You repeat your statement a little louder, but she still cannot hear you. You ask her husband if she has any hearing impairments, and he says that she is deaf in one ear and uses a hearing aid in the other. After assisting her in placing her hearing aid, you begin to ask her questions.

By her responses, you determine that Mrs. Vaughn is conscious with an open airway and is exchanging air adequately. Despite the fact that Mrs. Vaughn displays only minor respiratory distress at this time, because of her age you decide to treat her as a priority patient. Your partner leaves to get the stretcher while you continue with the history and physical exam.

Secondary Assessment
While waiting for your partner to return with the stretcher, you obtain more information regarding the respiratory distress complaint. In answer to the OPQRST questions, Mrs. Vaughn tells you that she was almost over a cold when she started to experience some trouble breathing and a cough, which started yesterday. She complains of no other discomfort and denies any dizziness, nausea or vomiting, chest pain, or abdominal pain. On a scale of 1 to 10, she calls her breathing discomfort “about 5.” Mrs. Vaughn adds that she just took her temperature and found it to be only slightly elevated at 99.2°F.

As you continue to obtain the history, you find that the patient is not allergic to any medications and does not take prescribed medicine for high blood pressure or any other condition, although she states that she has a medical history of hypertension and arthritis. She has not had anything to eat or drink since last night when she started to feel worse. She reports no events that brought on the breathing difficulty other than the cough and cold.

During your secondary assessment exam, you determine that the patient has moist mucous membranes and her pupils are equal and reactive to light. You note no jugular vein distention. Breath sounds reveal crackles to the right and left lung fields. The patient is not using any accessory muscles to aid respirations. You assess baseline vitals and find the blood pressure to be 130/88, the heart rate is 96 and regular, and the respirations are somewhat rapid at 30 times a minute. The skin is warm and still slightly flushed.

You place her on the stretcher in a Fowler’s position, which helps her to breathe, and start moving her to the ambulance. While en route to the hospital, you complete your assessment and determine that there are no visible or palpable areas of injury to the head, neck, torso, or extremities, nor indications of elder abuse. You ask her if she has experienced any injuries recently, and she denies this.

Reassessment
You reassess the patient every 15 minutes. Mrs. Vaughn states that the oxygen must be working, because she feels much better and her respiratory distress is diminishing. You notify the receiving physician of your findings and emergency care thus far. Reassessment of the vital

continued
signs reveals a pressure of 126/86, the breathing is regular at a normal rate of 20 per minute, and the pulse is 78 per minute. The SpO₂ reading on the pulse oximeter has increased to 95% while Mrs. Vaughn is on the nasal cannula. After you arrive at the hospital, you give your verbal report, write the prehospital care report, and prepare the ambulance for another trip.

On the way out of the hospital, you check in on Mrs. Vaughn, and she tells you that the doctor said she has pneumonia and will be starting antibiotics. As you leave, you recall that even though she did not display the “classic” signs of pneumonia as seen in younger patients, such as high fever, chills, and chest pain, she did display signs classic to the elderly patient with pneumonia: increasing breathing difficulty, rapid respirations, and a cough. You remember that the differences are due to physiological changes as a result of aging.

IN REVIEW

1. A 79-year-old male patient is crossing the street to get his mail when he is struck by a vehicle traveling at 45 miles per hour. Discuss the changes in the following body systems from the normal aging process that would increase his susceptibility to injury and the aftereffects of injury: cardiovascular system, respiratory system, and musculoskeletal system.

2. Describe communication challenges caused by sensory degeneration in an elderly patient, and outline strategies for overcoming these challenges.

3. List questions you should ask the elderly patient in order to help obtain an accurate history.

4. Explain the reasons why a secondary assessment should always be performed on all geriatric patients, whether trauma or medical, unresponsive or alert.

5. Give emergency care guidelines for positioning and packaging the following geriatric patients: the alert medical patient, the patient with altered mental status, and the patient with suspected spinal injury. Also explain procedures for immobilizing a patient with spinal curvature.

6. Discuss how an assessment finding of denial of chest pain in the geriatric patient differs from the same finding in a younger adult patient.

7. List factors that make the elderly more likely to fall.

8. List at least five possible causes of, and discuss special treatment considerations for, altered mental status in the geriatric patient.

9. Explain why geriatric patients are predisposed to environmental heat or cold emergencies.

10. List signs and symptoms of geriatric abuse and discuss emergency care procedures when there is a high index of suspicion for geriatric abuse.

CRITICAL THINKING

You respond to a nursing home for an 82-year-old female patient. On your arrival, the staff indicates that the patient’s mental status has deteriorated over a period of several days. They indicate that she is normally awake and alert, however, she is usually disoriented, especially at night. As you enter the room, you find the patient lying supine in bed with her head propped up on two pillows. You hear an obvious snoring sound with each respiration. She responds to a trapezius pinch with moans. Her respiratory rate is 22/minute. Her radial pulse is present at a rate of 92 bpm. The skin is warm and dry. She has a history of type 2 diabetes mellitus and takes an oral hypoglycemic agent. Her blood pressure is 178/72 mmHg and the SpO₂ reading is 95% on room air. Her blood glucose is 98 mg/dL.

1. What action would you immediately take to manage this patient’s airway?

2. What other emergency care would you provide in the primary assessment?

3. What is your interpretation of the SpO₂ reading?

4. What is your interpretation of the blood glucose reading?

5. What conditions might cause this patient to experience an altered mental status?
Patients with Special Challenges

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Special Patient Populations (Content Area: Patients with Special Challenges)

**COMPETENCY** • Applies fundamental knowledge of growth, development, aging, and assessment findings to provide basic emergency care and transportation for a patient with special needs.

**OBJECTIVES** • After reading this chapter, you should be able to:

40-1. Define key terms introduced in this chapter.
40-2. Explain the importance of understanding the care of patients with special challenges.
40-3. Give examples of special challenges and their causes.
40-4. Describe accommodations and modifications to patient assessment and management required for patients with sensory impairments.
40-5. Describe accommodations and modifications to patient assessment and management required for patients with cognitive and emotional impairments.
40-6. Describe accommodations and modifications to patient assessment and management required for paralyzed patients.
40-7. Describe accommodations and modifications to patient assessment and management required for patients with special needs.
40-8. Describe accommodations and modifications to patient assessment and management required for home or poor patients.

40-10. Describe accommodations and modifications to patient assessment and management required for patients who are dependent on the following types of technology:
    a. Airway and respiratory devices
    b. Vascular access devices
    c. Ventricular assist devices
    d. Renal dialysis
    e. Gastrointestinal and genitourinary devices
    f. Intraventricular shunts

40-11. Describe accommodations and modifications to patient assessment and management required for patients who are terminally ill and describe the philosophy of hospice care.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

INTRODUCTION

Because of changes in medicine and lifestyle, the life span of Americans is increasing. Another positive outcome of these changes is the compression of morbidity that many individuals now enjoy—that is, maximizing the number of healthy years in one’s life while simultaneously minimizing the number of years of disease or disability at the end of life.

Despite these improvements in life span and length of healthy years, there are still people born with congenital defects and those who suffer significant trauma or endure illnesses that leave chronic residual deficits. Nevertheless, advances in medical care and medical technology are allowing people with certain deficits to live at home (either independently or with family) who formerly could only have been properly cared for in an extended-care facility. Deficits that today can be compensated by medicine and technology may be as minimal and common as a hearing impairment that can be ameliorated with hearing aids and communication-assist devices or as severe as a loss of the ability to breathe spontaneously that requires dependence on a mechanical ventilator.

During your career in EMS, you will certainly encounter patients who have special medical challenges or who are dependent on medical technologies to live. When a preexisting condition worsens, a medical device fails, or the patient experiences an emergency not related to his special challenge, EMS is usually the first called on to intervene. The challenge to the EMT is determining how to properly assess, manage, and transport a patient with a special challenge—especially if there is medical equipment or other conditions that complicate the situation—while focusing on and treating the complaint that prompted the call for help.

This chapter introduces some of the special challenges you may find in patients you are called to assist and provides guidelines on how to recognize and accommodate these special conditions in order to provide the best possible care.

Estimating the number of people in the United States with some type of disability is next to impossible since there is no common registry for these people, nor is there a unified definition of what a “special needs” or “specially challenged” patient is. While it is known that over 8 million such patients receive health care from professional providers, it is estimated that millions of others receive their care from family members or other volunteers.

As already mentioned, with the aid of medicine, medical technology, and medical equipment, many people with special challenges are now living at home rather than in an extended-care facility. Although the person’s primary care provider or providers are usually well versed in the equipment or technology being used, they may not be as well trained in what to do if that equipment fails or if the patient’s status begins to deteriorate. Situations like these require sensitivity on the part of the EMS provider. Even if the patient’s condition is terminal and death is expected soon, emotions can run high and easily overwhelm the capabilities of the family when the person deteriorates. Recognize that this may happen and do not allow yourself to get caught up in the emotional turmoil. Maintain your professional demeanor and focus on what you can do to help.

A person may be receiving care at home for any of a multitude of reasons. Perhaps his condition is not severe enough to warrant admission to a hospital or rehabilitation center. Perhaps the patient’s status or condition is expected to improve over time and he wants to be with his family. Some patients have conditions that will not improve, but they want to live at home and, with the help of medical technology, they can do so with some degree of normality.

Case Study

The Dispatch
EMS Unit 114—proceed to 86 Skyline Drive—you have a 2-year-old male patient who, family states, is lethargic. Be advised, parents state the patient had a “ventricular shunt” replaced about a week ago. Time out is 1132 hours.

Upon Arrival
You safely park the ambulance on the side of the street and keep your emergency lights illuminated. You exit the ambulance with your partner and look around at the quiet, mature neighborhood while you don your gloves. As you approach the house, a woman who turns out to be Mrs. Davidson comes out the front door and says, “It’s my son, Bryan. He’s been sleeping more lately, which hasn’t been bothering me, but today I can’t get him to wake up.” She adds, “He really hasn’t been quite the same since they replaced the shunt in his brain last week.” You proceed into the house and find the patient lying supine in bed, with no outward signs of acute distress, lying there just as if he were peacefully asleep.

How would you proceed to assess and care for this patient?
During this chapter, you will learn about assessment and emergency care for a patient with a “special challenge.” Later, we will return to the case and apply the procedures learned.
While it is impossible to discuss everything that you may encounter regarding patients with special challenges, this chapter is intended to provide you with the fundamental knowledge required to meet the needs of these patients. After completing your EMT class, however, it becomes your responsibility as an EMT to stay abreast of current home health care trends and equipment commonly found in use by these patients. It may be necessary to work closely with the specialty hospitals in your area to better understand the constantly emerging technologies.

**RECOGNIZING THE PATIENT WITH SPECIAL CHALLENGES**

Any number of medical or traumatic conditions can cause loss of function to a body system. As noted earlier, these changes can be mild (such as hearing loss) or substantial (such as inability to breathe spontaneously). For example, a patient may be born with a birth defect that renders him incapable of communicating with you. There may be a number of lost functions as well. For example, a patient who had experienced a stroke may be paralyzed on one side of the body and unable to feed himself normally; so in addition to accommodations for the muscular paralysis, you may find that a special feeding tube has been inserted through the patient's abdominal wall.

Impairments may result from aging, birth defects, chronic illnesses, traumas, abuse, neglect, and other causes. Following are some of the more common causes for these challenges.

**SENSORY IMPAIRMENTS**

A sensory impairment might involve hearing, vision, or speech. This may lead to difficulty in the patient communicating with you or you communicating with the patient. You must be resourceful when dealing with patients with these disabilities in order to provide effective emergency care.

**Hearing Impairment**

Hearing impairment occurs when there is a loss or diminishment in the person’s ability to hear sounds. This becomes especially problematic when the hearing loss is significant enough to hamper normal verbal communication. Deafness is a term that is commonly used to describe the inability to hear. Deafness may involve both ears or just one ear, and the patient may be partially deaf or totally deaf.

**Vision Impairment**

Just as there are multiple causes for deafness, there are also multiple causes for visual impairments, which can be loosely categorized into three etiologies: loss from disease, loss from injury, and loss from degenerative disorders. Certain diseases, such as glaucoma, result in an abnormal increase in intraocular pressure that damages the optic nerve, resulting in peripheral vision loss and eventual blindness. Patients with diabetes mellitus may become blind from diabetic retinopathy, which occurs when the long-term effects of their disease damage the small blood vessels of the eye. Injury to the eye can be caused by puncture or penetration injuries, blunt trauma to the face, or chemical and thermal burns. This type of vision loss is usually acute but may not be permanent, depending on the degree of trauma endured by the eye and associated structures. With aging there may be some degeneration of the eyeball, the optic nerve, the optic nerve pathways, or all three. Cataracts are a condition in which the lens of the eye becomes cloudy from pathologic changes within the lens itself. Cataracts cause the pupil of the eye to look cloudy on assessment, and over time the patient experiences a diminishment in visual acuity to the point where he may not be able to carry on with activities of daily living.

Vision loss may have an acute onset or a slow onset. It may affect one eye or both eyes. It may affect just a certain field of vision in the patient (for example, peripheral vision or central vision). Some types of vision loss are reversible, while others are progressive and permanent. It is important to understand common etiologies of vision loss, so that you can determine if vision loss in a patient is the result of a chronic disability or a new finding from some acute illness or injury that you are there to treat.

**Speech Impairment**

Communicating with the patient is of utmost importance. There are times when the patient is unresponsive and communication is impossible, but that is not the norm. In the majority of patient contacts you will have during your career, the patient will be able to communicate. However, that does not mean that there is always effective communication. Communication can become deranged by four basic types of speech impairments: articulation disorders, voice production disorders, language disorders, and fluency disorders.

With articulation disorders caused by impairment of the tongue or other muscles needed for speech, called dysarthria, the patient cannot pronounce words correctly. Improper articulation can result from learning words incorrectly or from a hearing impairment. It may also be manifested in a patient with damage to the nerve tracts that coordinate the brain with the larynx, mouth, or lips.

Voice production disorders occur when there is damage to the larynx, vocal cords, or related supporting structures from illness or injury. The patient may attempt verbal communication, but the sounds he produces may
be abnormally harsh, hoarse, or of an unusual pitch, or have nasal distortion that makes his speech difficult to understand.

Language disorders occur when the patient displays an impaired or absent ability to understand the spoken word. This can result from congenital problems in children, hearing deficits, or inadequate language stimulation in early life. In later life, language disorders can occur as a result of a stroke, head trauma, brain tumor, or even significant emotional distress.

Fluency disorders present as “stuttering” speech patterns. Although the exact cause for this disorder is not fully understood, the patient struggles with pronouncing words fluidly. The resulting speech pattern has sounds or syllables that are repeated. Communication may be possible, but stuttering typically lengthens the interview process as the patient struggles to provide answers.

Accommodations for Patients with Sensory Impairments

The hearing-impaired patient may have a hearing aid. If so, try to ensure it is on and working properly before you try to communicate with the patient. Many hearing-impaired patients lip-read, so always try to position yourself so your face is in clear view and the area is adequately lit. It may be necessary to communicate in writing if vital information is unobtainable through oral communication. If the patient is able to sign, it may be necessary to have a family member or other person at the scene who knows sign language to act as an interpreter.

For the visually impaired patient, be sure to speak clearly, since the patient may not be able to see your lips, and always explain what you are going to do before you do it (Figure 40-1). Some visually impaired patients use a service dog. This may become an issue with the patient when making the decision to transport. The patient may insist on taking the service dog to the medical facility. You will have to follow your local protocol and service policies and procedures. It may be necessary for you to act as the patient’s guide. Most often the visually impaired patient will want to take your arm or place his hand on your shoulder for guidance.

In any situation of speech impairment, whether from a congenital defect or from an acute process, ask questions in a way that allows the patient to answer in as few words as possible. Do not attempt to finish the patient’s words or statements for him; this typically frustrates the patient and tends to worsen the speech impairment. Remember that a speech impairment does not equal inadequate intelligence. Allow the patient the time to respond to your questions, and only utilize the family or other communication techniques (e.g., writing responses or using hand gestures) when verbal communication has failed. Never pretend that you understood something the patient said when in fact you didn’t. You may miss an important piece of information that would have an impact on how you treat the patient.

Cognitive and Emotional Impairments

Mental or Emotional Impairments

As discussed in the behavioral emergency chapter, mental and emotional illnesses can present as a unique challenge to the EMT. The impairment that the patient demonstrates may range from being so mild it's almost imperceptible to being significant. For example, a patient with a psychosis in which he struggles with interpreting reality may be incapable of communicating effectively with you. A patient with an extreme emotional dysfunction such as depression or anxiety may be so mentally and emotionally impaired that he is unable to focus on your questions or respond appropriately. For a more detailed discussion of mental and emotional problems and how to deal with them, review Chapter 26, “Behavioral Emergencies.”

Developmental Disabilities

Developmental disabilities are conditions that interfere with how a body part or system operates. They typically are present at birth (birth defects), although they may not be diagnosed until later in life. Many times the developmental disability involves the brain and causes an inability to learn at a normal rate. The problem may not be noted until the child fails to reach certain developmental milestones. Developmental disabilities can occur as a result of trauma in utero, during the birth process, or at any time after birth.

Developmental disabilities may involve the brain, spinal cord, nervous system, and endocrine system. In addition to a negative impact on intelligence and the ability to learn, they may cause problems such as speech...
Although patients may display significant cognitive or verbal disabilities, they are often sensitive to body language and tone of voice. They can often recognize anger, disrespect, or carelessness as easily as other people, and their response to it may be anger, frustration, or even swinging their fists at the care providers. This will only complicate your assessment and management and may raise your stress level, which will, in turn, heighten the patient’s.

Keep in mind that many patients with disabilities have been taught to be wary of strangers, and they may become frightened by you, your uniform, your equipment, your cot, and your ambulance. It is important to gain trust with the patient from the outset. Make it clear that you are there to help, and enlist the support of the care provider or another person the patient trusts. These patients may not understand, or even remember, that you are there to help them. Avoid loud noises or extreme changes in lighting when caring for the patient, and consider keeping the primary care provider within eyesight of the patient during transport to the hospital.

At the hospital, the primary care provider needs to be nearby in order to answer questions the emergency department staff may have.

**Brain-Injured Patients**

Previously traumatized patients can be another type of patient with special challenges. Trauma to the brain at any age can result in permanent damage as evidenced by changes in cognition, learning abilities, emotional abilities, and/or use of muscles. Causes can include infant abuse, meningitis, encephalitis, and head injury.

*Cerebral palsy* is an umbrella term for motor impairments that result from brain abnormalities that arise early in development. Although there are different types and degrees of impairment, most people with cerebral palsy demonstrate difficulties in controlling muscle function and may demonstrate muscular stiffness and joint contractures. You may also see wringing of the hands, and some patients may not be able to swallow normally so they tend to drool. Facial grimacing may be noted as well. Although many people with cerebral palsy have some degree of mental retardation, others are highly intelligent. In some, muscular control

---

difficulties and speech impairments are mild. Many patients with cerebral palsy have difficulties communicating verbally, but these patients have probably developed some mode of communication that their care providers will be aware of.

**PATHOPHYSIOLOGY PEARLS**

Brain dysfunction from head trauma is a debilitating injury that usually leaves the patient permanently dependent on outsiders for medical care. The dysfunction of the brain from the injury may result in problems in breathing, heart rate, and blood pressure regulation.

Brain trauma can easily result in a multitude of residual disabilities. The disability may be mild, such as changes in speech pattern or mild cognitive changes, or may be so severe that the patient is unresponsive to external stimuli and dependent on ventilators for breathing, feeding tubes for nutrition, and care providers for day-to-day washing, turning, and bedding changes. Most patients with previous head injury lie somewhere between those two extremes.

**Accommodations for Brain-Injured Patients**

Beyond their current chief complaint, patients with a history of brain trauma will display abnormalities based on the site of injury. The presenting signs and symptoms you note must be categorized as either a “chronic” finding (a residual effect of the trauma) or an “acute” finding (a recent change to a body system that is in need of diagnosis). Gathering a history in these patients will reveal the type of injury sustained earlier and will help identify the changes in the patient’s current condition as either chronic or acute. You should also be methodical when completing your primary and secondary physical assessments.

Brain injury patients may use a large amount of medical technology in order to survive (e.g., pumps, ventilators, catheters), and the EMT must be aware of and manage this equipment during patient transfer. Because of their reliance on medical equipment in the severest of brain injuries, these patients are more likely to develop upper respiratory infections or even pneumonia, to have infected sites where tubes or lines are inserted into the body, to experience problems with nutrition regulation, and to develop bed sores at pressure points of the body.

The care you render for this patient will depend on the condition(s) for which you were summoned. Above all, remember to maintain a patent airway, ensure adequate breathing and oxygenation, and keep peripheral perfusion intact. Consider summoning ALS for a patient who is critically unstable or deteriorating.

**ASSessment Tips**

Patients with preexisting brain trauma may range anywhere from being awake and oriented, to confused, to combative, to unresponsive. It is important to accurately determine their baseline mental state and whether their current status is normal for them.

**PARALYSIS**

It is not uncommon for EMS, summoned to the scene of an accident, to find a patient who has sustained an injury that has resulted in paralysis, or the complete loss of muscle function to one or more groups of muscles. Similarly, it’s not uncommon when summoned to a medical emergency to find a patient experiencing a stroke who has paralysis to one side of his body. What may be uncommon, however, is being summoned to a patient complaining of respiratory distress or chest pain to find that this patient is also paralyzed from some previous traumatic event or medical condition. In this situation, you will have to make necessary accommodations for the patient’s preexisting paralysis while concurrently treating him for the complaint that occasioned the call to EMS.

**PATHOPHYSIOLOGY PEARLS**

A patient who is paralyzed or has significant muscular weakness will be unable to perform many activities of daily living and will be dependent on others to provide care. In addition, ongoing muscle weakness and paralysis may lead to breathing inadequacy and reliance on a mechanical ventilator.

Patients who are paralyzed are susceptible to multiple additional problems. For example, if the paralysis involves the respiratory muscles, the patient may be ventilator dependent. Such patients have frequent respiratory infections because of their inability to cough and clear inhaled debris from their airway. They may also be susceptible to urinary tract infections. (Totally paralyzed patients are routinely catheterized.) Because many of these patients are bedridden and unable to turn themselves from side to side, they may develop pressure necrosis (bed sores) over bony areas of the body. If there is a feeding tube inserted (as will be discussed later), the insertion site may become infected or the tube may become occluded. Secondary emergencies from feeding tube problems can include blood sepsis, dyspnea, chest pain, open soft tissue deterioration, and a myriad of other problems.

**Accommodations for Paralyzed Patients**

Accommodations that need to be made for a paralyzed patient will depend on the degree of paralysis. If just one extremity is paralyzed from some preexisting event,
chances are the patient will still be able to lead a nearly normal life, so there would be nothing too unusual that the EMT would have to manage. If a patient is paraplegic, he will display paralysis from the waist down. He may be found in a wheelchair, and so long as there is no cognitive decline, he should be able to communicate with you normally. Your assessment and management will be almost identical to that for any other patient; the only real concern is moving the patient from his bed or wheelchair onto your cot. Many paralyzed patients will want you to take their wheelchair to the hospital. This is often not allowed by the EMS agency because ambulances do not have the mounting hardware needed to properly secure the wheelchair in case of a sudden stop or ambulance crash. Coordinate with the family or primary care provider to ensure assisting devices the patient relies on (e.g., wheelchairs, canes) are taken to the hospital by someone else (Figure 40-3).

If a patient is paralyzed to all four extremities, he is said to be quadriplegic. If the patient with quadriplegia has had a spinal injury in the vicinity of C3–C5, or if he is suffering from a neuromuscular disease, he may be unable to breathe adequately on his own. In this case, the patient will be ventilator dependent and will likely have an airway tube placed into the trachea near the base of the neck anteriorly. When you are dealing with a home ventilator, keep the settings the same as they were when you arrived. Keep suction nearby in case the breathing tube that the ventilator is attached to becomes occluded. (There will be more information on dealing with ventilators and stomas later in the chapter.) Keep a bag-valve unit nearby as well in case a problem occurs with the home ventilator.

Always look to see if the patient has a urinary catheter in place before you move the patient. You do not want to accidentally pull the catheter out of the urethra during patient movement. Never place the urinary collection bag at a level above the insertion site or at the same level as the insertion. Doing so may cause urine to flow back into the patient or may inhibit drainage from the urinary bladder, increasing the risk of urinary tract infection. Ensure that any feeding tubes or colostomy bags (to be discussed later) are properly secured.

Remain alert to the patient’s needs and to the medical equipment used to keep the patient alive. Be careful while moving the patient to ensure that no care or medical equipment is accidentally disabled. Many times, the family members or primary care providers can offer suggestions about how to best move the patient, given all this technology. If they offer a suggestion, it is usually wise to heed it.

There is a lot to take care of with paralyzed patients. Do not allow these necessary tasks to distract you from the fact that you were probably called for some other emergency that you must concurrently attend to.

### OBESITY

**Bariatrics** is the branch of medicine that deals with the management of obese patients. There is much concern about obesity in the United States. In fact, escalating rates of adult and childhood obesity are one of the nation’s leading health problems. According to the Centers for Disease Control, in 2009 approximately one-third of adult Americans were obese, while nearly 70 percent of adults were either obese or overweight. A person who weighs any amount over his ideal weight is considered to be overweight. Traditionally, a person who is 20 percent or more over his ideal weight is considered to be obese. Some obese patients are considered to be morbidly obese. Morbid obesity has multiple definitions. Commonly accepted definitions are that a morbidly obese person weighs 50 to 100 percent more than his ideal weight or is more than 100 pounds over his ideal weight.

Obesity is the second leading cause of preventable death today, second only to smoking. More than $80 billion in public and private health care money is spent each year to combat obesity and its associated disease states. Of great concern is the increase of obesity in children and the consequent multiple risk factors for additional disease over their lifetime. Obesity is associated with coronary heart disease, type 2 diabetes, immobility, sleep apnea, and hypertension, all of which can reduce the life span if no corrective measures are taken (Table 40-1).

### PATHOPHYSIOLOGY PEARS

**Obesity** places great demands on the body’s systems. Over time, this heightened demand can lead to serious medical conditions such as high blood pressure, sleep apnea, diabetes, and cardiovascular disease.

As rates of overweight, obesity, and morbid obesity continue to climb, EMS crews are encountering these patients more often. It is likely that you will be treating...
Accommodations for Obese Patients

When an emergency occurs, assessment of the obese patient follows a normal assessment format, but modifications may be required because of the patient's size (Figure 40-4). Often, obese patients have “extra” skin and adipose tissue around the face, chin, and neck, and on the posterior surface of the upper thorax. When the patient is standing or sitting upright, the extra tissue usually doesn’t interfere with normal respiratory function; however, when placed in a supine position, problems can develop. Extra adipose tissue in the cheeks, lower jaw, and anterior neck places pressure on the tongue and airway structures, causing closure. Airway complications may arise from the “fat pad” or “buffalo hump” sometimes seen between the patient’s shoulder blades and behind the neck (if no cervical injury is suspected) to provide cervical extension. To displace the tongue mechanically, use an oral or nasal pharyngeal airway. Remember that the oral airway can stimulate vomiting in a patient with an intact gag reflex. In that case, use a nasal pharyngeal airway. You may need to perform a modified jaw thrust to move the jaw and tongue forward and prevent a partial airway obstruction.

Once the airway is ensured, turn your attention to oxygenating and ventilating the patient. Spontaneous breathing in this patient may be impaired by his body size when he is in a semireclined or supine position. In these positions, the posterior thoracic wall has limited mobility and the anterior thoracic wall is weighed down by the patient’s own adipose tissue. Rapid fatigue of the respiratory muscles may occur. In an attempt to compensate for decreased respiratory effort, the patient’s respiratory rate may be elevated, but with tachypnea comes hypopnea (shallow breathing). You must always remember that a breathing patient does not necessarily equal an adequately breathing patient. Along with the rate of ventilation, you must be astute in assessing the depth of ventilation. If the patient needs ventilatory assistance or requires mechanical ventilation, the patient’s size must be taken into account. Lung size is not increased in the obese patient; however, tidal volume is based on ideal body weight, not actual body weight. It is significantly more difficult to ventilate a patient weighing 380 pounds than a patient weighing 180 pounds.

One or more patients within your community who weigh in excess of 500 pounds.

Obesity can occur for a number of reasons. While the short explanation is that the patient is consuming more calories than he is burning (i.e., overeating with a sedentary lifestyle), obesity can also be caused by physiological problems. For example, a patient with hypothyroidism may have a lowered metabolic rate, which means he burns calories more slowly. Some medications, such as CNS depressants and anticonvulsant medications, can lower the metabolic rate and contribute to weight gain. Genetic factors have been cited as contributing to obesity in certain people. It has also been noted that obese people tend to form relationships with each other, and their children are often obese as well, whether from genetics, predisposition, or lifestyle.

A technique that is often overlooked is positioning the obese patient with multiple towels or bath blankets under the shoulder blades and behind the neck (if no cervical injury is suspected) to provide cervical extension. To displace the tongue mechanically, use an oral or nasal pharyngeal airway. Remember that the oral airway can stimulate vomiting in a patient with an intact gag reflex. In that case, use a nasal pharyngeal airway. You may need to perform a modified jaw thrust to move the jaw and tongue forward and prevent a partial airway obstruction.

Once the airway is ensured, turn your attention to oxygenating and ventilating the patient. Spontaneous breathing in this patient may be impaired by his body size when he is in a semireclined or supine position. In these positions, the posterior thoracic wall has limited mobility and the anterior thoracic wall is weighed down by the patient’s own adipose tissue. Rapid fatigue of the respiratory muscles may occur. In an attempt to compensate for decreased respiratory effort, the patient’s respiratory rate may be elevated, but with tachypnea comes hypopnea (shallow breathing). You must always remember that a breathing patient does not necessarily equal an adequately breathing patient. Along with the rate of ventilation, you must be astute in assessing the depth of ventilation. If the patient needs ventilatory assistance or requires mechanical ventilation, the patient’s size must be taken into account. Lung size is not increased in the obese patient; however, tidal volume is based on ideal body weight, not actual body weight. It is significantly more difficult to ventilate a patient weighing 380 pounds than a patient weighing 180 pounds.

Assessment and care of the obese patient follows a normal format, but modifications may be required because of the patient’s size. (© Mark C. Ide)

Assessment Tips

How the obese patient is positioned on the cot for transport may have a significant impact on how well he can breathe. Try to keep the patient upright or lowered to no more than a semi-Fowler’s position, and diligently monitor the airway and breathing status.
After the airway is secured and oxygenation and ventilation have been established, a rapid circulatory assessment can be performed. One of the first signs of inadequate circulation and perfusion is a change in mentation. Alterations in heart rate (tachycardia or bradycardia) and blood pressure (hypotension or hypertension) can influence the patient’s mental status. Treat these abnormalities in accord with your protocol.

The extra weight is problematic when it comes to lifting and moving the obese patient. Beyond enlisting the help of additional personnel to move the patient to the portable cot (one of the greatest injuries to health care providers everywhere is back injuries from lifting), the patient’s weight may exceed the structural limitation of the cot. Cot manufacturers now design “bariatric devices,” which include special cots (able to hold greater weight) and bariatric loading devices such as special ramps and winches that interface with specially designed ambulance cot-locking systems (Figure 40-5).

During transport, continue assessment and management according to the patient’s needs. When you notify the receiving facility about this patient, let them know that they will need to prepare their special stretcher and that help may be needed for patient off-loading. Many EMS systems have not gone to specialized transport equipment such as dedicated rigs, lifts, and cots.

**HOMELESSNESS AND POVERTY**

During a “single point” assessment that was made in January of 2007, the U.S. Department of Housing and Urban Development (HUD) reported that there were almost 700,000 people in the United States that met the definition for homelessness. Worldwide, this number is estimated to exceed 100 million people. HUD defines chronically homeless as “an unaccompanied homeless individual with a disabling condition who has either been continuously homeless for a year or more, or has had at least four episodes of homelessness in the past three years.”

Several factors contribute to a person becoming homeless, or as said in legal circumstances, having “no fixed abode” (NFA). These factors include:

- Poverty (from unemployment or underemployment)
- Substance abuse
- Lack of affordable housing
- Mental illness
- Prison release back into society
- Domestic violence
- Mortgage foreclosures and forced evictions
- Natural disaster

Homeless people, because they do not have a safe and suitable home, typically face social disadvantages and reduced access to services provided by both public and private entities. In fact, services that could be available to them may be denied because they cannot document their date of birth or address. Because of the inability to protect their personal items, documents like identification and birth certificates are lost, stolen, or destroyed. Trying to obtain replacements is difficult because either they lack the money for required replacement fees or they don’t have an address for the documents to be mailed to.

Many times, a homeless person is so focused on surviving day to day that he is unable to devote time or resources to activities that would help get him off the streets. The following are examples of disadvantages and reduced access to services that homeless people must endure:

- Increased risk of violence and abuse
- Increased risk of illness/disease
- Discrimination from others (perception that they are “crazy” or “lazy”)
- Reduced access to health care
- Limited or no access to education
- Limited or no access to modern communications (telephone, Internet)
- Not seen as suitable for employment purposes

Because of the lack of a permanent residence or place for storage of their possessions, the homeless have to cart their belongings with them from place to place, for example in bags or shopping carts. When an emergency arises, there is no “address” for you to respond to. Often you’ll be summoned to street corners, alleys, or phone booths when an emergency involves a homeless person (Figure 40-6). The following are types of locations where homeless people may find refuge:

- Abandoned or condemned buildings
- Public places such as parks, train or bus stations, airports, college campuses
- Vehicles (their own or abandoned)
- Outdoors in improvised shacks or on the ground with sleeping bags
obstructive pulmonary disease (COPD) because of a lack of normal medical care. The first time this patient presents to you with dyspnea may well be his first indication of deterioration since developing the disease. While you should always listen to what the patient tells you, do not disregard physical assessment findings that tell you a different story. Patients who live at or near the poverty level are more likely to be subject to accidental trauma, physical abuse, or crimes and to develop chronic medical conditions (e.g., heart disease, lung disease, hypertension, diabetes) and yet have limited access to health care. All too often, impoverished people have to choose between buying medications for themselves and buying food for the family or paying the heating bill.

Accommodations for Patients Who Are Homeless or Poor

The health of a person living in the United States is strongly correlated with the income of that person (or family). The poor or homeless are less healthy than those who are financially better off. Regardless of how you measure it—by mortality, the incidence of diseases, or the frequency of mental health issues—people lower on the economic ladder suffer from higher rates of illness and death.

Statistics show that over 90 percent of Americans will, at some time, live below the poverty level for at least a year and will face the challenges just discussed. In making special accommodations for these patients, perhaps one of the best things you can do is not be judgmental. Homeless and impoverished people are
well aware of their surroundings and their lack of monetary resources. They do not need someone telling them that they “need a job” or “could have prevented this.” The patient has summoned EMS because he is in a situation that he cannot handle on his own, and he should be treated with the same respect and compassion as any patient who may have access to more services. You are as much an advocate for this patient and his needs as you are a skilled provider delivering emergency care. Remember, you're treating the patient because he needs your help, not because he has a bank account.

In the absence of a specific mental, emotional, or physical disability (such as those already discussed in this chapter, all of which are more prevalent in this patient category), your assessment and management of the patient will not vary much from that provided to other patients with similar complaints. One concern you may hear from the patient is that he does not have the money to pay for the ambulance or hospital bill. In this situation, explain to the patient that almost all health care providers offer a certain degree of reduced cost or free medical care. Become familiar with hospitals and services in your community that provide medical care, shelter, food, or other services to families (or individuals) in need.

**ASSESSMENT TIPS**

If you spend any amount of time in EMS, you will undoubtedly encounter homeless people. Your duty to assess and care for these patients is the same as for patients who are not as disadvantaged.

---

**ABUSE**

Abuse and neglect have many definitions and can present in numerous ways, but consistent features include any action or failure to act that results in unreasonable suffering, harm, or misery to a person, whether physical or mental. Although commonly thought of as affecting children or the economically disadvantaged, abuse transcends all age, gender, race, and socioeconomic groups. In addition to child abuse, common categories include elder abuse and partner abuse. More detailed information on child abuse is found in Chapter 38, “Pediatrics,” and more detailed information on elder or geriatric abuse is found in Chapter 39, “Geriatrics.”

**TECHNOLOGY DEPENDENCE**

There was a time when the patient would remain hospitalized to receive ongoing treatment until the injury/illness that he was suffering from had been treated to the greatest extent possible. The result was prolonged hospital stays with the expenditure of significant health care dollars.

This practice began to change in the latter half of the twentieth century because of governmental and insurance initiatives designed to curb rising health care costs. Concurrently, there has been the development of medications and medical technology designed to help sustain life in the home setting. Consequently, there has been a shifting of patients from an in-hospital setting for ongoing medical care to the home setting. The result has been a dramatic increase in the number of health care providers who function outside the hospital, usually in the patient’s home, as well as a large increase in the use of medical technology in the home setting for patients who rely on it for survival. Studies indicate that over 8 million people in the United States receive some type of professional health care at home, with millions of other patients receiving ongoing care from family members, friends, or other volunteers.

While some medical equipment is designed to enhance the quality of life and allow patient independence (e.g., feeding tubes or urinary catheters), some medical equipment found in the home setting actually sustains life (e.g., ventricular assist devices and mechanical ventilators). You must remain abreast of trends in home-based medical technology. It is now common for the EMT to be summoned to the home of a patient where the medical equipment has failed, or where the patient’s clinical status has changed to the point where the medical equipment can no longer provide the needed support, or where the patient who is dependent on the medical equipment has suffered some other emergency that exceeds the primary care provider’s ability to manage the situation. You must be able to determine what the medical device is supposed to be doing for the patient, how critical its function is to patient survival, and what type of impact the device has, if any, on other medical or traumatic emergencies the patient may suffer. Often you will need to depend on the primary health care providers for information about the equipment the patient is reliant on prior to initiating any care (Figure 40-8).
For the discussion in this chapter, we categorize the most common medical equipment as airway and respiratory devices, vascular access devices, dialysis shunts, gastrourinary support devices, and intraventricular shunts. It is impossible to cover all types and makes of medical technology used in the home, so as you approach the technology-dependent patient you should ask yourself the following questions to help determine the best course of action for ongoing assessment and care:

1. Where would I get the best information regarding this piece of equipment?
2. What does this device do for the patient?
3. Will this equipment have an effect on how I assess the patient, or on the findings I may discover?
4. Has this problem ever occurred previously, and if so, what fixed it?
5. Has anyone attempted to remediate the problem?
6. Are there specific considerations I need to make when deciding how to best prepare the patient for movement and transport?
7. Where would I get the best information regarding this piece of equipment?

Although much of the equipment you will see in patients’ homes is similar to what you would see in a hospital setting, there is usually a difference in the size and the complexity of the device. Try not to become overwhelmed with the medical equipment, but realize that since the patient is dependent on this equipment, his clinical status is probably already diminished and he may decompensate faster than other patients. Constantly assess the patient and be prepared to intervene should deterioration occur. In emergencies, keep your approach to the patient simple, focusing on the following tasks:

- Keep the airway open.
- Establish and maintain adequate ventilation while supplying supplemental oxygen.
- Maintain adequate oxygenation at 94% or greater.
- Intervene as needed to support any lost function to the circulatory system.

If, at a minimum, you provide this care, you will ensure the patient the best chance for survival regardless of the immediate emergency and the patient’s dependence on medical technology.

**AIRWAY AND RESPIRATORY DEVICES**

These are devices that support the most vital of body functions: airway, ventilation, and oxygenation. Equipment that will be discussed relates to use of medical oxygen in the home, apnea monitors, pulse oximetry, tracheostomy tubes, and respiratory devices (continuous positive airway pressure and mechanical ventilators).

**Medical Oxygen**

The use of medical oxygen has been increasing over the past several decades with the advent of better portable devices for oxygen delivery as well as better diagnostic procedures for determining its need. The use of oxygen in the home significantly increases the quality of life and life span of those who need it. Oxygen use in the home is easy to manage, with most problems able to be corrected by the patients themselves.

Home oxygen equipment is similar to the oxygen equipment you would use on the ambulance. For example, there is an oxygen source (compressed liquid or an oxygen concentrator machine), a flow regulator, oxygen supply tubing attached to the oxygenation adjunct such as a nasal cannula, and an in-line system for humidifying the oxygen. It is often easy to determine if the patient is on oxygen at home because you will see a sign indicating oxygen use as you approach the front door or the patient’s bedroom, or you will see the oxygen supply tubing extending from the oxygen source to the patient.

While the EMT uses oxygen that is compressed in a tank, oxygen may be provided somewhat differently in the home setting. Three sources of oxygen for patients at home are:

- **Oxygen cylinder.** This design is similar to, if not exactly like, what the EMT is already accustomed to. The oxygen is compressed in a tank, just like on the ambulance, and it is adjusted by a flowmeter and administered to the patient via an oxygenation adjunct (for example, a nasal cannula).
- **Oxygen concentrator.** This medical device extracts oxygen from the ambient environment and then supplies it to the patient. Because of the oxygen extraction limits of the machine, the flow commonly delivered is less than 6 lpm.
- **Liquid oxygen.** Liquid oxygen is atmospheric oxygen that has been cooled to −183°C and then stored under pressure in a container (similar in structure to a thermos). In liquid form, it can be stored for long periods, which makes this storage system especially attractive to patients who are chronically dependent on oxygen. (One liter of liquid oxygen will produce 860 liters of gas.) There will usually be a larger liquid oxygen storage unit in the home that is used to refill small portable oxygen containers the patient can carry, allowing mobility not possible with other oxygen sources like a tank or concentrator.

As already noted, few problems arise from the oxygen systems themselves, and if a problem does arise, it is usually remediated by the patient or primary care providers (Table 40-2). Usually the problems that require EMS involve some equipment failure in which the system stops providing oxygen. The EMT can easily correct this situation. Another situation in which EMS may be summoned is if the patient’s condition changes...
or worsens, and the amount of oxygen he is receiving at home for his chronic condition is no longer sufficient. (For example, a patient with COPD may develop pneumonia and start to complain of dyspnea.) In these situations, administer oxygen according to the same protocols as for any other patient with respiratory distress who is in need of oxygen.

**Apnea Monitors**

An apnea monitor is designed to constantly monitor the patient’s breathing and emit a warning signal should breathing cease. Some are also designed to monitor heart rate, since changes in the heart rate may signal failure of the respiratory system. This type of equipment is commonly found in the home with an infant, especially a newborn infant who was born prematurely. These devices emit a loud piercing sound to signal a problem, and often emit a series of beeps indicating how long the machine has been alerting should the care providers be out of hearing range when the signal starts. For example, the device may emit one beep as an initial warning, then progress to two beeps as time elapses, and then three beeps, and so on.

Try to ascertain from the primary care provider how long the machine was alerting a problem prior to EMS arrival. Also ascertain what type of interventions the care provider has done prior to your arrival. Commonly the parents or care providers for neonates who need this equipment are taught basic airway and ventilation skills to use in an emergency. Remember to be thoughtful of the care providers. When the parents have an infant with medical problems and an emergency occurs, it can be an extremely frightening experience.

When you are summoned to the home of a patient with this technology, you should perform your normal scene size-up and primary assessment. Since the apnea monitor is designed to signal a respiratory problem, be especially diligent in your assessment of the patient’s respiratory rate and tidal volume. Apnea can also be a sign of a very serious infection in an infant. If you find that the patient is breathing adequately, it may be from some intervention provided by the parents, an incorrect alarm triggered by the machine, or the resumption of spontaneous breathing by the infant. In any instance, do not try to “diagnose” what is wrong with the apnea monitor. Instead provide oxygen to the infant and transport him to the hospital for evaluation. If the patient is found to be apneic or breathing inadequately, provide airway control and positive pressure ventilation with supplemental oxygen while you transport the infant to the hospital.

**Pulse Oximetry**

The pulse oximeter is a medical monitoring adjunct that the EMT is already familiar with. It is not only a device that EMTs can use to monitor oxygen saturation in patients, it can also be used as a monitoring device in the home. Often pulse oximetry is done in conjunction with apnea monitoring for newborn infants. Other common reasons for pulse oximetry in the home include the following:

- A patient with chronic pulmonary disease who needs to adjust oxygen intake to maintain a certain level of blood oxygen saturation
- Medical need to keep oxygen saturation within a specific therapeutic range
- Need to monitor oxygen needs in a patient who has a fluctuating oxygen demand (for example, during feeding, sleeping, or movement)

If a patient has continuous pulse oximetry monitoring at home, he is likely to have an acute or chronic pulmonary condition. This is important to note, because preexisting pulmonary conditions may rapidly

## Answer

**Apnea Monitors**

An apnea monitor is designed to constantly monitor the patient’s breathing and emit a warning signal should breathing cease. Some are also designed to monitor heart rate, since changes in the heart rate may signal failure of the respiratory system. This type of equipment is commonly found in the home with an infant, especially a newborn infant who was born prematurely. These devices emit a loud piercing sound to signal a problem, and often emit a series of beeps indicating how long the machine has been alerting should the care providers be out of hearing range when the signal starts. For example, the device may emit one beep as an initial warning, then progress to two beeps as time elapses, and then three beeps, and so on.

Try to ascertain from the primary care provider how long the machine was alerting a problem prior to EMS arrival. Also ascertain what type of interventions the care provider has done prior to your arrival. Commonly the parents or care providers for neonates who need this equipment are taught basic airway and ventilation skills to use in an emergency. Remember to be thoughtful of the care providers. When the parents have an infant with medical problems and an emergency occurs, it can be an extremely frightening experience.

When you are summoned to the home of a patient with this technology, you should perform your normal scene size-up and primary assessment. Since the apnea monitor is designed to signal a respiratory problem, be especially diligent in your assessment of the patient’s respiratory rate and tidal volume. Apnea can also be a sign of a very serious infection in an infant. If you find that the patient is breathing adequately, it may be from some intervention provided by the parents, an incorrect alarm triggered by the machine, or the resumption of spontaneous breathing by the infant. In any instance, do not try to “diagnose” what is wrong with the apnea monitor. Instead provide oxygen to the infant and transport him to the hospital for evaluation. If the patient is found to be apneic or breathing inadequately, provide airway control and positive pressure ventilation with supplemental oxygen while you transport the infant to the hospital.

**Pulse Oximetry**

The pulse oximeter is a medical monitoring adjunct that the EMT is already familiar with. It is not only a device that EMTs can use to monitor oxygen saturation in patients, it can also be used as a monitoring device in the home. Often pulse oximetry is done in conjunction with apnea monitoring for newborn infants. Other common reasons for pulse oximetry in the home include the following:

- A patient with chronic pulmonary disease who needs to adjust oxygen intake to maintain a certain level of blood oxygen saturation
- Medical need to keep oxygen saturation within a specific therapeutic range
- Need to monitor oxygen needs in a patient who has a fluctuating oxygen demand (for example, during feeding, sleeping, or movement)

If a patient has continuous pulse oximetry monitoring at home, he is likely to have an acute or chronic pulmonary condition. This is important to note, because preexisting pulmonary conditions may rapidly
deteriorate into respiratory distress or arrest, either from the original disturbance or from failure of some other body system. Often the patient with this type of home technology will have complaints that center around the pulmonary system. Be sure to determine from either the patient or care provider what the oxygen saturation trends were prior to arrival and what interventions, if any, were done (e.g., patient positioning, use of home oxygen). Even if the pulse oximeter the patient is using is portable, you should use your own pulse oximeter in assessing the patient. This will help to ensure that the reading you get is accurate, since your equipment on the ambulance may undergo more rigorous biomedical compliance procedures than a home unit.

Tracheostomy Tubes

A tracheostomy is performed when it becomes necessary to open a new airway in patients with certain medical or traumatic conditions. It is a surgical opening made through the neck and into the trachea to provide an alternative route for air to move into and out of the body, bypassing the mouth and nose. The site for this surgical opening is usually the inferior trachea, somewhere near the second through fourth tracheal ring anteriorly. A tracheostomy may be performed as a temporary measure, or it can be a permanent opening. If the opening is to be permanent, it is referred to as a stoma.

A tracheostomy is commonly provided for patients who have either long-term upper airway problems or medical conditions that result in long-term dependence on a mechanical ventilation. Patients who have sustained blunt or penetrating trauma to the larynx, epiglottis, or other upper airway structures that result in permanent airway damage may need a tracheostomy. Additionally, tracheotomies are sometimes performed on patients who have cancer of the larynx or neck with resulting long-term structural damage to the original airway structures. Patients with neuromuscular disorders, congenital deformities, coma, spinal cord injuries, or other conditions that affect the ability to breathe usually have a tracheostomy tube that is inserted into the stoma to keep the opening patent.

A tracheostomy tube placed in the stoma of an infant commonly has just a single lumen because of the small size of the trachea. For older children and adults, there is an outer cannula and an inner cannula (Figure 40-9). The outer cannula keeps the stoma open and is held in place by a Velcro strap or twill tape around the neck. The inner cannula is smaller in diameter and slides into the outer cannula. The distal end of the inner cannula has a low-pressure cuff (similar to that of an endotracheal tube) that when inflated helps to hold it in place and create a good seal against the walls of the trachea. The proximal end of the tracheostomy tube has an adapter that will fit a standard bag-valve-mask or flow-restricted, oxygen-powered ventilation device should positive pressure be needed.

A patient with a tracheostomy tube may or may not be able to speak, depending on the condition of the upper airway structures (larynx and vocal cords). If these structures are still intact, the patient can plug the tracheostomy with a finger, which directs the exhaled air through the vocal cords to permit speech. If these structures are damaged or have been surgically removed, normal speech will be impossible. To compensate for this, the patient may have a device shaped like a small flashlight that, when held up to the neck and activated, will produce a vibration sound the patient learns to manipulate by changing the shape of his mouth. This allows verbal communication to happen, but you may have difficulty initially trying to understand the words. In the absence of any form of spoken communication, you will need to use hand gestures or writing to communicate with the patient.

Emergencies that concern a patient with a tracheostomy tube usually involve one of two things. First, the tube itself may have become plugged by mucus. Since the upper airway is bypassed by the tube, the normal functions of the upper airway such as filtering and humidification of inspired air are lost, and as a result the tracheostomy tube needs regular suctioning. Second, the inner cannula of the tube could have become dislodged from movement or may have become occluded by a foreign body. Less common emergencies that pertain to the tracheostomy tube include infection or bleeding at the insertion site. During your assessment of a patient with an emergency pertaining to a tracheostomy tube, you must rapidly determine if the problem is that of airway occlusion or (if the patient is also ventilator dependent) if the ventilator is malfunctioning.

If the tube is partially or totally occluded from bleeding or heavy secretions, use a whistle-tip (soft) suction catheter to clear the airway (Figure 40-10).
Measure the depth of insertion for the suction catheter by comparing it to the tracheostomy tube obturator. (The obturator is a blunt-tipped plug that fits inside the tracheostomy tube during the insertion process and is then removed after successful placement. It can usually be found with the patient’s other tracheostomy supplies.) If the obturator cannot be found quickly, gently insert the catheter tip until mild resistance is met. Apply suction and slowly withdraw the catheter while twisting it between your fingers. Do not suction for longer than 10 to 15 seconds in an adult, and 5 seconds in a pediatric patient at once. Oxygenate your patient between suctioning attempts, and rinse out the lumen of the suction catheter with sterile water between attempts.

Manipulation of a tracheostomy tube may be outside the EMT’s protocol, so make certain that you are allowed to perform these interventions before doing so. The primary care provider, if available, is probably the most skilled in tracheal suctioning for this patient, so try to enlist the care provider’s help.

If you find the tracheostomy tube to be patent, the problem may be with the patient’s ventilator. This emergency will be discussed later in this chapter, but the short answer is to remove the ventilator circuit and provide positive pressure ventilation by attaching your bag-valve-mask device directly to the tracheostomy tube’s external fitting.

**CPAP and BiPAP**

Both continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) machines are designed to provide a therapeutic back-pressure during respiration via an airway circuit attached to a mask that covers the mouth and/or nose. While the CPAP device provides a constant pressure during the ventilatory cycle, the BiPAP machine provides a higher pressure during inhalation and a lower pressure during exhalation. The primary therapeutic goal of either device is to keep the bronchioles open during exhalation, which improves both oxygenation and ventilation and also decreases the work of breathing. Some CPAP and BiPAP machines also allow the administration of oxygen during their use.

**PATHOPHYSIOLOGY PEARLS**

When there is damage to the lower airway structures from disease, it is difficult for the airways to remain open. The use of CPAP or BiPAP will help keep these smaller airways stented open so that better ventilation can be achieved.

This equipment is commonly used in patients diagnosed with COPD or sleep apnea. A prehospital CPAP device is commercially available and is used in many EMS systems for patients suffering from respiratory distress from many conditions. Follow your local protocols in regard to the use and application CPAP.

Emergencies related to a CPAP or BiPAP machine are rare. During your assessment of a patient who uses a CPAP or BiPAP machine for sleep apnea, you will likely learn that EMS was summoned not for an emergency related to the device but rather for a respiratory distress complaint arising from the patient’s chronic pulmonary condition or some other medical emergency. This is because CPAP or BiPAP is used during sleep, and while the patient is awake he is not dependent on the device. During your assessment and management of this patient, you may utilize a CPAP machine if your protocol allows and the patient meets your inclusion criteria. If, however, you are assessing and treating a patient for some complaint and he also concurrently uses a CPAP or BiPAP while sleeping, you may want to transport the device to the hospital with the patient and be sure to alert the receiving facility of the patient’s need for it during sleep.

**Home Mechanical Ventilators**

A home mechanical ventilator is designed to assist a patient with breathing who cannot breathe adequately on his own. The patient may have any one of several reasons to be dependent on a ventilator. Causes typically center around the brain’s inability to initiate a spontaneous breath, a structural defect to the thorax or lungs that prohibits or greatly diminishes normal gas exchange, or a neuromuscular disease that renders the respiratory muscles of the body useless. Causes may also include history of a debilitating stroke, brain damage following head trauma, or long-term pulmonary problems (e.g., COPD, lung cancer). Commonly, you will learn the reason for the patient’s ventilator dependency while you are ascertaining his medical history.

There are two types of mechanical ventilators: negative pressure and positive pressure. Negative pressure ventilators, such as the “iron lung,” encircle the patient’s chest and generate a negative pressure around the thoracic cage. The negative pressure draws the rib cage out, which creates a negative intrathoracic pressure that causes air to be drawn into the lungs. These devices are rarely used in the home setting because newer and better technology is available. Today, the
devices commonly encountered are positive pressure ventilators. With these devices, air from the ventilator is pushed into the patient’s lungs, much as when an EMT squeezes a bag-valve-mask device in order to force air into the lungs during artificial ventilation. Exhalation ensues when the positive pressure stops and the chest wall and lungs recoil.

Home ventilation units come in various sizes. The small, newer devices can be similar in size to a laptop computer, weighing just pounds. Some ventilators are larger, and may weigh up to 20 pounds or more. There are several ventilators available for use in the home or extended-care facility, and they can vary significantly in cost and sophistication. Regardless of size, they are generally designed for convenience and ease of use by the patient or the patient’s primary care provider.

Home ventilation units typically have two or three controls: one for the ventilatory rate, one for adjusting the size of each breath (tidal volume), and in some cases one control that adjusts the amount of oxygen that is provided during ventilation. Tidal volume in most is adjustable, while the ventilatory rate and oxygen supply, if provided, may be either fixed or adjustable. The ventilator attaches to the patient by large-diameter tubing that is referred to as the ventilator circuit. The vent circuit attaches to the tracheostomy tube placed in the patient’s trachea. The proximal end of the tracheostomy tube has a standard 15/22 mm adapter on it, so any type of ventilatory device (bag-valve mask, flow-restricted, oxygen-powered device, or mechanical ventilator) can be operated through the same ventilation port.

Ventilators may have several alarms to alert the care provider if the ventilator is not functioning properly. In fact, one of the alarms going off may be the reason EMS is summoned. Because of variances among these devices, the particular ventilator your patient uses may or may not have the following alarms:

- **High-pressure alarm.** A high-pressure alarm is activated when the pressure needed to cause lung inflation exceeds the present value. The cause can be increased airway resistance, such as increased secretions occluding the tracheostomy tube, kinking of the ventilator circuit, movement of the tracheostomy tube, bronchospasms, or the patient coughing during inspiration. The alarm can also be triggered by decreased lung compliance. Causes for decreased lung compliance include the development of a pneumothorax, progressive pneumonia, development of acute pulmonary edema, or even atelectasis.
- **Low-pressure alarm.** The low-pressure alarm is usually set to activate when the tidal volume falls 50–100 mL below the set tidal volume. This usually indicates a problem in the breathing circuit, such as a disconnected segment or a leak in the cuff of the tracheostomy tube.
- **Apnea alarm.** Some patients who have a vent may still have some respiratory effort, but it is inadequate to sustain life. Their home ventilator may be set up to not trigger a breath until the patient starts to breathe in. In these models, the apnea alarm sounds when the patient stops breathing. Causes are usually physiological and include decreased mental status, overmedication, and respiratory muscle fatigue.

When approaching the patient with a ventilator emergency, be aware that the alarms going off may have been caused by a change in the patient’s clinical condition, not necessarily by ventilator malfunction. Although the ventilator may fail because of electrical supply interruption, failure of some internal component of the ventilator, or even a problem with the ventilator circuit, the real problem your patient is experiencing may not be the ventilator’s fault at all. A change in the patient’s clinical status, for example, could make the ventilator malfunction. If the high-pressure alarm goes off, it could be from tracheostomy tube occlusion resulting from mucus buildup, or from the development of a spontaneous pneumothorax causing an increase in airway pressure. Another example could be the patient who also uses a pulse oximeter for whom the low saturation alarm may alert, which could be from a malfunctioning ventilator but could also be from hypoxia related to pneumonia, lung collapse, or even a heart attack.

Do not assume that if the ventilator starts to alarm, the remedy is to disconnect it and use a bag-valve mask. Although it may seem logical to simply disconnect the mechanical ventilator and bag the patient manually, if the inadequate breathing is from a change in the patient’s status (e.g., pneumothorax, airway occlusion), ventilating him manually will provide no more help than the mechanical ventilator could supply. Always troubleshoot the ventilator and the patient.

**ASSESSMENT TIPS**

When dealing with a patient who has a malfunctioning ventilator, pay close attention to the quality of breath sounds and chest rise and fall during manual ventilation. Be sure not to overventilate or underventilate the patient.

**Accommodations for Patients with Airway or Respiratory Devices**

You may not always know that the patient is reliant on airway- or respiratory-assist technology prior to your arrival on the scene. That depends on what the caller told dispatch. You must be prepared to interact with this type of equipment at a moment’s notice. Your assessment of the patient will not change drastically despite the presence of this technology. Since this equipment is being used to support or replace a lost function of the body, you will automatically assess its adequacy in supporting that lost function while you perform your usual primary assessment, history, and physical exam.
Most likely, the complaint received by dispatch will be one of the following: airway occlusion, respiratory distress, altered mental status, ventilator/CPAP alarm, or low pulse oximeter finding. In most emergencies like these, the primary care provider has been taught by the medical equipment company to alert EMS when certain aspects of the device fail to function properly. Although the problem may turn out to be a false alarm, you must be ready to take over should some piece of technology fail.

Dispatch may be able to tell you the type of medical technology the patient uses. This will allow you to start planning your approach to the patient while you are en route. On arrival, do not be complacent and neglect to perform a scene size-up for your own safety. Information gained during the scene size-up will also let you know if you need to summon additional backup to help move the patient and his equipment from their current location to the ambulance.

The primary assessment should be conducted in the same sequence for a patient with airway or ventilatory devices as for those without such devices. Form your general impression as you approach the patient. While you are completing your primary assessment, talk to the patient’s primary health care provider to determine the history and recent status of the patient, if possible. After evaluating the patient’s mental status, focus on the airway. If the patient has an anatomically intact and patent upper airway, you will move to the assessment of breathing. If the upper airway is occluded, you will follow the steps for airway clearance as discussed in previous chapters.

If you find the patient has a tracheostomy tube, you will need to rapidly assess it for patency. If it is blocked by mucus or fluid, it must be immediately cleared or the patient will continue to deteriorate into cardiac arrest (just like any patient with an airway occlusion). If there is a primary care provider immediately available with experience in suctioning the tracheostomy, enlist that person’s help. If this is not an option, and if your protocol allows, select a soft or flexible suction catheter and insert it carefully into the tracheostomy tube. Remember that the trachea is considered to be a sterile field, so if at all possible use a sterile technique for suctioning with sterile gloves. Try not to insert the suction catheter farther than the length of the inner cannula of the tracheostomy. Measure the suction catheter against the obturator used for the insertion process (which, as noted earlier, is usually found with the patient’s other airway supplies). If the obturator cannot be located, insert the suction catheter carefully until you meet resistance.

Once the catheter is placed, apply suction (~80 to –120 cm H₂O) while you withdraw the catheter. Rolling the catheter between your fingers during extraction will provide better clearing of the mucus or fluid. Suction for only 10 to 15 seconds in an adult and only 5 seconds in a child. The tracheal stimulation from your suction catheter will probably cause the patient to cough, sometimes forcefully. Although this is to be expected, the coughing may cause mucus or fluid to be blown out of the opening. Be sure to wear the necessary protective equipment so that your eyes and face are not exposed.

After each episode of suctioning, rinse out the suction catheter with sterile water. If the tracheostomy tube blockage appears to be from dislodgment rather than fluid or mucus plugging, removing it may be the only option available to restore a patent airway. Remember that the adult tracheostomy has an inner cannula with a distal cuff. This cuff needs to be deflated with a 10 mL syringe prior to removal. After removal, the airway can be suctioned as needed and then reevaluated. Removal of the inner cannula should only be performed by the primary care provider if that person is capable of doing so, or by an ALS provider. Once the airway is patent again, only then should you focus on the next step of the primary assessment, breathing.

Determination of adequate breathing should be performed in the same manner as for any patient who is spontaneously breathing. If the spontaneously breathing patient is found to have inadequate ventilations, positive pressure ventilation with oxygen should be provided, just as it would for any other patient.

If the patient uses a CPAP machine at night, more than likely he will be awake while in your presence and not need the CPAP machine. In fact, medical emergencies related to the CPAP are uncommon. If problems arise with CPAP, it is usually handled by the company or provider that services the unit for the patient (if it’s mechanical), or the patient’s respiratory therapist if the problem relates to difficulty in use of the device. If, however, the patient is experiencing some medical or traumatic emergency independent of the CPAP machine, you should treat the patient as appropriate and may wish to take the CPAP unit to the hospital with the patient in case he is admitted and needs the device during sleep.

A patient who is dependent on a mechanical ventilator is a slightly different situation. If on arrival you find the patient to be breathing inadequately with the device (as evidenced by minimal chest movement and diminished to absent breath sounds in the bases of the lungs), you must rapidly determine if the inadequate breathing is secondary to airway occlusion, ventilatory circuit occlusion or kinking, mechanical failure of the ventilator, or a change in the patient’s clinical status that has rendered the ventilator ineffective.

First remove the ventilator circuit, place a bag-valve mask on the 15/22 mm adapter of the tracheostomy tube, and attempt one or two ventilations (Figure 40-11 ■). If the ventilations do go in easily and you see chest wall movement, the problem is likely either ventilator failure or a problem with the ventilation circuit. If that is the case and you can fix the problem with the ventilator, or if your protocol allows you to adjust the ventilator’s settings (rate and tidal volume) to meet the patient’s needs, the ventilator may be reapplied during transport to the hospital.
If you do not see immediate rise and fall of the chest, the bag-valve mask is hard to squeeze, and/or you don’t hear alveolar breath sounds, the problem may lie with the patient. First reassess the airway as described earlier and clear it as appropriate, then reattempt ventilation. If there is still a problem, assess for clinical findings such as bronchoconstriction, pneumothorax, tension pneumothorax, or severe pneumonia. Provide management as appropriate for the offending problem as discussed in previous chapters, contact ALS, and continue with manual ventilations while en route to the hospital.

Once the airway and breathing components are ensured or restored, next focus on the circulatory assessment. Assess the heart rate and skin characteristics to rapidly gauge the patient’s perfusion status. Provide management as appropriate for disturbances in the circulatory system.

The patient should be considered unstable and rapidly transported if there is some acute lost function to the airway, breathing, or circulatory components that the EMT must support during transport. The patient should be considered potentially unstable if there was a mechanical malfunction or clinical change that precipitated a critical intervention by the EMT but now the current status is seemingly stable. Finally, the patient should be considered stable if there was no acute loss of function, no critical interventions were warranted, and the patient is receiving primarily supportive care while en route to the hospital for evaluation.

Regardless of the interventions provided by the EMT for the patient who has a ventilator or CPAP emergency, special considerations will need to be made in transporting the patient to the hospital. If the ventilator is still operating normally for the patient, you may want to use the bag-valve mask to ventilate the patient carefully while you move him to the ambulance. Once inside the ambulance, plug the patient’s ventilator into the onboard inverter and place it back on the patient. If the ventilator is no longer functioning, you may still wish to take it to the hospital with the patient and explain any problems with the device to the receiving facility staff. Remain flexible in your approach, management, and transfer of the patient with airway or ventilatory equipment.

One final concern with airway and ventilatory devices is how you document your findings and care. A significant percentage of claims and lawsuits that are filed against prehospital providers involve inadequate patient ventilation. It is critical that you document in medically correct and legally sufficient terms exactly what was done in managing the patient’s airway and ventilation. Such documentation can save you from a claim or lawsuit being filed or, in the unfortunate event that one is filed, can help you to prevail.

### Vascular Access Devices

A vascular access device is a medical device that is used when a patient is in need of ongoing intravenous medications. Usually these devices are placed in patients who need medication for longer than 7 to 10 days, but they may be used on a longer-term basis as well. The type of device and duration of its use are largely dependent on the disease process and medical needs of the patient. Over half a million devices of this nature are placed annually, typically in patients who require ongoing chemotherapy, peritoneal dialysis, hemodialysis, total parenteral nutrition (TPN), or antibiotic therapy. Although the EMT does not access vascular access devices for medication administration, a knowledge of their presence, basic function, and how to care for them during assessment and transport is important (Figure 40-12).

![Figure 40-12](image-url) Vascular access devices include central IV catheters such as a PICC line, central venous lines such as the Broviac catheter, and implanted ports such as the MediPort system.
PATHOPHYSIOLOGY PEARLS

Sometimes a medication that is needed to manage a patient’s condition must be administered often or, because of the drug’s action, must be administered into a large central vein. Placement of a venous access device allows this to be done outside the hospital setting.

Central Intravenous Catheters

A central intravenous catheter is placed while the patient is in the hospital and is designed to deliver medication into the central circulation of the body. Generally speaking, these vascular access devices have a long, thin hollow tube (catheter) that is inserted into a vein of the arm or neck, or the subclavian vein just below the clavicle. The tip of the catheter is threaded into a large blood vessel of the chest, and provides a simple and painless means for the administration of medications or nutrients. These devices are somewhat similar to peripheral IV catheters that the EMT may be more familiar with when working in an ALS system, but central catheters can stay in place for several weeks or months at a time. One common type you may encounter is a peripherally inserted central catheter (PICC) line. This device is often inserted into the patient’s arm at the antecubital fossa and from there is threaded into the body until the tip lies in the central circulation.

Central Venous Lines

Another type of vascular access device is the central venous line. You will notice the proximal port(s) secured to the anterior chest, just below the clavicle. Several types of central venous lines exist, including Broviac, Groshong, and Hickman. The portion of the device remaining outside the body typically has a medication port similar to a traditional intravenous port. They are commonly sutured to the skin to help them remain properly placed.

Implanted Ports

You may also encounter surgically implanted medication delivery devices, known also as a totally implantable venous access system (TIVAS), which is commonly referred to as an “implanted port.” These medication administration devices are surgically placed beneath the skin, but outside the rib cage. Known as Port-A-Cath, MediPort, Microport, Bardport, Passport, or Infuse-a-Port, these disk-shaped devices can be easily palpated beneath the surface of the skin after they are placed. They are typically embedded into the upper chest on the right side.

Accommodations for Patients with Vascular Access Devices

Vascular access devices are not without problems. Since they involve a catheter inserted into the central circulation of the body, the catheter may become obstructed by clot formation at the tip. An associated emergency could be a thrombus that forms on the catheter but then breaks off and lodges elsewhere in the body. (This problem is more likely if the patient is physically inactive.) The person with a vascular access device may also be placed on systemic anticoagulant therapy, which renders the patient more susceptible to bleeding disorders. Gastrointestinal bleeding, strokes, and bruising are most commonly seen.

Another complication you should be aware of is the risk of accidental air embolism. Vascular access devices can allow air to directly enter the core circulation. If this happens, it is a dire medical emergency that can result in death of the patient if a significant amount of air makes its way into the body. You may need to respond for a patient who suddenly complains of dyspnea (but has clear lung sounds), has a severe headache, complains of sudden sharp chest pain, or displays an altered mental status. If the patient has a vascular access device in place, suspect an accidental air embolism as a potential cause of the condition.

ASSESSMENT TIPS

If a patient has a vascular access device that has an external port for medication administration, always inspect the site for bleeding or infection. Also note the depth of insertion and document this on your prehospital care report. If a problem arises with the depth of insertion, it should be made clear that the EMT was not responsible for causing either withdrawal or deeper insertion of the device.

During your care for the patient, keep the insertion site of the vascular access device dry and covered with a sterile dressing. Notice during your assessment if there is any redness, tenderness, warm skin, or purulent discharge at the site that may indicate an infection. (A patient may quickly become septic from a severe blood infection as a result of insertion site infection.) Also look for any bleeding at the insertion site as tension or tugging on the external portion of the vascular access device may cause it to dislodge. If this occurs, cover the site with a bulky sterile dressing and maintain pressure on the site.

VENTRICULAR ASSIST DEVICE (VAD)

A device that is being seen more often by EMS in the prehospital environment is a ventricular assist device (VAD). The device is used to assist the pump function of the ventricles. The device can be used to assist the left, the right, or both ventricles; however, it is most often placed in the left ventricle (left ventricular assist device, or LVAD). The VAD is often implanted while the patient is waiting for a heart transplant or as a long-term assist device in a patient who is not a candidate for heart transplant.

CHAPTER 40 • Patients with Special Challenges
The VAD consists of three parts: a pump, an electronic controller, and batteries. The pump typically weighs about 1 to 2 pounds and is placed in the abdomen or outside the body. The electronic controller is a computerized device that controls the pump function. The batteries are carried outside the body and connect to the pump via a cable that enters the abdomen.

The VAD is implanted during surgery that is similar to open heart surgery. The patient will have a large scar to the anterior of the chest over the sternum. The device is typically implanted in the upper portion of the abdomen.

Failure of the VAD will produce signs and symptoms of heart failure, which could be left, or right, or both, depending on which ventricle is being assisted.

**RENAL FAILURE AND DIALYSIS**

Under normal circumstances, the kidneys function to remove waste products in the bloodstream, and maintain water balance as well as regulate many electrolytes in the body. However, this function can become impaired by many causes, a condition that is generically called renal failure.

**Acute renal failure** (ARF) is said to occur when there is a rapid loss of renal function that results in decreased filtering, poor urine production, electrolyte disturbance, and fluid balance disturbance. ARF usually results from either a sudden cessation of renal blood flow (from vascular and/or direct kidney trauma or poor cardiac output) or from some type of toxic overload in the bloodstream (e.g., drug abuse or overdose, antibiotics, chemotherapy). Although the patient may need ongoing hospital treatment and may require short-term dialysis until normal kidney function is restored, ARF can often be reversed if treated promptly and the patient can continue to lead a normal life. However, these patients are typically more prone to developing renal failure again in the future.

**Chronic renal failure** (CRF) or **chronic kidney disease** (CKD) occurs when there is a progressive loss of kidney function over a period of months to years. The clinical findings of CRF/CKD are often insidious and the diagnosis of kidney dysfunction may not be made until irreparable damage has occurred. The most common causes for chronic renal failure are diabetes mellitus, long-standing hypertension, and inflammation or infection to the glomerulus.

**PATHOPHYSIOLOGY PEARLS**

The functional unit of the kidney is the glomerulus. The blood that passes through it is filtered, and water and electrolyte balance is maintained. If too many glomeruli are damaged, this function is lost and must then be supplemented by a machine.

**Dialysis** is a medical procedure designed to support the lost function of the kidneys, although total replacement of all renal functions is not possible. Dialysis removes the buildup of toxins that occurs when the kidneys can no longer filter these toxins out. **Hemodialysis** is the type of dialysis in which blood is extracted from the body and sent through a machine called a dialyzer. The dialyzer filters the blood from the body through a membrane that also uses a dialysate fluid to help cleanse the blood. Following the cleansing process, the blood is returned to the body. The process takes anywhere from 2 to 5 hours. Dialysis typically occurs in a dialysis center, and must be repeated two to three times per week.

**Peritoneal dialysis** is done in the home or the extended-care facility. With this type of dialysis (which the EMT is more likely to encounter), dialysate fluid is introduced into a port that leads into the peritoneal cavity. The fluid then surrounds the intestines where it interacts with the body to remove waste products. After a specific amount of time, the fluid is removed from the abdominal cavity and replaced with fresh fluid. Since this form of dialysis is not as effective as hemodialysis, it must be repeated several times a day. However, because of current technology, the procedure is relatively easy for the patient to do without assistance and allows the patient greater freedom in daily activities, since he is not bound to making several long appointments a week at the dialysis center.

**ASSESSMENT TIPS**

As an EMT, you may occasionally be called to a dialysis center for a patient with a medical emergency. Be sure to find out from the health care staff if the patient had completed his dialysis session, and if there is any known “volume overload” or “volume deficit.”

An important consideration when dealing with patients who receive regular hemodialysis for renal failure is their dialysis shunt. A dialysis shunt is a generic term for one of three different ways to join the arterial and venous systems together (arteriovenous or AV) in such a way that the repeated needle-sticks required to take and return blood to the body several times a week cause a minimal amount of damage to the body. An AV shunt is used on short-term hemodialysis patients or on patients who have recently started dialysis (Figure 40-13). Either an AV fistula or an AV graft is used for long-term dialysis patients. An AV fistula typically results in a visible or palpable “bump” immediately under the surface of the skin. Similar to a fistula, a graft will result in a visible and palpable mass beneath the surface of the skin. In addition, an AV graft often will have a soft vibration (called a thrill) with gentle palpation as a result of the blood passing through it.

**Accommodations for Patients on Dialysis**

If a patient is receiving dialysis at a facility and an emergency occurs (whether related to the dialysis or not), a couple of important considerations exist. First, if the patient is still attached to the dialysis machine, do not attempt to remove the patient prematurely. The removal of the patient from the dialysis machine should only
occur under the supervision of the dialysis center staff. Multiple complications such as volume overload, hemorrhage, or volume depletion could occur and complicate matters even more.

After the patient is removed from the machine, your assessment and management of the patient should follow steps already mentioned, given the presenting problem. One consideration that must be followed regards the dialysis shunt. You should never attempt to obtain a blood pressure in any extremity that has an AV shunt, AV fistula, or AV graft. The surgical procedures used to create the shunt can be significantly or irreparably damaged by the application and inflation of a blood pressure cuff. Always use an extremity that does not have an AV shunt.

You must also be aware that the AV shunt, if damaged, can bleed excessively. The bleeding could be external, with significant amounts lost rapidly, or internal, with the formation of a large hematoma beneath the surface of the skin. In either instance, you should apply direct pressure to the site to help control the bleed, treat for shock (administer high-concentration oxygen and keep the patient warm), and expedite transport to the hospital. Do not release your direct pressure until told to do so by the receiving physician.

Emergencies with peritoneal dialysis are usually not as severe and typically involve either a displaced catheter, inflammation at the catheter insertion site, or infection of the peritoneal space (peritonitis). The patient will probably complain of abdominal pain, there may be signs of infection at the insertion site for the catheter, and he may have missed one or more sessions of peritoneal dialysis. Management includes keeping the catheter insertion site clean and dry, supporting any lost function that may be present, and transporting the patient to the hospital for evaluation by the receiving physician.

Feeding Tubes

Feeding tubes are medical devices that provide nutrition to patients who cannot chew or swallow because of medical or traumatic conditions resulting in paralysis or unconsciousness. Patients who receive their nourishment this way are said to be receiving enteral feeding, or tube feeding. The device is typically a flexible tube that is long and small in diameter. It is named according to the site of insertion. If it is inserted through the nose and ends in the stomach, it’s termed a nasogastric tube, or NG tube. If the tube is inserted through the mouth and ends up in the stomach, it’s called an orogastric tube, or OG tube.

Nasogastric tubes are more commonly seen by the EMT because ALS and emergency department providers will place an NG tube so they can decompress the stomach if there is excessive air accumulation. NG tubes may also be placed so that ingested toxins can be suctioned out (in cases of accidental or purposeful overdoses). Lastly, they can be used for short-term nutritional support.

Orogastric (OG) tubes are slightly larger than nasogastric tubes but serve basically the same purposes (nutrition, decompression, and suctioning out the stomach). Some orogastric tubes end with the tip located in either the duodenum or jejunum. Nasogastric (NG) tubes are better tolerated than OG tubes.

When long-term nutritional support is warranted, a tube may be surgically inserted through the abdominal wall and directly into the GI system (Figure 40-14). The procedure that places a gastric tube into the abdomen is termed gastrostomy. A gastrostomy is performed for patients in need of long-term nutritional support from a variety of conditions, such as Alzheimer’s disease, severe mental retardation, or significant brain injury from head trauma or debilitating stroke.

Many types of gastric tubes may be used, and although they all serve the same basic function, they may be placed in different areas of the small intestine. A gastric tube (G tube) is a feeding tube that is placed through the abdominal wall with the tip residing in the stomach. A jejunal tube (J tube) is another type of feeding tube that is inserted through the gastric wall with the tip placed in the jejunum.
so that the flow of fecal material can be directed outside the body (Figure 40-15).

**Urinary Tract Devices**

A *urinary catheter* is a device that is used to divert urine out of the bladder when there is some type of urinary tract dysfunction. The least invasive of these is called a *Texas catheter* (or condom catheter), because it attaches to the external male urethra in the same manner as a prophylactic condom would (Figure 40-16a). At the tip of the condom, a catheter is attached that directs the flow of urine into a collection bag. This type of urinary catheter is often used when the patient can still expel urine from the bladder but cannot control when this happens.

There are also internal catheters that are threaded into the urethra (indwelling with the tip entering into the urinary bladder). The most common type is a *Foley catheter*, and this is the most common type used for a patient with a urinary tract dysfunction. Once placed in the urethra of the male or female, a small balloon positioned at the tip of the device is inflated to help keep the tip within the urinary bladder (Figure 40-16b). These devices are tolerated well, are used for long periods of time, and are commonly seen in home health care settings, hospitals, and extended-care facilities. As the urine drains from the catheter, it flows into a collection bag that can be emptied when needed.

A less common type of urinary catheter that you may encounter is the *suprapubic catheter*. This type of catheter is surgically inserted through the abdominal wall.

**Ostomy Bags**

Just as there are special tubes and procedures to ensure that the patient with a debilitating problem is nourished properly, there are also medical procedures that help to remove feces from the body by directing them through the abdominal wall and into a pouch or bag that is attached outside the body. These are referred to as *ostomy bags* or ostomy pouches. This procedure may be done on a temporary or a long-term basis and is used in patients with Crohn’s disease, ulcerative colitis, colon cancer, or diverticulitis. During this procedure, a surgical opening is made through the abdominal wall, and a section of the bowel is diverted through this opening

![Figure 40-14](image1) For long-term nutritional support, a feeding tube may be surgically inserted through the abdominal wall and directly into the gastrointestinal system.

![Figure 40-15](image2) Ostomy stomas may be found at various abdominal locations.
wall just superior to the symphysis pubis and into the urinary bladder. It also drains the urine into an external collection bag and is used when there is some problem with the external genitalia that precludes insertion of a Foley catheter.

You may encounter a patient who has a urostomy. This procedure is performed when the urinary bladder is unable to collect urine. In this procedure, the urinary tract is surgically diverted through a stoma created in the abdominal wall where a collection bag is attached.

**Accommodations for Patients with Gastrointestinal and Genitourinary Devices**

Most problems that occur with gastrointestinal and genitourinary (GI/GU) devices are from insertion site infection, device malfunctions from misplacement, or obstruction. The nutrition that is administered through a feeding tube is usually thick and may block the feeding tube. In other situations, the primary care provider must crush medications and administer them through the feeding tube. If the pills are not crushed enough, they may block the feeding tube. Dislodgment occurs when there is accidental tugging on the device (e.g., when the patient is being moved or rolled over). It may also happen if the patient has an altered mental status and pulls at the device. Indwelling catheters are prone to infection because they provide a portal of entry for bacteria. In some settings, the primary care provider may not clean and care for the site as well as necessary, also fostering the development of a urinary tract infection (UTI). UTIs may be identified by lower abdominal pain and cloudy, blood tinged, or “tea-colored” urine.

The surgical sites where feeding tubes enter or ostomy bags exit the abdominal wall are also prone to infections from improper or insufficient care and cleaning. Like feeding tubes, ostomy bags may become obstructed. This may be due to the consistency of fecal material, and the digestive enzymes in the bowel may start to break down the skin surrounding the stoma if the infection goes unnoticed for too long or if the patient is immunosuppressed.

If any of these problems are identified, it is beyond the EMT’s scope of practice to correct the situation. If EMS was summoned because of a malfunction of a GI/GU device, the patient will need transport to the hospital along with his medical device for evaluation and repair.

**ASSESSMENT TIPS**

If during inspection of a GI/GU device it appears that the device has shifted or become misplaced, do not attempt to correct the situation yourself. Secure the device in the location found and transport the patient to the hospital while monitoring the site.
to accommodate the extra fluid, the pressure within the skull (intracranial pressure, or ICP) builds, which can result in compression of brain tissue. To alleviate the rising ICP, a long, hollow tubelike device called an **intraventricular shunt** is surgically placed. It originates within a ventricle of the brain and extends to a blood vessel in the neck, the heart, the pleural space, or the abdomen to drain excess CSF and keep the ICP at an acceptable level. In some patients, you may also find a reservoir on the side of the skull, placed beneath the scalp, that collects the excess CSF for testing purposes (Figure 40-17). Intraventricular shunts cause emergencies only about 30 percent of the time with only 5 percent being serious. Most common problems include infection, shunt occlusion, and subdural bleeding. Since the shunt is placed within the brain and extends to a distal site (neck, heart, abdomen, or external collection reservoir), there is always a chance for infection. With infection, the patient may present with feelings of malaise, fever, and headaches. If the shunt drains into an external reservoir there may be signs of local skin infection where the tube exits the body. In severe cases, or in situations where the patient is immunosuppressed, a local infection involving the shunt may result in a systemic blood infection (sepsis). Another infection that may occur secondary to the device is meningitis, or an inflammation of the meningeal layers. A patient with meningitis will typically complain of general malaise, headaches, and fever. This patient may also display a fine rash over the body’s surface and have neck stiffness or pain.

**INTRAVENTRICULAR SHUNTS**

Certain patients, mainly pediatric patients, may have a medical illness or anatomical defect that results in either the overproduction of cerebrospinal fluid (CSF) in the brain, inadequate reabsorption of CSF, or irregular flow of CSF through the ventricles and/or meningeal layers of the brain. When excess CSF accumulates, the patient is said to have **hydrocephalus**. Regardless of the reason for the hydrocephalus, excess CSF within the cranial vault is bad. Since the skull is a fixed size and cannot expand...
The intraventricular shunt may become occluded. The obstruction may occur because of the body trying to block off the shunt, because one of the two ends has become dislodged and can no longer allow CSF to flow out, or because of a physical obstruction within the shunt itself. When this occurs, excess CSF will accumulate in the brain and start to raise ICP to potentially dangerous levels. With slight elevations in the ICP, the patient may complain of headaches, vertigo, nausea, and weakness. As ICP continues to rise, more significant findings of brain compression include vomiting, changes in mental status, sensory/motor dysfunctions, seizures, and respiratory depression. If the ICP becomes so high that the brainstem starts to herniate through the base of the skull, the patient may display increased blood pressure, unresponsiveness, and pupillary changes.

Accommodations for Patients with Intraventricular Shunts

Although hydrocephalus is more common in infants, adults may develop it also. The speed with which the patient’s symptoms develop as it relates to the intraventricular shunt depends on the type of problem. Infection usually takes a few days to develop, so symptoms will be more subtle in their onset. If the shunt causes bleeding beneath the outer meningeal layer (subdural bleed), the findings may also develop over a short course of time. If the etiology is occlusion of the shunt, the speed with which CSF accumulates and pressure builds will directly impact the clinical deterioration of the patient.

Commonly, the initial complaint seen with intraventricular shunt emergencies is confusion, difficulty with simple tasks, and headaches. As the problem continues, symptoms will worsen. The treatment is geared to supporting depressed or lost functions. First, manage the airway. Be alert for occlusion by the tongue if the mental status is diminished. If the breathing is found to be inadequate, provide positive pressure ventilation with oxygen. Keeping the patient in a lateral recumbent position will help maintain the airway. Rapidly transport the patient to the hospital. If the patient is a high priority, contact ALS to either meet you on-scene or intercept with you en route to the hospital.

TERMINALLY ILL PATIENTS

Terminally ill patients have a disease process that is realistically expected to result in death, despite current medical treatment designed to halt or reverse the condition. Terminal illness is the medical term used to describe the actual disease process that results in the progressive deterioration causing death. Although the life expectancy of a terminally ill patient is generally considered to be six months or less, the estimate made by the patient’s physician is not usually exact. In other words, a terminally ill patient may die of the disease process in less than six months or live beyond the six-month estimate. Despite this, it is believed by both the physician and the patient that the course of the disease will certainly result in death.

Given the definition of terminal illness, there is no cure for the disease, but patients may still pursue medical interventions or therapies that minimize pain or discomfort during this final stage of their life. The term palliative care is used to describe medical interventions centered on reducing the severity of disease symptoms and providing comfort for the patient (not on reversing progression of the disease).

Hospice is a philosophy of care that is aimed at providing palliation of symptoms for the patients and support for their families. Commonly, patients who receive hospice care do so during the terminal stages of the following conditions:

- Cancer
- AIDS
- Alzheimer’s disease
- Cystic fibrosis
- Congestive heart failure
- COPD

These programs seek to alleviate symptoms, manage pain or discomfort, and provide a certain degree of control to the patients and their families during the final stage of life. Although hospice programs primarily work with the elderly, services are also provided to children with terminal diseases.

Accommodations for Terminally Ill Patients

The benefit of hospice programs is that they aim to make the final stages of one’s life as comfortable as possible while preparing the family for the inevitable. This, however, does not mean that the EMT will not be faced with a difficult situation. For example, a family member or primary care provider may summon EMS when the patient nears death rather than contacting the hospice provider as instructed. Although rare, the patient’s feelings or the family’s feelings may change with the realization that death is imminent. It is important for the EMT to provide emotional support to both the patient and the family during this time and to determine clearly their intentions. The EMT will need to communicate with the patient’s hospice program provider if the hospice does not already have a care provider at the patient’s side to help determine the best course of action. Remember, the desire of the patient to not receive resuscitation does not mean the patient does not desire or need comfort care. If you transport the patient who is in a hospice program to the hospital,
you should make all efforts needed to minimize additional discomfort or pain during transport as well as provide emotional support and reassurance.

**ASSESSMENT TIPS**

It is not uncommon to encounter a hospice patient at the end of life who has accepted that death is imminent while the family is more frightened or in denial than the patient. Your emotional support to these families can be just as valuable as the palliative care you may be providing to the patient.

Not all patients who have a terminal illness receive hospice care, and the EMT cannot make an assumption one way or the other. You will need to communicate with the patient, the family, or the primary care provider about any advance directives that may be in place in the absence of a hospice program. Although this discussion often clarifies what you should do regarding resuscitation in the event of arrest, it does *not* mean that you need not provide comfort care and emotional support. In these situations, your ability to be compassionate far outweighs your clinical skills.

### Chapter Review

**SUMMARY**

During your career as an EMT, you will encounter patients with a variety of challenges, such as hearing or sight impaired, obesity, poverty, and homelessness. You must understand the special characteristics of these patients and variations in assessment findings and emergency care.

Home medical devices are becoming more commonplace. Primary care providers who are responsible for these patients are also becoming more knowledgeable about how to handle such devices. Never discount the intelligence of primary care providers. Use them as a valuable resource during your assessment and management of the patient.

Remember the reason that you are summoned to a patient who relies on any of these devices, and intervene with the equipment only if you identify a malfunction. Usually, your intervention will involve either shutting off or removing the medical device (especially those that provide nutrition, ongoing medication, or mechanical ventilation) if you are comfortable and knowledgeable about how to do so. Again, ask family members or the primary care provider for assistance if needed. The failure of medical equipment that replaces the airway and ventilations can easily result in death of the patient. In such a case, intervene quickly and support lost function while transporting the patient to the hospital.

Finally, do not become overwhelmed with the multitude or complexity of medical devices the patient may be using. Analyze each piece, ask questions, and intervene only when it is obvious that the equipment is malfunctioning and is detrimental to the patient’s condition. Summon ALS early as needed, communicate with the receiving hospital early so they can prepare for your arrival, and carefully document all findings, care rendered, and medical equipment used on yourprehospital care report.

### Case Study Follow-up

**Scene Size-up**

You have been dispatched to the home of a 2-year-old male patient who has a diminished orientation according to the patient’s mother. After ensuring scene safety you enter the home and are directed into the young boy’s room. When you walk in you see a child lying in bed, wearing pajamas, covered with his blanket, and seemingly sleeping. The mother tells you that the boy has a “shunt in his brain” that was replaced just a week earlier. The history, according to the mother, is that the child’s orientation had been diminishing and he had started to develop a fever.

**Primary Assessment**

Your general impression is that the patient appears to be sleeping quietly in bed. As you approach him, you address him by his name but get no response. You call his name louder but he still does not open his eyes. As your partner goes around to the other side of the bed, you apply a light noxious stimulus with a trapezius pinch. The boy moans and his eyes flutter, but he does not wake up or move his extremities. You pinch again a little harder, and this time the boy's arm moves as if to try to push your hand away.
You listen to his airway and hear no sonorous or gurgling sounds. The rise and fall of his chest is normal, but the rate seems quick. You can palpate both central and peripheral pulses. They are strong and regular. The rate feels to be about 120 per minute. The skin is very warm to the touch and moist. Since the child’s mental status appears to be altered but the airway and ventilations are currently adequate, and the $SpO_2$ reading is 95%, your partner applies oxygen via a nasal cannula at 2 lpm. You categorize the patient as potentially unstable because of the diminished mental status.

**Secondary Assessment**

Since this change in mental status is not normal for this child, nor normal for a 2-year-old boy, you elect to perform a thorough but rapid secondary assessment. His pupils are equal and respond to light. Slight jugular vein distention is noted in the neck, but the child is lying supine. You can palpate the shunt that courses under the skin of the neck. The breath sounds are equal bilaterally. His abdomen is soft and no tenderness is noted. You find good pulses in all extremities, but he is tachycardic. You find no evidence of trauma anywhere on the body. You find no medical alert identification tag.

The patient’s blood pressure is 94/54 mmHg. His heart rate is 118 per minute. Respiration is 26 per minute and of normal depth. His skin color is flushed, very warm to the touch, and moist. You record the vital signs.

During the secondary assessment, you gather a history. On questioning the mother, you learn that the patient has had an intraventricular shunt placed for “quite a while now” for “excessive water in the brain.” You recognize this as probably the medical condition known as hydrocephalus. She further adds that his shunt was just replaced about a week ago because of his growing bigger, but ever since then his mental status has been gradually diminishing to the point where it is now. As you learn more about the patient’s medications and allergies, your partner readsies the cot. You carefully pick up the young child and carry him into the living room where the cot has been prepared. After properly securing him to the cot and ensuring the oxygen is still flowing normally, you begin transport to the hospital some 25 minutes away and contact your dispatch for an ALS intercept.

**Reassessment**

En route to the hospital you continue to evaluate the patient’s vital functions. His airway remains intact, breathing is still adequate, and his peripheral perfusion is normal. There has been no significant change in his mental status or vital signs during the transport. After reassessing the vitals, you document them on your computerized prehospital care report. The pulse oximeter is still reading 99% to 100%. ALS intercept occurs about 10 minutes out from the hospital and you resume transport to the hospital. En route, you converse with the ALS provider and you both conclude that either the patient is developing an infection in the brain secondary to the shunt placement, or perhaps the shunt is occluded and pressure in the brain is starting to rise.

As you arrive at the hospital, you prepare the patient for movement out of the ambulance. The patient’s mental status has not changed; he still responds to deep noxious stimuli with purposeful motion. Vitals are stable and there has been no change in the patient’s vital functions. You give the hospital an oral report of the patient’s condition and help transfer him to the hospital bed. You complete your prehospital care report, restock the ambulance, and prepare for another call.

**IN REVIEW**

1. Identify and describe sensory problems commonly encountered in the prehospital environment.
2. Name some common emergencies the obese patient may suffer that would require EMS help.
3. Describe the medical care warranted for a patient with an occluded tracheostomy tube.
4. Explain why airway management is a major concern in the patient with a severe brain injury.
5. What are the most common reasons for a mechanical ventilator to fail?
6. Why might a patient have a VAD placed?
7. A CPAP machine would be used by what type of patient?
8. Describe alternative ways of ventilating a patient whose mechanical ventilator has failed.
9. Discuss the types and purposes of GI/GU devices commonly encountered.
10. If a patient has an intraventricular shunt placed, how might the patient present if it becomes occluded and stops draining excess CSF?
You respond to a call for an unknown emergency at a residential address. On arrival at the scene, you are directed to a 68-year-old female in her bedroom, lying supine in a hospital bed. A loud beeping is coming from a mechanical ventilator sitting on a table beside the patient’s bed. The ventilator is attached to a tracheostomy tube placed in her trachea. She is not alert, and you hear rattling sounds of mucus congestion coming from the ventilator circuit. The red light that is illuminated on the ventilator is signaling a high-pressure alarm. The distressed family on scene tells you quickly that the patient just came home from the hospital the day before. She was in the hospital because of a massive stroke and was placed on the ventilator there. She was brought home so the family could provide ongoing care, rather than placing her in a geriatric facility. The family, however, is not very familiar with the mechanical ventilator and became scared when it started to alarm.

1. What emergency care would you provide during the primary assessment?
2. Based on the signs, what condition do you suspect the patient is experiencing?
3. What in your opinion is causing the ventilator to alarm?
4. What type of care would you provide to this patient to support lost function?
5. Should this patient be transported to the hospital, and if so, why?
STANDARD • Special Patient Populations

OBJECTIVES • After reading this chapter, you should be able to:

41-1. Define key terms introduced in this chapter.
41-2. Discuss the psychophysiology of stress response.
41-3. Define Post-Traumatic Stress Disorder (PTSD).
41-4. Describe the four essential features of PTSD.
41-5. Recognize signs and symptoms of PTSD.
41-6. Discuss the difference between traumatic brain injury (TBI) and PTSD.
41-7. Discuss the assessment and emergency care for a returning combat veteran exhibiting signs and symptoms of PTSD.

KEY TERMS • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

post-traumatic stress disorder (PTSD) p. 1146
traumatic brain injury (TBI) p. 1150

Case Study

The Dispatch
You and your partner are dispatched Code 3 to a local residence for an “injured person.” While en route, you receive additional information from dispatch that your patient is a 34-year-old male with a possible broken right hand. You are told that the police department is also responding to the same address. Your crew is then asked to stage upon arrival so the police can secure the residence. Your alarm room states that you will be assigned a fire engine with ALS capabilities.

Upon Arrival
Upon arrival, you notice several police vehicles that line the street. You stage at the corner and await confirmation that the scene is secured. You document your “on scene” time and the reason for your delayed patient contact. After approximately three or four minutes, a police officer signals at you to approach the scene, while waving the “code 4 scene is safe” hand gesture. Simultaneously, you tell your dispatcher a police officer has cleared you to enter the scene and that it is secure. The alarm room acknowledges as you don your personal protective equipment, grab your EMS equipment and the gurney, and proceed to the front door.

How would you proceed?
What is your primary responsibility when entering this scene? What will you look for in your primary scene survey to identify any safety issues or nature of illness or mechanism of injury? Is there any pertinent information that you can gather from the police or other bystanders prior to patient contact? What other resources may be required to successfully mitigate this situation.
INTRODUCTION

As an EMT, you will almost inevitably encounter a returning combat veteran. The term returning does not necessarily mean that he just arrived from combat. The veteran may have been back for weeks, months, or years. Although veterans make up less than one percent of the population, the effect of their combat traumas will often present to EMS in a way that other patients will not. The etiology of this unique presentation is post-traumatic stress disorder (PTSD), which develops from the extreme stress of combat.

Although PTSD is a relatively new term, the condition and how it affects people have existed for as long as there has been war. It is even mentioned in the Bible, when Jeremiah laments his flashbacks as he recalls the trumpets of war. During the American Civil War, the condition was called “soldier’s heart,” or “nostalgia.” During World War I, physicians referred to it as “shell shock” and then renamed it again during World War II and Korea, in which it became known as “combat neurosis.” The condition known as PTSD was not recognized during, but only after, the Vietnam War. It was then called “delayed stress,” because war veterans began to experience issues related to combat long after the war’s end.

PTSD does not indicate a “weak mind” or any sort of predisposing flaw in one’s personality. Anyone, anywhere, and at any time will predictably exhibit these signs and symptoms if they have undergone a trauma that was sufficiently dangerous or stressful. There is debate among professionals as to whether or not PTSD is even a “psychiatric” condition. Some people, including portions of the military, assert that PTSD is “weak” or “mental,” when it is not. PTSD happens when normal people are exposed to abnormal stressors or dangerous conditions.

Many combat soldiers exhibit a facial expression that has been termed “the thousand-yard stare” (Figure 41-1) that is a response to abnormal stressors or dangerous conditions.

THE PSYCHOPHYSIOLOGY OF STRESS RESPONSE

As discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” the human nervous system is divided into voluntary and involuntary functions. Walking, talking, and eating are examples of functions controlled by the voluntary nervous system (VNS). Heart rate, pupil dilation, and digestion are involuntary and are controlled by the autonomic nervous system (ANS). The ANS is further divided into the excitatory or sympathetic nervous system (SNS) and the inhibitory or parasympathetic nervous system (PNS).

When faced with danger, the human body immediately goes into a survival mode, which is a burst of SNS activity. Even before the stress is recognized by the individual, the adrenal glands secrete epinephrine (also called adrenaline) and norepinephrine to give the body the means to manage the stressor. As a result of the adrenaline rushing throughout the body, the SNS will increase heart rate, channel blood into the core of the body, dilate pupils, and slow food digestion. The body also reacts by increasing systolic blood pressure, sharpening the senses (such as hearing and smell), signaling clotting factors in the liver to be released into the bloodstream, and, in general, preparing the body for action.

During this burst of adrenaline, mental activity and acumen are heightened, and an individual becomes hyperalert to the flood of new sensory information and prepares for any needed physical response (e.g., running or fighting). It is this “high-speed” mental activity that later will be perceived as though “everything was in slow motion.” It is also during this burst that mental activity can become so accelerated that it leads to confusing and chaotic or disorganized behavior, such as panic or screaming. The PNS functions to offset this SNS activation and restores the system to a level of homeostasis by lowering systolic blood pressure and reducing heart rate.

Combat veterans experience exactly these events. However, with some forms of PTSD, the body and mind stay on alert long after the emergency is over. This is why delayed symptoms present in PTSD.

COMBAT VETERANS

Since not every soldier goes to war, the distinction between an “era vet” (the soldier who trained for combat but never went to war) and a “combat vet” (one who did) is important. An era veteran can have PTSD, but it will not be the result of combat. The Veterans Administration (VA) does not make this distinction and, therefore, treats every veteran the same. However, the EMT must recognize that all veterans are not the same and treat every veteran patient as an individual with individual issues. Clues that can help identify a returning combat veteran include the following (Figure 41-2):
A history of combat service may be relevant to the emergency your patient is now experiencing. A variety of clues may help identify the patient as a combat veteran, such as (a) a “high and tight” military haircut; (b) military clothing, such as combat boots; (c) a photo of the patient in combat gear; (d) photos of combat buddies; (e) a combat patch; (f) a license plate indicating the owner’s status as a veteran. (Photos a and b: © Fotolia; photo d: © Getty Images)
**Clues to Help Identify a Combat Veteran**

- Military-style haircut
- Military clothing, such as combat boots
- War memorabilia, such as photos showing battle gear
- Photographs of other soldiers, combat buddies
- K.I.A. bracelet (commemorating a person killed in action)
- Tattoos
- Combat patches
- Commendation awards
- American flag
- Veteran license plate
- Military vocabulary/demeanor/bearing
- Respect for authority
- Reluctance to seek assistance

As already stated, combat veterans are less than one percent of the American population of 330 million. Today, this results in 22 million combat vets, of whom 250,000 are female. Given the lengthy list of America’s wars, surviving veterans may range in age from under 20 to 80 or greater. The EMT must be a good detective and ask appropriate questions. Due to the sensitive and personal nature of things or events that the veteran has seen or been a part of, the wording and the delivery of the EMT’s questioning must be carefully phrased. Questions such as, “Were you in the military?” or “Where did you see combat?” should be used instead of, “Were you in combat?” since some of their own denial—will not think they really were in combat. The real question is, “Were you shot at or under fire?” Under no circumstances should the EMT ever ask any variation of the question, “Did you kill anyone?” This particular question is highly offensive to vets and could aggravate the situation.

Of all combat vets, 98 percent were under fire; 90 percent know someone who was killed; 80 percent were attacked by rocket, bullet, or bomb; 80 percent saw dead bodies (men, women, and children); 40 percent know someone who committed suicide; and two-thirds have had severe relationship problems since their return. Nearly all will have other social, job, or financial problems. Approximately 25 percent of homeless people are veterans, and of combat veterans, at least two-thirds will have PTSD. And keep in mind that the definition of PTSD includes the fact that symptoms are delayed. Therefore, as delayed symptoms emerge over time, these numbers can only rise.

There is no cure for PTSD; there is only symptom relief.

**THE NATURE OF PTSD**

PTSD is a collection of signs (what the EMT observes about patients) and symptoms (what the patients experience and may tell the EMT). The pivotal feature of this disorder is what happens when a normal individual is exposed in any way to an abnormal event. It is abnormal because it signals actual or perceived immediate death, serious injury, or horrific trauma. It is also considered abnormal because there is sustained SNS activation, and memories of the trauma linger and are disruptive to the person.

PTSD has four essential features and numerous associated aspects. The four features are response, reliving, avoiding, and anxiety/anger.

1. **The veteran’s response** involves feelings of anger, fear, horror, and helplessness.

2. **The individual relives** these events by way of flashbacks, unwanted thoughts, or nightmares. These episodes are painful and uncontrollable, lasting seconds to hours, and can occur even decades after the combat exposure.

3. **The person avoids** anything that even reminds him—physically or emotionally—of the trauma. This “emotional anesthesia” protects the individual from having to repeat the trauma. This could include avoidance of involvement with people, crowds, war movies, loud noises, diesel fumes, or any intimate, sexual, or other interpersonal interactions.

   Any event or circumstance related to the original trauma can trigger this re-experience. For example, snow is a reminder of Korea. A palm tree is a reminder of Vietnam. Even the Arizona desert looks like Afghanistan. Any robed person could bring about a recall of enemy soldiers or even civilians from the country where combat was experienced. Driving along any road means needing to watch for improvised explosive devices (IEDs). The number and types of triggers are endless. One hundred percent of combat veterans will at some point have flashbacks and a sleep disturbance, usually with nightmares. The person may use phrases like, “I can’t seem to sleep” or “I don’t like crowds.” There is an emotional and physical distancing from others.

   The key to understanding the person’s avoidance of any situation that may cause reliving the trauma is grasping the personal pain to the veteran and his fear that it will become personally overwhelming (again) and that he will “freak out.” In its extreme, a flashback can resemble a psychotic episode but should be approached differently by clinicians.

4. **The person might display anxiety or anger.** The nervous system’s arousal caused by the trauma can result in a “fight or flight” response that is so extreme the veteran is simply not able to suppress it. The traumatic event is perceived as immediate, even though it may be months or years later. Because of this, the EMT will observe a hypervigilant or exaggerated startle response on the part of the veteran to any threatened or perceived danger similar to his response to the original event. The veteran spends much of his time in this state of perceived imminent threat. It is constant and painful. This is why alcohol or drug use is a common way to attempt to calm these demons. Suicide is a way to permanently end the pain.
Associated Signs and Symptoms of PTSD

Guilt (guilt for what I did, guilt for what I did not do), shame, avoidance of others, depression, paranoia, hostility, feeling they will not live much longer, agitation, and anger are all common among combat veterans. The level of frustration and anger cannot be overstated; these emotional states can be overwhelming to the veteran as well as to the EMT.

Physical responses are another category of problems associated with PTSD. The traumatized person can experience any kind of pain—pain whose origin may be unsubstantiated. Vague, unfocused pains that seem unfounded are common in vets with PTSD. Trauma victims other than combat vets—for example, rape victims, POWs, and sexually abused children—can also experience these symptoms. It is pain that says, “My trauma was so severe that I physically hurt.” Physical pain can be an attempt by the body to manage the high levels of emotional distress associated with the trauma without the mental stigma—diverting the mental anguish to physical anguish.

For an EMT or anyone else to indicate there is no “real” basis for a medical problem is to erroneously dismiss the vet’s experience of trauma. The combat veteran is really speaking to the EMT about his anguish, not about a headache.

PTSD has the consequence of “making young bodies old,” a fact that is now better understood by the medical community. Combat vets show early signs of aging, such as heart disease, type II diabetes, and a loss of brain gray matter. These aging-related physical problems occur among combat vets at twice the rate as in healthy adults of the same age. The patient may be 22 but feels like he is 62. This is a chief reason why vets suffering from PTSD are simply more likely to come to the attention of emergency medical services.

Alcohol and Drug Use

Drug or alcohol dependence or abuse is notorious for its high level of denial and minimization among veterans. As a result of SNS activity, the veteran is always in a heightened state of awareness; drugs and alcohol are used to suppress the SNS activity and slow the body down. Sometimes vets feel that turning to these substances is the only way they have to stop or dull the mental and physical pain.

Approximately 40 percent of vets engage in pathological use of alcohol or drugs. At some point the effect of anesthesia is surpassed and it becomes addiction. The Japanese saying, “The man takes a drink, then the drink takes a drink, and then the drink takes the man” applies here. It is insidious and often effectively camouflaged. Accordingly, a good assessment question is, “What’s the most you can drink (or drug you can use) and still walk and talk?” The answer can lead the EMT to understand the actual level of use because of the structure of the question, as opposed to “How much do you drink?” It also takes into account the reason why individuals use alcohol or drugs to dampen SNS events and to relieve the stress. Drugs and alcohol can be used to help the person relax or make the person feel “more normal.”

Danger to Self or Other

Part of any scene assessment is the evaluation for potential violence, known as danger to self or other (DTSO). It is a myth that combat veterans are more dangerous than others. Research of combat veterans makes clear that they are no more likely to commit homicide or assault than their noncombat peers, the previously mentioned era veterans. However, their suicide rate is more than 30 percent above that of their noncombat peers, a rate that is rising drastically for reasons that are not entirely clear. Almost certainly, one factor is the nature of their return from a war that can often be seen as unpopular and difficult to understand. Returning combat veterans are much more likely to harm themselves rather than others because their anger is directed inward. The suicide rate for combat veterans is 18 per day and increasing.

The people who research potential for violence—using the best data, credible theories, and extreme situations—are accurate to about 65 percent in their prediction of violence. This is only slightly better than flipping a coin. The EMT must keep this in mind when faced with a situation that has potential for violence. The prediction of suicide, homicide, and assault is inexact. One will never be able to predict with confidence when someone will kill or attempt to kill himself or someone else. EMTs should do the best they can with the information and tools available to them. If they do this, they will have some, even if limited, success with the potentially violent combat veteran patient. Factors that can help in this assessment include:

Factors in Assessing Danger to Self or Others

- **Ensure your own safety first.** You will do no one any good if you yourself are not physically safe.
- **Involve others whenever you can.** This would be family, friends, clergy, or a neighbor. This includes the patient: “How do you want me to help you?” “Is there someone who knows you that I can talk to?” “What is it you need right now?”
- **A past history of violence** is one of the better predictors of future violence. “Has this happened to you before?” “What was the outcome?” Similarly, a history of the use of deadly force increases the risk of deadly force now.
- **Talking about suicide or homicide** will not increase the likelihood of it happening. In fact, your concerns will be welcomed. This might be the only time that the patient will reach out to others, so be specific.
- **Get rid of any possible weapon.** Veterans are, by definition, trained to use violence as a solution to
problems, so violence already has a higher probability of use in any given situation. They are also resourceful. They have been trained to improvise weapons in precarious situations. The lethality of the weapon involved is a factor. Higher risk weapons are those that are easily accessible, more lethal, and faster.

- **If your patient is tense, agitated, yelling and pacing, has had no sleep, or is intoxicated or high, then you, the EMT, will need to take action to ensure scene safety.**

- **Take care with physical restraints.** Any physical restraint will only escalate the situation. Straps, handcuffs, or even seat belts can aggravate a patient. Chemical restraints should always be an option, which would require an advanced life support response.

- **The “gut test” or the “orientation reflex” is unscientific, nonempirical, and unresearched, but never to be excluded in one’s assessment of violence.** It is that sinking feeling one gets just below the sternum that is outside one’s consciousness and control and appears suddenly. It is the body’s way of saying “There is danger here,” and one must pay attention to it. The body’s personal radar has just noticed that there is a need for survival. Instincts, because that is exactly what it is. The “suicide formula” is this: pain or emotional turmoil that is believed to be unchangeable, unending, and unbearable. Suicide risk increases with any recent loss someone has experienced, such as divorce, death of a friend, or loss of a job or house. The loss has to be significant to the vet, so do not judge the severity by any other values. It also increases with the presence of chronic, unending, unbearable and untreatable pain that cannot be helped by any means. The fact of previous suicide attempts should be a very large red flag for the EMT. A very specific plan increases the risk of suicide. In the end, if a person has decided to commit suicide, that person will find a way to do it.

- **“Anniversary reactions” can cause an acute level of stress or increase existing stress, which will increase the risk of violence.** The calendar date on which a friend died, a close battle occurred, or the date of serious injury is an anniversary date. A veteran can have one or as many as seven or more critical anniversaries dates.

- **Know that the following is a MYTH:** “When someone talks about suicide, it means they are not really serious; they just do it to be dramatic or get attention.”

  **FACT:** A full 70 percent of those who successfully commit suicide have told at least one other person of their intent or ideation before they killed themselves.

---

**Signature Wounds of the Combat Veteran**

War brings physical scarring and pain of all kinds. As advances in weaponry and treatment of combat injuries progress, soldiers gain advantages when it comes to surviving battlefield wounds. Before the conflict in Vietnam, combat personnel were likely to die of seemingly minor wounds that became infected. Since the use of medevac helicopters, the likelihood that a soldier could survive an injury greatly increased. As a consequence, there was an increase in amputations and an increase of survival with other debilitating injuries.

The “signature wound” of Vietnam was a gunshot wound to the chest because of the prevalence of face-to-face firefights. Tragically, the signature wounds of Iraq and Afghanistan are those caused by improvised explosive devices (IEDs). An amputation is an indication that one may have seen combat, as is a traumatic brain injury (TBI), a mild concussion.

TBIs are defined as an alteration in brain function or other brain pathology caused by an external force such as concussion. Because of the prevalence of IED explosions in Iraq and Afghanistan, TBI/concussion is a signature injury associated with those conflicts. Since 2000, some 300,000 soldiers have been diagnosed with TBI/concussion resulting from an IED. Generally, such vets are identified early on by the VA, but some with TBI go undiagnosed. The EMT will be in a position to help identify these undiagnosed vets.

The signs and symptoms of TBI are urgent in nature, but there are some disease processes that will not show up until later. High cholesterol, hypertension, and diabetes are examples of other issues a veteran may eventually experience. Inexplicably, a full 50 percent of vets with PTSD also are later diagnosed with Type II diabetes.

---

**TBI Versus PTSD: Signs and Symptoms**

The signs and symptoms of PTSD and TBI overlap considerably. At the scene, it is preferable to use the word “concussion” as opposed to “traumatic brain injury” because of the emotional impact of the latter on the patient.

When collecting a history related to the event, a loss of consciousness (LOC) is no longer required to make a diagnosis of concussion. The veteran may deny a brain injury event because he never experienced a loss of consciousness. However, it is very likely the patient will have already been diagnosed, following return from combat duty, as having a traumatic brain injury.

It will not be the responsibility of the responding EMT to make a determination of the presence or absence of traumatic brain injury related to a combat event. However, when you are considering the presenting signs and symptoms in your assessment, it is important to understand the difference in presentation between PTSD and TBI so that if the latter is the suspicion, proper acute care can be sought for the patient (Table 41-1).

PTSD and TBI are not mutually exclusive diagnoses; both can and often do occur in the same person. In fact, TBI increases the likelihood of PTSD. This fact should
help the EMT decide what actions to take regarding patient care when there is a suspicion of PTSD, especially if the patient has a history of TBI. PTSD may not require any action on the EMT’s part other than transportation to an emergency department for a referral or consultation with a mental health professional. By contrast, a patient with TBI will likely already have been diagnosed and almost certainly will have been under the care of a physician for the condition.

Problems in patient care can arise when the veteran goes undiagnosed or misdiagnosed. In the patient’s history since combat, a TBI could have been overlooked because it was mistaken for PTSD, since the two conditions present so similarly. A patient who presents with signs and symptoms of a TBI that has been overlooked requires emergency care, whereas PTSD requires assessment and treatment by a mental health professional. PTSD might not need the attention of a neurologist or imaging studies, but a TBI will. Thus any suspicion of TBI should prompt you to transport the patient to the emergency department for further evaluation and care. When you are collecting a history regarding the event that may have caused the injury, the patient might not even remember an explosion that would cause a TBI. This absence of memory is the result of the retrograde and antegrade amnesia that explosions can cause. That is, the explosion (e.g., from an IED) may prevent the formation of a memory just before or just after the explosion. The patient has no memory of an explosion and so may not believe he was even involved in one.

Concussion/TBI may be hard to detect. The damage may not always show up on brain imaging studies, which would be considered a false-negative finding. Additionally, the true symptoms of TBI/concussion—dizziness, sensory changes, memory problems, or confusion—are often downplayed by the patient. Because of these two factors, TBIs are often missed by the patient’s caretakers. If a concussion is missed as a diagnosis, and further brain injury occurs before the brain has time to repair itself, permanent damage can result. Again, any patient presenting with the signs and symptoms of a TBI requires emergency care and transport.

Repeated concussions—especially those that go undiagnosed—can later evolve into chronic traumatic encephalopathy (CTE) or some other form of highly debilitating neurological disorder (e.g., Parkinson’s disease). TBI is not a disorder to be “toughed out” or ignored, because doing either could make brain damage worse. The military’s dictum that “if you ain’t bleeding, you ain’t hurt” is the poorest possible advice that could be given at this point to a TBI patient. This disorder is real and treatments are available. A worst-case scenario would be a combat soldier given a second deployment to combat who already has an undiagnosed TBI. This existing injury will only increase the vulnerability to PTSD in subsequent tours.

The following are key points to follow when arriving on scene and providing assessment and emergency care to a combat veteran:

1. **DO NOT** ask the veteran if he has ever killed anyone. *Ever.*
2. Veterans are used to structure. Provide your patient with organization and limits.
3. Remind the patient who you are. You are there to assist him with any needs or concerns he may have.
4. Reassure the patient in a calm, firm voice. Be soothing, but be in charge.
5. If you, yourself, were in combat, tell the combat veteran just that. If not, DO NOT say, “I understand,” because you don’t.
6. Anything you do with a patient can build rapport. Casually talking about news, weather, or sports can go a long way.
7. Combat vets have an “invisible disease” and are facing a new and different “battle” at home. This patient will be reluctant to talk to you about PTSD and might not even be aware of just how much he has been impacted by it. Part of this is human nature, but part of it is the stigma some of the military holds toward its soldiers who are “mental.”
8. Focus on what the combat veteran wants from the encounter with EMS as well as what you assess as appropriate. Maybe all the veteran wants to do is get something off his chest and be able to sleep tonight.
9. Do not assume PTSD, but be sure that you do not rule it out in your assessment. If it does not exist in its full-blown form, there is a part of it always present. Remaining aware of it will add another dimension to your patient care.
10. Regarding weapons, the correct question to ask the combat veteran is not “Do you own a weapon?” but rather, “How many weapons do you own and are they secure?” Confirm that weapons are secure before you start.
11. Do not bang on the door and do not crowd the vet. Respect his personal space. Limit the number of people involved and, if you need to, get the veteran to move to an area that affords more privacy and quiet. Keep your line of sight to the doorway clear. Try to keep the general “buzz” down. Do not do anything to the veteran without first explaining your actions.
12. Diesel fumes, dust, and helicopters are a trigger for combat vets. Tanks, vehicles, and other heavy machinery use diesel fuel in combat. These fumes are ubiquitous for EMTs but will immediately remind the veteran of combat.
13. Combat vets have trouble asking for help. Part of this is due to the military ethos “Don’t quit, handle your mission, don’t leave anyone behind.” You will help things if you give the veteran permission, “I’m here to help you and to understand what’s going on—it’s okay to talk to me.”
14. Even though the current situation may not be directly related to PTSD, this may be the first time this patient has asked for help. Slow things down, and plan on taking the time to listen to your patient.

Chapter Review

SUMMARY

PTSD involves an intense emotional and physical response to abnormal trauma. It is a condition that affects normal people exposed to abnormal stressors or dangerous conditions. The four essential features are visceral responses to trauma, reliving the trauma through flashbacks and nightmares, avoiding the smallest reminder of the trauma, and a predominate demeanor of anxiety and anger. Additional associated features will include guilt and shame, complaints of physical pain without clear origin, and depression and suicidal ideation. The EMT should also consider that the signs and symptoms of PTSD and TBI are similar but do have their differences.

A TBI or mild concussion occurs in combat vets principally because of IEDs. In addition to many of the symptoms of PTSD, TBI signs and symptoms include sensory dysfunction, disorientation, confusion, headaches, and memory problems.

The returning combat veteran is a patient who will require very specialized attention by the EMT. It is important to remember that the trauma this patient has incurred is mental as well as physical. The pain that the patient feels is very real, and it is not the EMT’s job to qualify or dismiss any pain that seems to be unfounded.

Although the returning veterans are a small percentage of possible patients, once identified they will present the EMT with challenges that will not apply to other patients. Be prepared to take time and listen to the concerns of the vet. These patients might ask for assistance only once, and if they do, the EMT must understand what they had to go through to get to the point where they could ask for assistance. It must also be understood that there are other resources available to the EMT to further assist in the treatment of the combat veteran patient.

Combat veterans have made countless sacrifices for their country, their family, their health, and other aspects of their lives. The EMT must recognize this when dealing with these patients and give them the care and respect that they deserve.
Case Study Follow-up

Scene Size-up
Your crew has been called to a residence for an injured person. After the house has been cleared by police for any obvious threats, you make primary contact with your patient in his living room. Around the room you notice some military items. You spot a black bracelet on the patient’s wrist that appears to be a killed-in-action “KIA” bracelet. You notice that the patient seems to be a bit “on-edge” as you and the ALS fire crew approach.

Primary Assessment
The patient is a 34-year-old male, approximately six feet tall with a muscular build. He appears unkempt, and you smell alcohol on his breath as he speaks. He says, “My hand hurts but it’s nothin’ I can’t handle, doc . . . I’m good to go.” When asked about the pain, he states, “It’s like a 4 out of 10.” You note that his right hand is swollen with an obvious deformity to the tarsal and metatarsal region. The police are in the kitchen taking a statement from the patient’s wife.

Secondary Assessment
You begin your history taking by asking the patient what happened this afternoon. He replies, “You know, doc, she just doesn’t get it. I’ve told her at least a dozen times not to sneak up on me while I’m reading . . . or any other time for that matter. She knows I’m having a hard time right now.” You notice a bottle of whiskey that is almost gone sitting by your patient’s side. You inquire about his alcohol usage today, and the man states that he has only had about half of the bottle this afternoon.

As your partner and the fire crew stabilize the patient’s hand, you make your way into the kitchen to get information from the man’s wife. She tells you that the man is a combat veteran and has had some “adjustment issues” since returning home about six months ago. She says he had seen some heavy fighting and had lost several men from his unit. She also states that they have been arguing lately and that today’s incident resulted in him hitting the wall with his fist after she startled him while he was reading. She denies any physical abuse and tells the police that she will not want to press any charges against her husband.

As she is saying this, she begins to sob and says, “He’s just so different. He’s not the same person I married. He drinks all the time, he yells at me, and he has horrible nightmares that scare me in the middle of the night. Just last week, he got a speeding ticket and another citation for reckless driving. He never used to do that.”

You acknowledge the wife’s concerns and tell her that you or your partner will come back to talk with her after you complete your patient interview and assessment.

Returning to the patient’s side, you ask the patient if there is anything that you or your crew can do for him besides treating his hand. The patient says that he doesn’t understand why he is angry all the time, and that he wants to stop fighting with his wife. He points to the bracelet on his left wrist and, in a statement full of heartfelt grief, declares, “This isn’t what he would have wanted me to do. I let him down. He was my responsibility and I let him die in my arms.”

As you are obtaining a set of vital signs, you make a note that the patient’s hand appears to be heavily bruised and severely deformed and that he should be evaluated by a physician at the hospital. The vital signs come back stable, and you bring your gurney forward. The man begins to cry and tells you that he is sorry that you have to see him in his current condition. He apologizes to his wife as you load him into the ambulance.

Transport and Follow-up
As you secure the gurney in the patient compartment, your partner returns to the patient’s wife to see if she has any further needs or requests. Your partner tells you the man’s wife stated that she doesn’t know what to do to help him. He says that she seemed very distraught by the fact that her husband is in pain all the time, and she also said that she feels “very helpless.”

Using your knowledge of the community resources division of your local fire department, you know that there is a crisis response (CR) team that is available for incidents like this. You calmly ask the patient if he would like to speak to someone about this other than the ER physician. He states, “I’m not crazy, doc. I’m NOT! I don’t want to talk to anybody about my dreams. They wouldn’t understand:"

You politely explain to the patient that the CR unit is a great resource and that he would have to talk to them only about whatever he wants. You also assure him that the CR staff are not there to judge or criticize him, but to assist him by listening to his concerns and helping him find the appropriate resources so he can stop fighting with his wife.

Finally, he nods his head in agreement and you call your alarm room to have the CR unit meet you and your patient at the hospital. Leaving the patient in the care of your partner, you tell the patient’s wife your plan and you ask if she would like to accompany you to the hospital where she could also speak with the members of the CR crew. She agrees and tells you that she will follow in her car after the police leave.

Reassessment
En route to your base hospital, you are reassessing the patient’s vitals when he looks at you and says, “Thanks doc. You know, since I’ve been back, nobody has offered to do anything for me. Hell, other than my wife, you’re the only one that has even tried to listen. We lost a lot of guys over there and I miss ’em a lot. Nobody gets it, nobody wants to listen, and they just think I’m a drunk or I’m tired or crazy.”

You reply by thanking your patient for his service to his country, and you express your sincere sympathy for the loss of his fellow servicemen. He nods his head in continued
IN REVIEW

1. What is the EMT’s primary responsibility?
2. The knowledge of PTSD from this chapter has wider applicability to patients other than combat veterans. Who might those be?
3. EMTs are exposed to trauma due to the very nature of their work. What will you do if or when you start to develop symptoms of PTSD?
4. PTSD can be missed as a problem. What are some reasons for that?
5. What are the four main features of PTSD?
6. Which symptoms are similar between PTSD and TBI?
7. Which symptoms differ between PTSD and TBI?
8. Since 2000, how many service members have been diagnosed with a TBI?
9. What percentage of vets use drugs or alcohol to help them cope?
10. Is there a cure for PTSD?
11. What is the definitive treatment for returning combat veterans suffering from PTSD?
12. What is the definitive treatment for returning combat veterans suffering from TBI?
13. What other resources does the EMT have available to assist in treating the veteran patient?
14. What are some other disease processes that might be found in the veteran patient more often than in the general population of the same age?
15. What is the suicide rate for returning combat veterans?
16. Unfocused pain is common in the combat veteran. Name three other types of patients who may have the same signs and symptoms as the returning veteran.
17. What are some “triggers” that may exacerbate a situation involving a veteran?

CRITICAL THINKING

You are called by the police for a person behaving strangely. You arrive on the scene and find a young male, approximately 23 years of age, hiding behind a garbage dumpster near a crowded street corner in the city. The patient appears to be very anxious and scared. He has a military haircut and a recognizable KIA bracelet on his left wrist. He is mumbling something about hearing an RPG (rocket propelled grenade).

1. What characteristics of the scene imply the patient is potentially a returning combat veteran?
2. How would you manage for scene safety? What are your concerns for keeping the scene safe?
3. How would you approach the patient?
4. What characteristics would you notice during your assessment that would make you suspect the patient is suffering from PTSD or TBI?
5. What emergency care would you provide to the patient?
6. What additional resources would you contact to assist with this patient?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • EMS Operations** (Content Area: Principles of Safely Operating a Ground Ambulance; Air Medical)

**COMPETENCY •** Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

**OBJECTIVES •** After reading this chapter, you should be able to:

42-1. Describe the privileges afforded to EMTs operating emergency vehicles and the precautions that must be observed while using these privileges.

42-2. Give examples of habits and behaviors that improve driving safety.

42-3. Discuss factors that can affect your ability to maintain control while driving an ambulance.

42-4. Explain precautions that should be taken when driving an ambulance in inclement weather.

42-5. Explain precautions that should be taken when driving an ambulance at night.

42-6. Describe the appropriate use of emergency warning devices, such as lights and sirens.

42-7. Describe the safety precautions to be taken when working at scenes on and near roadways.

42-8. Give examples of the EMT's responsibilities during each of the major phases of an ambulance call.

42-9. Describe post-run actions that should be taken to reduce the spread of infection to you, your coworkers, and patients.

42-10. Discuss situations in which air medical transport should be considered, potential disadvantages of air medical transport, and guidelines for setting up a landing zone.

42-11. Describe the recommendations of the National Association of Emergency Medical Technicians with respect to EMT security and safety.

42-12. Explain precautions to avoid exposing yourself or others to increased levels of carbon monoxide associated with ambulance operations.

---

**Case Study**

**The Dispatch**
Medic One—respond to the rest area at Interstate 80 and the Black Canyon Exit. You have a 33-year-old female patient with labor pains. Time out is 1511 hours.

**En Route**
You move quickly to your vehicle. Your partner is driving. You fasten your seat belt. The garage door opens. The engine starts. Your vehicle moves slowly and then picks up speed. Additional patient information from dispatch crackles over the radio. It’s difficult to hear. You inhale deeply and tell yourself, “Relax.” You are prepared. You begin to picture in your mind what you need to do and how you should perform throughout the ambulance call.

This chapter will provide you with information on how to prepare yourself, your equipment, medical supplies, and your vehicle for an ambulance run. Later, we will return to the case study and apply the steps learned.
INTRODUCTION

The ambulance is the vehicle that brings care to the patient in times of emergency and transports the patient to a medical receiving facility for follow-up care. It is a crucial part of the EMS system.

An ambulance should be a place of comfort and support to patients suffering from life-threatening problems. It should not pose additional hazards to them. But statistics tell a different story: There are approximately 5,000 ambulance crashes each year in the United States. On average, there is one fatality each week from an ambulance crash and many more serious injuries.

To keep from adding to these statistics, the EMT must learn to drive an ambulance skillfully and safely. The process takes time; however, the regulations and guidelines can be learned before getting behind the wheel. This chapter describes how to operate an ambulance safely. It also details other procedures to help ensure the most efficient operation of a properly equipped ambulance.

DRIVING THE AMBULANCE

As an EMT, you have the responsibility for getting an ambulance safely to the scene of an emergency and transporting patients safely in it to medical care. To drive an ambulance well, you need a combination of the right knowledge, skills, and attitude.

Laws, Regulations, and Ordinances

As an ambulance operator, you should be familiar with the laws and regulations that apply on both the state and local levels and consistently obey them. You have certain privileges under the law as the operator of an emergency vehicle, as do the operators of police vehicles and fire apparatus. At no time is it justified to operate an ambulance in a manner that jeopardizes anyone else. Remember that your first duty to your patient is to arrive at the scene—safely! After that, you must get your patient to definitive care carefully and safely.

While statutes in each state vary slightly, most states give you the privilege, with proper precautions, to do the following while driving the ambulance to an emergency:

- Exceed the speed limit posted for the area as long as you are not endangering lives or property.
- Drive the wrong way down a one-way street or drive down the opposite side of the road.
- Turn in any direction at any intersection.
- Park anywhere as long as you do not endanger lives or property.
- Leave the ambulance standing in the middle of a street or intersection.
- Cautiously proceed through a red light or red flashing signal.
- Pass other vehicles in no-passing zones.

In passing, you must first signal, ensure that the way is clear, and avoid endangering life and property by driving with due regard for the safety of others.

By law, you must meet several qualifications before you can exercise these privileges:

- You must have a valid driver’s license. Most states mandate that you attend an approved driving course.
- You must be responding to an emergency of a serious nature.
- You must use warning devices—emergency lights, horns, and sirens—so that other vehicles on the road will be aware of you and have a chance to yield. You must use these devices in the manner prescribed by law.
- You must exercise due regard for the safety of others. You may cautiously move through a red light, but you must slow down while entering the intersection so that all traffic can stop to allow you to pass. You may park your ambulance anywhere to care for a patient, but you must not park it just over the crest of a hill on a busy highway unless you post flares and get a police officer or a volunteer to divert traffic out of your lane, and you must use good roadway safety practices, which are discussed later in the chapter. The law states that if you do not exercise due regard for the safety of others, you are liable for the consequences.
- Many EMS systems provide additional guidance. For instance, some specify that your top speed cannot be more than 10 miles per hour over the speed of traffic, which may or may not be the posted speed. This allows the emergency vehicle to overtake other moving traffic but promotes safer driving. In some areas, ambulances entering an intersection against the light must come to a complete stop before proceeding.

Be sure that you know the general vehicle code, the regulations for emergency vehicles, and your agency code. Also, know the qualifications in your state for operating an ambulance and be sure that you can qualify. Several states require special licenses and/or special training for ambulance operators.

Driving Excellence

An excellent ambulance operator understands the capabilities and limitations of his vehicle, evaluates weather and road conditions quickly and accurately, appraises and responds to traffic conditions quickly and appropriately, and minimizes risk and discomfort to other members of the crew and to the patient. Notice that fast, dramatic driving is not part of the definition.

Basics of Good Driving

Always wear seat belts when you drive the ambulance. Make sure other team members wear theirs as well.
Hold the steering wheel with both hands at all times. One hand should be in the 9 o’clock and the other in the 3 o’clock position. In turning, one hand pulls while the other slides, paralleling the pulling hand’s position. Neither hand should pass the 12 or 6 o’clock positions to prevent them from becoming tangled. When you reach these limits, the opposite hand begins to grip the wheel and the first hand slides.

You need to practice enough with your ambulance that you are familiar with how it accelerates and decelerates, the kind of space it requires for its fenders and bumpers, how it brakes, and how it corners.

When driving an ambulance, you must recognize and respond to changes in weather and in road conditions. Adjust your speed to allow for decreased visibility at night and in fog and road handling during rain, snow, and ice storms.

During transport, select the route best suited for safe travel—this is not necessarily the shortest route. Avoid schools, railroad crossings, detours, construction sites, bridges, tunnels, and similar trouble areas whenever you can, even if it means driving a few extra miles. If you are unfamiliar with the roads in your city or area, get a detailed local map and study it. Patrolling will help you get a feel for topography. Keep informed about roads undergoing repair or new building sites, and avoid them when you can. Select an alternative route during rush-hour traffic. If you are responding to a traffic collision that can back up traffic on a busy highway, select an alternative route to avoid being caught in the traffic jam.

Maintain a safe following distance. Use headlights to improve your vehicle’s visibility. Exercise caution when using red lights and the siren.

**Maintaining Control**

For vehicle control, remember the rule about speed: Go the posted limit unless the situation is critical. Speed can complicate patient care by providing a rougher ride, decrease ambulance stability, and risk the safety of everyone in the ambulance (Figure 42-1). A number of factors other than speed affect your ability to control the ambulance, and you need to be alert to them to stay in constant control as you drive.

- **Braking.** Sudden braking may result in loss of control. In older ambulances without antilock braking systems, the brakes will cause wheels to lock, and you may skid dangerously. In these vehicles, you should pump your brakes slowly and smoothly. Newer ambulances typically have an antilock braking system in which the brakes should be applied firmly and steadily, not pumped. Never brake on a curve. Brake when going into the curve and gradually accelerate when going out. When decelerating, rest your foot lightly on the brake. Your stopping distance is the time it takes you to react plus your braking time.

- **Driver Distractions.** When driving an ambulance, it is important to minimize distractions as much as possible.

Always remember that those driving the vehicles around you may be distracted by cell phone use, loud music, conversations, eating and drinking, or a number of other things. When you are driving an ambulance, you are subject to all of these same distractions, as well as additional ones such as global positioning systems, mobile computers, mobile radios, and the operation of the lights and siren. Particularly when driving in an emergency situation, you must focus your attention on the road. Your primary goal is to arrive safely at your destination.

**Driving Alone.** When transporting a patient to the hospital, you must operate the vehicle without any support from other crew members, who will be in the patient compartment. In these cases, maintain focus on the safe operation of the ambulance and the safe transportation of your crew and patient. Do not allow yourself to be distracted by operation of the lights and siren, communications equipment, global positioning systems, or other activities within the ambulance.

**Fatigue.** Driving while fatigued greatly increases the risk of an accident. Proper rest and nutrition can decrease this risk. When on duty, you must be physically prepared for any driving situations that may arise.

**Railroads.** You may encounter a railroad crossing and have to wait for a long train to crawl along the tracks. Keep calm and monitor the patient. If there is simply no way to get around the train, such as an underpass or overpass within a reasonable distance, wait it out instead of trying inappropriate stunts. Plan an alternative route when you can.

**School Buses.** Be especially alert when approaching a stopped school bus with its red lights flashing. You must always be prepared for the possibility that a child will dart out across the road heading to or from the bus. Laws regarding ambulances and school buses vary from state to state. In some, an ambulance must come to a full stop and remain stopped until signaled ahead by the bus driver. Follow your state law.

**Bridges and Tunnels.** There is little room for passing on bridges or in tunnels. If you are in heavily
congested traffic near a bridge or tunnel, consider an alternative route. If there is none, try to get control of the situation before you enter the bridge or tunnel. Remember that you probably will not be able to pass, so go with the flow of traffic at a safe speed until you emerge. Also be sure the height of the bridge or tunnel will accommodate the height of the ambulance.

**Day of the Week.** You can expect less traffic on weekends than on workdays in most areas. Traffic around shopping centers is heaviest on Saturdays, to and from resort areas on Fridays and Sundays, and on commuter routes or in urban and industrialized areas on Monday through Friday. Keep in mind what kind of traffic you are likely to encounter and, when possible, adjust your route accordingly.

**Time of Day.** Rush-hour traffic is more congested in most urban centers than rural areas, so plan accordingly. Watch for school zones and industrial plant shift changes.

**Road Surface.** Always be on the lookout for potholes and bumps. Your goal is to give your patient the smoothest ride possible. The two inner lanes on a four-lane highway are generally the smoothest. At times, it may be necessary to drive the ambulance on unpaved roadways in order to get to the scene of an emergency. In these situations, decrease speed and exercise increased caution.

**Backing Up.** Many ambulance collisions occur when the ambulance is backing up. Use all resources (e.g., mirrors, EMT in the rear of the ambulance) and back up slowly and carefully.

**Higher Speeds.** At higher speeds, be alert to the following:

- Be especially careful on curves that lead into population pockets (a town or school), curves that lead to intersections, and curves that crest hills. Practice negotiating curves in the ambulance during the early mornings when there is little traffic. Get a good idea of what speed you need to get around the curve safely.
- Brake to the proper speed before you enter a curve. Enter the curve at the outside (or the “high” part), and start turning as early as possible. Go only as fast as feels comfortable while in the curve. Do not accelerate or brake in the curve—the scrubbing action of the tires will slow the ambulance down sufficiently. It is dangerous to brake after you have entered the curve, so make sure that you decelerate to a safe speed before entering.
- Accelerate carefully and gradually as you leave the curve. Too quick an acceleration can cause you to lose control.
- Keep your exit from the curve slow and steady.
- When going down a long hill, use a lower gear instead of riding your brake to maintain control.
- Always use a smooth braking motion. Your stopping distance increases dramatically as your speed increases; allow for it.

**Aggressive Drivers.** It is important to remember that driving an ambulance does not necessarily change the habits of other drivers on the roadways. Aggressive drivers, in particular, can pose a significant increased risk to you and your vehicle. If you notice another vehicle weaving in and out of traffic, speeding, or otherwise driving in an aggressive or erratic manner, exercise extreme caution when approaching or passing that vehicle. Aggressive drivers are often distracted and may not even notice the presence of the ambulance. When in doubt, it is always best to slow down, assess the situation, and choose the safest method for continuing to your destination, even if that means choosing a different route of travel to avoid dangerous roadway situations.

**Escorts.** Using a police or other emergency vehicle escort en route to a response or the hospital should be a last resort. It is dangerous, not only to the escort, but also to the EMT driver, to the patient in the ambulance, and to others on the road. All hazards associated with ambulance driving are doubled when an escort is involved, because you are the second vehicle through an intersection and motorists may expect only one.

Use an escort only if you are unfamiliar with how to get to the hospital or if you do not think that you can find the patient’s location. Allow for a safe distance between the escort vehicle and your ambulance.

**Intersection Collisions.** The most common collisions in which ambulances are involved are those at intersections. There are three main causes of intersection collisions:

- A motorist approaches the intersection just as the light is changing; he does not want to sit through the red light, so he sails through the intersection. Always slow down at each intersection to make sure that it is clear. If you are crossing against the light, come to a complete stop and proceed only when all traffic is clear or appropriately stopped.
- There are two emergency vehicles when motorists expect only one. Maintain a safe distance between your vehicle and the emergency vehicle in front of you, but follow closely enough so that the motorist can see both of you in the same glance. Do not use the same siren mode on both vehicles. Whenever you are using the emergency privileges that allow you to suspend traffic regulations, always use your flashers and siren for the fullest possible warning to the public. In some states, use of your siren when you are driving in the emergency mode is mandated by law.
- Vehicles waiting at an intersection may block your view of pedestrians in the crosswalk. Again, slow down and anticipate people in the crosswalk. Come to a complete stop if you are unsure if pedestrians are entering the intersection.

**Driving in Inclement Weather**

Bad weather affects your ability to control your ambulance. Stopping on wet pavement takes approximately twice the distance as stopping on dry pavement.
On ice or sleet, it takes you five times the distance to stop. Leave adequate space between you and the vehicle in front of you in any kind of weather. Utilize the following precautions for specific weather situations.

**Rainy or Wet Weather.** About six times more people are killed on wet roads than on snowy and icy roads combined. Roads are most slippery as a rainstorm begins. When the road is wet, your vehicle can hydroplane—that is, the front tires literally lift so that the vehicle is riding on a film of water rather than on the pavement itself. Hydroplaning can begin at speeds as low as 35 miles per hour if the tires are worn. Do the following when driving on wet roads:

- Keep your mirrors cleared of water.
- Avoid sudden braking and sudden moves of the steering wheel.
- If you are about to go through a large standing puddle, slow down and turn on your wipers before you hit the water. As you leave the water, tap the brake lightly a few times to dry it out. If the ambulance pulls to one side, pump the brake slowly and smoothly to dry the brake out.
- If you begin to hydroplane, hold the wheel steady, take your foot from the accelerator, and gently pump the brake. If you turn the wheel from side to side, or jam on the brake, you will probably skid.

**Winter Driving.** Sleet, freezing rain, packed snow, and ice decrease visibility and increase skidding. Powder snow and gusty winds can create a total whiteout with zero visibility for several hundred yards. To ensure safety, do the following:

- Make sure that your engine is tuned, your heater and defroster are in good working order, and your battery is charged.
- Carry emergency weather equipment—chains, a shovel, sand, booster cables, and a towing device.
- Equip the ambulance with studded snow tires if you can. Chains are the best insurance against skidding. Follow local and state protocols and laws.
- Stay aware of the temperature. Wet ice and freezing rain, the most hazardous road conditions, occur between 28°F and 40°F. Bridges and overpasses freeze sooner than road surfaces.
- Avoid sudden movements of the steering wheel and sudden braking.

**Fog, Mist, Dust Storms, Smog.** When visibility is poor, do the following:

- Slow down but avoid decelerating suddenly.
- Watch the road ahead and behind carefully for other cars that are traveling slowly.
- Turn on your lights, regardless of the time of day, and use your wipers. (Never use the high beams on your headlights. The reflection of the high beams from the fog will actually reduce your ability to see.) Even if the lights do not improve your ability to see ahead, they will make it possible for other motorists to see you better.
- If you are traveling 15 miles per hour or more below the speed limit, use four-way flashers. (These may not be legal in some states.) Use the four-way flashers if you pull off the road and stop.
- Use the defroster to keep as much fog as possible off the inside of the windshield.
- If you need to slow down, tap your brake pedal several times so that the flash of your brake lights will warn motorists behind you.
- Fog can occur suddenly, and patches of greater density may appear. Vehicles in front may brake suddenly or come to a complete stop when encountering a thicker patch of fog. Be alert for vehicles in front of you.

**Driving at Night**

While only about one-third of all collisions occur at night, more than half of the fatalities from collisions stem from nighttime driving. In fact, based on miles driven, there are two and a half times more fatal collisions at night than during the day (Figure 42-2). This is because less light is available and vision is restricted. Night vision varies considerably among people. Older people generally cannot see well in the dark, and eye-strain can substantially reduce night vision. Bright light, such as lightning or high-beam headlights, can cause temporary blindness at night.

Headlights on low beams illuminate the roadside for about 150 feet. On high beams, visibility will be 350–400 feet. At 55 miles per hour, it takes 4.5 seconds to cover 350 feet. For night driving, control speed so that your stopping range is within headlight range.

To improve your visibility and the ability of others to see you, do the following:

- Make sure that your ambulance has quartz-halogen headlights, which provide much more light to the road.
- Have your headlights on whenever you are traveling in an emergency.
- Keep your headlights clean and properly aimed. Check them each day before your shift begins. If the

![FIGURE 42-2 Take extra care when driving at night. (© Mark C. Ide)](image-url)
weather is bad, especially if there is sleet or snow, stop as necessary during your shift to clean debris off your headlights.

- Replace burned-out bulbs immediately.
- Dim your high beams within 500 feet of an approaching vehicle or within 300 feet of a vehicle in front of you.
- Never stare into the high beams of another car; guide your ambulance by watching the right edge of the road.
- Do not flick your high beams up and down to remind another driver to dim his brights—it can blind him temporarily.
- Never use high beams when going into a curve.
- Keep your windshield clean, inside and out. Keep a bottle of windshield or glass cleaner in the ambulance for mirrors and interior windshields.
- Keep your instrument panels dim.
- Keep your eyes moving; avoid focusing on any one object.
- If the washing solution under your hood does not leave the glass clean after ten wiper cycles, replace the blades or use a stronger concentration of washing fluid.
- Be sure that you are rested before you begin a night driving shift. Between 11:00 P.M. and 3:00 A.M., be particularly alert for intoxicated or drowsy drivers. If you notice erratic speeds, weaving across lines, or delayed starts at intersections, use extreme care in passing.

**WARNING DEVICES**

Ambulances are equipped with a variety of warning devices. The use of these devices may save some time when responding to a call or when transporting a patient to definitive care. However, they may also increase the risk to ambulance personnel, patients, and the general public. Always take the increased risk of warning device usage into consideration, and weigh it against the benefit of saving a few minutes in transit time. Most agencies, and many counties and states, have specific protocols for use of these devices. Remember that they are only a means of requesting the right of way from others on the road and do not give the ambulance any special rights or guarantee of clear traffic. Due regard for the safety of others must still be exercised at all times, particularly when using warning devices. Following are some general guidelines and suggestions for the use of warning devices.

**Colors and Markings**

Ambulance colors and markings are an aid to traffic safety and reduce the need for excessive dependence on lights and sirens. An early U.S. Department of Transportation (DOT)/EMS study, “Ambulance Design Criteria” by the National Academy of Sciences, recommended a nationwide system of specific colors and markings. Later, the General Services Administration and DOT developed and published federal specifications for ambulances (1974:KKK-1822). The colors and markings are typically designed to provide quick identification that the vehicle is an ambulance and also to maximize visibility in traffic (Figure 42-3).

![Ambulance](a)

![Ambulance](b)

**FIGURE 42-3** (a) Colors and markings are typically designed to provide quick identification that the vehicle is an ambulance and (b) to maximize visibility in traffic.

Warning Lights and Emergency Lights

Activate emergency lights on the ambulance at all times when responding to an emergency call. Lights should be used even when you are not using the siren. You should also turn on your headlights during the daytime—in some situations, the warning lights on top of the vehicle are not noticeable because they blend in with traffic lights, signs, Christmas decorations, building colors, and tail lights of vehicles traveling in the opposite direction.

Placement of the ambulance emergency lights on the vehicle is very important. They should be high
enough to cast a beam above the traffic. Lower lights are needed to be visible in the rearview mirror of the car ahead of you.

When an ambulance has strobe lights, use them with emergency lights that flash or revolve with a longer duration. White lights can be seen from a longer distance than red or blue, especially at sunrise or sunset. They can also be seen more effectively when wet streets are reflecting.

Headlights are a part of the emergency lighting system and should be on whenever you are traveling in an emergency. Specially wired headlights that flash alternately are also effective in gaining attention. (These are not legal in some states—check local protocol.) You can use a spotlight to get the attention of a driver who has not noticed you, but do not panic him. Quickly flash the light across the driver’s rearview mirror so that it gets his attention but is gone before he looks in the mirror. The glare could blind him or oncoming traffic, so be careful.

Use only minimal lighting during heavy fog or when you are parked. Use your emergency lights only when needed, such as when the patient's condition requires rapid transport.

### Using Your Siren

Even if you are operating your flashing lights and sirens, do not assume that drivers are aware of you unless they look up to check their interior rearview mirror, look to the left to check the exterior rearview mirror, pull over, or stop.

The insulation in newer automobiles can reduce the interior decibel level of an approaching siren by 35–40 percent when parked. In motion, the noise of the motor, air-conditioner/heater, and radio in the automobile may make the siren completely inaudible. (This also applies to you in the ambulance!) Other sources of interference may be conversation, pelting rain, dense shrubbery or trees, buildings, and thunder. If the driver is wearing headphones, talking on a cell phone, inattentive, or hearing-disabled, your problem is even more severe. Some drivers may not even recognize a two-tone klaxon as a siren.

Never pull directly behind a car and blast your siren. The driver may panic and slam on the brakes or swerve into another lane. Be prepared for the irrational maneuvers of inexperienced, intoxicated, or disoriented drivers.

Since the siren signals “emergency,” it can create emotional stress (as well as physical stress from the noise level) for your patient. This is another reason for using your siren sparingly. Always let your patient know before you activate the siren.

Be aware of the siren’s effect on you. Even if you can normally drive your own car or the ambulance flawlessly, the siren can have a bizarre effect on your ability to drive the ambulance safely. Studies have shown that ambulance operators tend to increase their speed about 15 miles per hour when the siren is going—an increase that sometimes takes them out of the limits of safe speeds. Some drivers are easily hypnotized by the siren and are unable to negotiate curves, turns, and obstacles; this hypnotic trance makes it seem as though the siren itself were controlling the vehicle. The siren can also prevent you from hearing sirens or horns of other emergency vehicles responding to the same or other incidents.

Follow your state laws and local protocols regarding siren use.

### Using Your Air Horn

Avoid overuse of the air horn, but consider it when you need to clear traffic quickly. You can use the air horn with or without the siren, depending on your state law and local protocol. Do not sound your horn when you are close to other vehicles—it may frighten a driver and cause him to slam on the brakes or swerve. (The air horn may, however, be used safely much closer to other cars than may your siren.) Do not assume that other drivers can hear or will heed your horn.

### ROADWAY INCIDENT SCENE SAFETY

There is an increasing number of incidents where emergency response personnel are severely injured or killed while attending to patients on a roadway. These incidents occur not only on freeways and highways with fast moving traffic but also on residential and city streets. You expose yourself to a high risk when you are working in or near moving traffic. EMS personnel must set up an environment so that they are best protected from injury whenever they are managing a patient on or near a roadway.

The same characteristics that make drivers hazardous to you while you are driving the ambulance on an emergency response also make them a hazard while you are on the scene in moving traffic. Factors such as vision impairment, inexperienced drivers, loud music, cell phone use, distraction from conversation, inclement weather, intoxication, medical conditions that impair reflexes, and high speed can make these drivers and vehicles a significant threat to you on the scene of a roadway incident. Nighttime incidents are even more hazardous because of the reduction in visibility and a reduction in the reaction time of drivers.

### High-Visibility Apparel

A recently approved federal law requires all EMTs and other rescue personnel responding to accidents or other emergencies on or near a roadway to wear approved high-visibility apparel in an attempt to reduce the incidence of injury to emergency responders.
The American National Standards Institute (ANSI) and International Safety Equipment Association (ISEA) created the standard ANSI/ISEA 107-2004, American National Standard for High-Visibility Safety Apparel and Headwear. Three classes of garments were established:

• **Class 1.** Designed for workers in parking lots and other areas with traffic flow moving at less than 25 mph
• **Class 2.** Designed for personnel whose attention is diverted from traffic or where the traffic flow is moving at 25 mph or greater
• **Class 3.** Designed for personnel whose work greatly diverts their attention from the roadway and where they are at serious risk from hazards created by moving vehicles

The ANSI/ISEA 207-2006 American National Standard for High-Visibility Public Safety Vests (PSV) was approved to increase the visibility of emergency personnel on the roadway and to reduce the incidence of roadway hazards. The newer standard made significant changes to standard class garments to accommodate the public safety responder. The PSV has the same retro-reflective material as the Class 2 vest and nearly the same amount of fluorescent material. The PSV includes breakaway features, specific vest dimensions to allow for fit over turnout gear, and color-specific markings to allow for differentiation between law enforcement, fire, and EMS personnel.

Currently, the Code of Federal Regulations requires all emergency personnel who are exposed to traffic within the right-of-way of a highway that receives federal funding to wear high-visibility safety apparel that meets the Class 2 or 3 standards of ANSI/ISEA 107-2004 or the Public Safety Vest standard ANSI/ISEA 207-2006.

**Safety Benchmarks**

According to the University of Extrication *Safe Parking Standard Operating Procedures* by Ron Brown, there are certain safety procedures, or “safety benchmarks,” that you can practice at the scene of a roadway incident to lessen your chances of becoming a casualty of the scene. They are:

• **Do not trust approaching traffic.** Approaching traffic may not be aware of the scene ahead or may be distracted and not paying attention to any warning lights, cones, or other markers.
• **Do not turn your back to approaching traffic.** Always position yourself so that you can see oncoming traffic when walking to and from the scene or while working on scene. If that is not possible, use a spotter to continuously monitor the traffic and notify you immediately of any unsafe or irregular traffic flow.
• **Position the first arriving emergency vehicle to create a block and a physical barrier between upstream traffic and the scene.** Using a vehicle as a block will provide some protection to those working on the scene. The wheels of the vehicle should be turned away from the scene. Block at least one additional lane and block the most critical lane or the lane in which there is the highest volume of traffic. Ambulances should be positioned so that personnel are protected when loading the patient. Park the ambulance in the safe zone of other blocking vehicles, and face the loading area away from the closest lane of traffic. Load patients only while in a protected zone area.
• **Wear appropriate personal protective equipment and ANSI high-visibility vests.** Federal law requires EMTs to wear approved high-visibility vests. By doing so, you will be more visible to oncoming traffic and better protected.
• **At nighttime, turn off vision-impairing lights, including headlights and spotlights, on emergency vehicles that are positioned to oncoming traffic.** The high-visibility lights, especially white lights, may blind or confuse oncoming traffic.
• **Use other emergency vehicles, such as police and fire apparatus, to initially slow down and redirect the flow of traffic.** When arriving on the scene of an incident that potentially involves critically injured or ill patients, there may not be enough time to set up traffic control devices to slow down and redirect the flow of traffic. Emergency vehicles could be positioned to do so until other units and personnel arrive on the scene to provide better traffic flow control.
• **Use advance warning signs and other traffic control measures upstream of the scene to reduce the speed of the oncoming traffic.** Advance warning signs and other traffic control devices should be used to slow the speed of traffic approaching the scene.
• **Use traffic cones for traffic control.** Traffic cones can be used to alert motorists and divert the flow of traffic away from the scene.
• **Assign a person to monitor oncoming traffic.** Assign an emergency responder to monitor the oncoming traffic and to immediately sound an alarm to notify you of any motorist who deviates from the traffic control measures.
• **Uphill/upwind.** When approaching an unknown roadway incident that may involve hazardous materials, it is always best to place your vehicle uphill and upwind from the scene to avoid potential contamination from leaking or airborne chemical or other hazards.

By taking some traffic control measures to protect yourself, your partner, the patients, and other personnel at the scene of a roadway incident, you may prevent an injury or death.

## PHASES OF AN AMBULANCE CALL

The major phases of an ambulance call are:

1. Daily prerun vehicle and equipment preparation
2. Dispatch
3. En route to the scene
4. At the scene
5. En route to the receiving facility
6. At the receiving facility
7. En route to the station
8. Post run

**Daily Prerun Preparation**

The key to response readiness is a properly maintained and equipped ambulance. Having a vehicle ready to respond at all times and in all conditions and equipped with all necessary supplies will ensure that you can reach, care for, and transport your patients.

**Ambulance Maintenance**

Basic ambulance maintenance should include oil and filter changes, transmission and differential checks, wheel bearing check, brake check, and tie rod end inspection.

A comprehensive and regularly scheduled preventive vehicle maintenance schedule is essential. Benefits of a professional vehicle maintenance and inspection schedule include:

- Decreased vehicle downtime
- Improved response times to the scene
- Safer emergency and nonemergency responses
- Improved transport times to the medical facility
- Safer patient transports to the medical facility

You should know and practice your service’s policies and procedures for reporting and correcting vehicle problems. Do not be afraid to take personal responsibility for ensuring that your vehicle is fit for duty. Remember, proper care for your ambulance is part of proper care for your patients and helps to ensure the safety of you and your crew.

**Daily Inspection of Vehicle**

Inspect the vehicle systems daily (EMT Skills 42-1). Most ambulance systems have a checklist of the items to be checked, which will typically include the items listed in Table 42-1.

Your service should have a clear protocol for reporting problems with vehicles, taking them out of service if they are deemed unsafe, and performing regular service and maintenance. Legally, you may be within your rights to refuse to use a vehicle that you have reason to believe is unsafe; and incidentally, you may be legally liable for damage caused by a malfunctioning ambulance if you are aware of the problem.

**Ambulance Equipment**

Your ambulance must contain supplies and equipment for handling medical emergencies, injuries, extrications, and childbirth. Supplies and equipment should be checked each day and restocked, cleaned, or maintained after each run. Table 42-2 lists supplies and equipment as identified in the EMT curriculum. All equipment and supplies located in the ambulance must be properly secured to prevent them from becoming projectiles and endangering personnel and patients. This applies to equipment within the cab area, as well as the rear compartment and cabinets.

![Table 42-2: Basic Ambulance Supplies](image)

**Table 42-2: Basic Ambulance Supplies**

**Medical Supplies**

- Basic supplies
- Patient transfer equipment
- Airways
- Suction equipment
- Artificial (positive pressure) ventilation devices
- Oxygen inhalation equipment
- Automated external defibrillator (AED)
- Basic wound care supplies
- Splinting supplies
- Childbirth supplies
- Medications

**Nonmedical Supplies**

- Personal protective equipment (Standard Precautions)
- High-visibility safety vests
- Preplanned routes, comprehensive street maps
Personnel
A properly equipped and maintained ambulance is important to emergency prehospital care. Properly trained personnel to operate the ambulance and make optimum use of its equipment are even more important. Staffing requirements for ambulances vary among states and localities. In some states, one EMT in the patient compartment is considered the minimum standard; however, two are preferred in some situations involving critically injured or ill patients. Follow your state laws and local protocols about staffing.

Dispatch
A message from the communications center will start you on your run. The communications component of the EMS system has been discussed in greater detail in Chapter 5, “Communication.” The call taker will usually have performed the first assessment of the situation when receiving a call. The dispatcher should provide you with the following information:

- Location of the call
- Nature of the call
- Name, location, and callback number of the caller
- Location of the patient or patients at the scene
- Number of patients (if more than one) and the severity of the problem
- Any other special problems or circumstances that may be pertinent

Write this information down so you can refer to it. Use it to prepare yourself physically and mentally for the call. Ask the dispatcher to repeat or restate information if anything is unclear.

En Route to the Scene
Your ambulance is checked and ready to respond. The vehicle’s medical and nonmedical equipment and supplies are clean and operational. You receive a call. Follow these guidelines on your way to the scene:

- Before departure, quickly check the vehicle to make sure outside compartment doors are closed and secure, external shoreline cords are disconnected, and any jump kits are retrieved and properly stowed.
- Fasten your seat belt and ensure that the seat belts of all other people in the ambulance are fastened.
- Write down information from the dispatcher on a notepad.
- Confirm the following dispatch information:
  - Location of the call
  - Nature of the call
  - Location of the patient or patients
  - Number of patients and the severity of the problem
  - Any other special conditions or problems
  - If any other units are en route

- Listen for status reports from other units on the scene.
- Think about what equipment you will want to take into the scene.
- Remain relaxed, yet focused. (Studies indicate that fewer than half of all ambulance runs are requested as emergencies. Only half of those are true emergencies, with less than 5 percent being life threatening.)
- Drive responsibly, maintaining a 3- to 4-second following distance between your ambulance and the vehicle directly ahead of you.
- Determine what the responsibilities of team members will be before arriving on the scene and make sure those responsibilities are clear.
- Call for advanced life support, if necessary.

At the Scene
Follow these guidelines while at the scene:

- Notify dispatch of arrival on scene.
- Park the ambulance in the safest place that will allow you to load the patient and later depart from the scene, taking into consideration the traffic, the roadway, and any known hazards. Follow local ordinances regarding the use of warning signals and devices at the scene (Figure 42-4).
- Perform a full 360-degree scene survey, paying particular attention to any downed electrical lines, leaking fuels or fluids from accident vehicles, smoke or fire, broken glass, trapped or ejected patients, mechanism of injury, and other indicators of increased risk to you, your crew, or your patients. Review the procedures discussed in Chapter 12, “Scene Size-up.”
- If other emergency vehicles are on scene and are positioned to block the scene, park in front of or behind a collision, but never alongside it. If no other vehicles are on scene, position the ambulance to provide a safety zone. On a narrow, no-parking road, take up the entire road so that no one will try to squeeze past you. Park in a driveway or on the shoulder of the road whenever possible. Stay a minimum of 100 feet from wreckage or a burning vehicle and 2,000 feet from a hazardous materials spill, ideally uphill and upwind (Figure 42-5). Come to a complete stop. Set the parking brake prior to placing the transmission in the “park” position.
- Prior to exiting the ambulance, put on an approved high-visibility safety vest if you will be working on or near a highway or other roadway.
- Take the necessary Standard Precautions. Determine if you will need eye protection, gloves, mask, and gown before making patient contact.
- Determine if it is safe to approach the patient. Identify and control hazards. If the scene is unsafe, make it safe or do not enter until the scene is secure for you, incoming units, any bystanders, and your patient. Review the procedures discussed in Chapter 12, “Scene Size-up.”
On arrival, you find the police have controlled the scene.

Your unit is the first emergency vehicle on the scene.

- Utilize vehicle warning lights
- Set the emergency brake
- Shut off headlights — unless they are needed to illuminate the scene

FIGURE 42-4 Safety at the scene.
• If a mechanical failure occurs or you need backup equipment or personnel to help, call the dispatcher immediately.
• Although your dispatcher has told you what to expect, be prepared to shift your perspective quickly. You may encounter an entirely different situation or incident. Remain calm and poised. Unruffled management of the unexpected emergency is part of your job.
• Carefully observe the complete incident or situation as you approach. Look for children, curiosity seekers, or patients who may have wandered away from the scene. Decide if the patient may require immediate movement because of hazardous conditions.
• Determine the patient’s mechanism of injury. Follow guidelines from Chapter 12, “Scene Size-up,” Chapter 13, “Patient Assessment,” and Chapter 27, “Trauma Overview: The Trauma Patient and the Trauma System.”
• Determine the total number of patients. Initiate multiple-casualty-incident response if necessary, following the procedures described in Chapter 45, “Multiple-Casualty Incidents and Incident Management.” Do this before making patient contact. You are less likely to call for help once you begin intense patient care and treatment. If necessary, begin patient triage.
• Determine your priority of care. Your approach to medical and trauma patients during your primary assessment should be organized. Keep the goal of prompt transport foremost in your mind.
• For motor vehicle crashes, carefully gain access to the patient or patients and extricate them safely. Proper procedures to follow are discussed in Chapter 43, “Gaining Access and Patient Extrication.”
• Take the time needed to properly splint and immobilize injured extremities before you move the patient, unless he is unstable and determined to be a high priority for immediate transport. Proper spinal immobilization is critical to appropriate patient care. Review the procedures discussed in Chapter 50, “Musculoskeletal Trauma and Nontraumatic Fractures,” and Chapter 32, “Spinal Column and Spinal Cord Trauma.”
• Carefully remove the patient from any wreckage and move him to the ambulance, choosing methods of moving the patient based on his illness or injury. Follow the patient lifting and moving principles and procedures you learned in Chapter 6, “Lifting and Moving Patients,” and Chapter 32, “Spinal Column and Spinal Cord Trauma.”
• Transfer the patient to the waiting ambulance. Keep him warm, and watch for any changes in his condition. Make sure the patient is securely strapped on the wheeled stretcher with spinal immobilization performed as necessary. Lock the stretcher securely in place within the ambulance.

![FIGURE 42-5](http://www.bradybooks.com) Park the EMS unit uphill and upwind from any leaking hazardous materials.
En Route to the Receiving Facility

Once you are ready to transport your patient to the appropriate medical facility, follow these guidelines (EMT Skills 42-2):

- Prior to leaving the scene, ensure that all hazards have been controlled, pick up and dispose of equipment properly, and turn the scene over to the appropriate agency if required (e.g., law enforcement, fire department, or highway department).
- Make sure your patient is settled and securely strapped to the cot before moving the ambulance. Calmly reassure the patient. If you have not already done so, tell him where he is being taken.
- Before departure, the vehicle driver should quickly check the unit, making sure the outside compartment doors are closed and secure. All equipment and supplies should be appropriately secured within the cab, rear compartment, and cabinets prior to departing for the hospital.
- All personnel riding in the vehicle should be properly seated and secured with safety belts, including those attending to the patient.
- Prior to departing, determine the necessity of using lights and sirens during the transport. Keep in mind the increased risk to the ambulance and its occupants when warning devices are used, and weigh this against the patient’s condition and need for rapid intervention at the receiving facility.
- Begin your reassessment. This includes a reassessment of the patient’s mental status, airway, and breathing, and the recording of vital signs. Conduct a reassessment at least every 15 minutes for a stable patient, every 5 minutes for an unstable patient.
- Notify dispatch that you are en route to the hospital. Follow local protocols regarding transmission of additional patient information.
- Check any patient interventions. Make sure oxygen is delivered at the correct flow rate. Check dressings and splints. Continue to reassure the patient.
- If a patient’s relative or friend accompanies him, follow local guidelines as to where this person should sit. Allow the companion in the patient compartment only if local protocols permit it and if the relative or friend is in emotional control. If the patient is a child, it is often helpful to have a parent with you. Safety restraint in the back of the ambulance when transporting more than one patient or companions of the patient is a major concern. Any patient or companion in the ambulance must be in a safety restraint, including children. It is not an acceptable practice to place the child in the lap of the parent or primary caregiver and strap both to the cot. For children under 40 pounds, a car seat should be used for transport unless the child requires full immobilization to a backboard. Follow your local protocol on transport of children, one or more patients, and companions, paying particular attention to safety restraint.
- Focus on the patient. Reassure him as often as you can. Take advantage of brief stops to monitor blood pressure. Treat each patient like an individual, not a “case.” Gentleness, listening, answering questions honestly, and providing as much explanation as the patient wants will make a world of emotional difference—for him and for you.
- The driver should drive prudently, use only the necessary speed, and obey all regulations to keep the patient as comfortable as possible during the trip.
- If you are the EMT with the patient, you should keep the driver informed of the patient’s condition. Instruct him to slow down or take a different route if the patient is uncomfortable from the speed and bouncing.
- During your reassessment, if the patient’s condition worsens and it becomes urgent to reach the hospital immediately, tell your driver so he can proceed as quickly as possible.
- Notify the receiving medical facility as soon as your patient’s condition permits you to call in a report. Sometimes this may not be possible. In those situations where the patient’s condition demands your full attention, request that your partner notify the hospital. Refer to Chapter 5, “Communication,” to review the information that should be radioed to the receiving facility.
- Continue to reassess your patient’s condition and notify the receiving facility if that condition deteriorates.

At the Receiving Facility

Once you arrive at the receiving facility, you should follow these guidelines:

- Notify dispatch of your arrival at the medical facility.
- You must make an official transfer of care to an appropriate health care provider at the receiving facility. As you make the transfer of care, continue to concentrate your care on the patient. If the receiving facility is crowded, continue to care for your patient until you can officially transfer your patient care responsibility to qualified personnel. Never leave the patient unattended or make a transfer of care to an unqualified individual!
- When you are able, transfer all records and information about the patient to appropriate emergency department personnel.
- To ensure proper continuity of care, a complete oral report should be given to emergency department personnel at the patient’s bedside. You should summarize the information given over the radio:
  - Introduce the patient by name (if known).
  - Repeat the patient’s chief complaint.
  - Provide additional vital signs taken en route.
  - Report any history not given previously.
  - Report any additional treatment you provided.
- If requested, assist emergency department personnel in lifting and moving the patient to a hospital gurney or bed.
Post Run

Follow these guidelines after the run (EMT Skills 42-3):

- Fill out and file any reports as required by local protocol. Do not postpone this activity.
- After each run, check fuel; fill the fuel tank when necessary.
- Complete an inventory of equipment and supplies. Replace what you used during the run, and complete the cleaning and disinfection of nondisposable equipment used.
- Change soiled uniforms.
- Notify soiled dispatch you are in service, available for calls.

Infection Control Procedures

To prevent the spread of infection, follow the procedures outlined next as you ready your unit and yourself for return to service.

Dispose of Sharps. Make sure that needles, blades, and all other disposable sharp items have been placed in clearly labeled, puncture-resistant containers for disposal. (This should have been done immediately after use throughout the call.)

Wash Hands. Use ordinary soap and water to wash your hands at the end of the run and after all cleaning procedures have been completed. (You should also have washed your hands immediately after each contact with a potentially contaminated patient or item.) Use waterless antiseptic hand cleaner if ordinary washing facilities are not available. As soon as you are able, wash your hands thoroughly with soap and water.

Clean, Disinfect, or Sterilize Contaminated Equipment. Use proper procedures to clean (wipe up), disinfect (kill some microbes on), or sterilize (kill all microbes on) contaminated reusable patient care equipment or any items that have or will come in contact with patients. (Review cleaning, disinfecting, and sterilization in Chapter 2, “Workforce Safety and Wellness of the EMT.”)

1. First, clean up visible spills of blood, vomitus, or other body fluids. Put on protective gloves (use gloves that are heavy enough to resist puncture from sharp edges or while scrubbing). Wear appropriate face and eye protection if you anticipate splashing. If there is a great amount of blood in the area, wear impervious shoe coverings. Use disposable towels or use other materials that can be placed in a plastic bag of contaminated laundry after use. After removal of visible material, decontaminate surfaces with a germicide or a 1:100 or 1:10 solution of household bleach and water (see guidelines that follow). Use clean towels with germicide to wipe the area. Let the area air dry. After the area has been decontaminated, place shoe coverings, gloves, and other contaminated items in a sealed plastic bag for disposal.

2. Then disinfect reusable patient care equipment. For disinfecting surfaces and equipment, choose an...
appropriate level of disinfection or sterilization as outlined next. Some judgment about the level of disinfection or sterilization required must be exercised:

- **Use low-level disinfection for routine housekeeping on environmental surfaces such as floors, ambulance seats, and countertops when there is no visible blood and contamination by body fluids or exposure to tuberculosis is not suspected.** Use a 1:100 solution of household bleach and water or an EPA-registered “hospital disinfectant” chemical germicide with no claim on the label for tuberculocidal activity. These disinfectants will destroy some viruses, most bacteria, and some fungi but not *Mycobacterium tuberculosis* or bacterial spores.

- **Use intermediate-level disinfection for surfaces that come into contact with intact skin, such as stethoscopes, blood pressure cuffs, or splints.** Use a 1:10 solution of household bleach and water or an EPA-registered “hospital disinfectant” chemical germicide with a claim on the label that it is tuberculocidal. These disinfectants will destroy *Mycobacterium tuberculosis*, most viruses, vegetative bacteria, and most fungi, but not bacterial spores.

- **Use high-level disinfection for reusable instruments that come into contact with mucous membranes, such as laryngoscopes, blades, and handles.** Use either hot water pasteurization (80°C–100°C for 30 minutes) or immerse in an EPA-registered chemical sterilant for 10–45 minutes (follow the instructions specific to the sterilant). This method will destroy *Mycobacterium tuberculosis*, most viruses, vegetative bacteria, and most fungi, but not bacterial spores.

- **Sterilize equipment that will be used invasively.** Immerse in an EPA-registered chemical sterilant for 6–10 hours (only if a heat sterilization process is not available) or expose to steam (autoclave), gas, or dry heat sterilization. This method will destroy all forms of microbial life. It is used primarily in hospitals rather than in prehospital settings. When possible, disposable items are preferred to avoid the need to disinfect or sterilize and to prevent transmission of disease to other patients.

** Launder Soiled Clothing and Linens.** The risk of disease transmission from soiled clothing or linen is minimal. However, follow these recommendations:

- Handle soiled laundry as little as possible. Always wear protective gloves when doing so.
- Bag soiled items in clearly marked biohazard bags to prevent leaking or contamination of other clothing, persons, or equipment.
- Wash in normal laundry cycles with regular detergent according to the recommendations of the washing machine manufacturer.

- Wear gloves when bagging and placing contaminated clothing into washing machines.
- Launder uniforms according to the label instructions.

**Dispose of Infectious Wastes.** Place all infectious wastes in clearly labeled and sealed biohazard bags for disposal according to your local protocols.

**AIR MEDICAL TRANSPORT**

Many medical personnel involved in helicopter rescue consider a helicopter to be not just transport but an extension of the emergency department (Figures 42-7a and 42-7b). Fixed wing aircraft (airplanes) may be used where transport distances are long.

**When to Request Air Medical Transport**

Follow local protocols or seek on-line medical consultation when you think air medical transport may be needed. Air transport should be considered according to the following general guidelines:

- **Operational guidelines.**
  - The patient needs to be transported to a trauma center or other specialty care facility that is distant from his present location.
• A high-priority patient is entrapped and a pro-
longed extrication is expected.
• Air transport will clearly save time over ground
transport in a time-critical patient.
• The patient is in a remote area that cannot be
reached by ground vehicles.
• Ground ambulance transport is blocked.
• The air transport crew possesses specialty medical
skills, supplies, or equipment not available with
the ground ambulance.
• **Medical guidelines.** The patient is a high priority
for air transport where the patient has a time-critical
illness or injury, such as the following:
  • Acute stroke
  • Head injury with altered mental status and signs of
  herniation
  • Chest or abdominal trauma with signs of respira-
tory distress or shock
  • Serious mechanism of injury with unstable primary
  assessment findings or unstable vital signs
  • Penetrating injury to the body cavity with unstable
  primary assessment findings

Some air medical services may also provide aerial
support to search and rescue operations. Consult with
your regional air medical services to find out if they
provide this service.

### Requesting Air Medical Transport

In many cases, local and state guidelines exist regarding
the use of air medical transport and may even provide spe-
cific criteria for when it can be used. Some city, county, or
regional ordinances may require that the fire department
be present when landing a helicopter. Make sure that you
are familiar with any guidelines or policies in your area.

When calling for a helicopter transport, you should
be prepared to provide the following information:

- Your name
- Department name
- Callback number
- Nature of the incident
- Exact location of the incident (landmarks and cross-
roads or GPS coordinates are helpful)
- Radio frequency you use, so that you can communi-
cate with the helicopter or plane
- Exact location of the landing zone and surrounding
hazards

### Additional Considerations

**for Air Medical Transport**

When considering the use of air medical transporta-
tion, you should also consider some of the potential
disadvantages:

- **Weather/environmental limitations.** Inclement
weather, such as snow, rain, fog, or heavy winds, may
prevent helicopters from being able to fly. Establish
communications with the air medical service's dis-
patch to determine flight capability during bad weather.

- **Altitude limitations.** Patients with certain medical
conditions and injuries, such as lung trauma or cer-
tain diving injuries, may not be good candidates for
the increased altitude associated with air transport.

- **Airspeed limitations.** In windy conditions, air
travel may actually take longer than travel by ground.
Consult with the air medical service's dispatch center
to help determine feasibility of air transport.

- **Aircraft cabin size.** The space inside a heli-
  copter's cabin is often quite small, depending on the
  type of aircraft. Obese patients, or those with exten-
sive deformities or large impaled objects, may not
be suitable for air transport because of these space
restrictions.

- **Terrain.** Irregular terrain may make it difficult to lo-
cate a safe landing area for a helicopter. When this
occurs, ground transport or rendezvous with the heli-
copter at a predetermined approved helipad or land-
ing zone may be considered.

- **Cost.** Aircraft are quite expensive to operate, and re-
  quests for their use should only be made when the
  benefit to the patient is likely to outweigh the risk and
  additional cost. Under no circumstances, how-
  ever, should access to air medical transport be denied
  based on a perceived ability to pay.

- **Patient preparation.** Because of the small cabin
  size of many helicopters, it is necessary to ensure
that splinting, proper immobilization, and complete
assessments are performed prior to loading into the
aircraft. The EMT can help to expedite patient trans-
port by ensuring that these procedures are complete
prior to transfer of care to the air medical crew.

- **Noise-limited assessment.** Noise within the aircraft
will limit your ability to conduct a thorough assess-
ment of the patient, especially when hearing is neces-
sary as in monitoring breath sounds or auscultating
blood pressure.

### Setting Up a Landing Zone

In setting up a landing zone for a helicopter, keep these
guidelines in mind:

- Make sure that the landing area is clear of obstruc-
tions. This area should ideally be a flat square with
  60-foot sides by day for a small helicopter, but larger—
  about 100-foot sides—by night. If the helicopter is
  medium or large in size, it will need about double
  that area. Pick up loose debris that might blow up
  into the rotor system. Choose a landing site at least
  150 feet away from collision vehicles, if possible, so
  that noise and rotor wash will not be a problem for
  rescuers. Contact your local service for landing zone
requirements and safety specifications.
If the landing site is a divided highway, stop the traffic going in both directions, even though the aircraft will land on only one side of the highway.

Consider the wind direction. Helicopters take off and land into the wind by preference, rather than making vertical descents and ascents. Establish radio communications with the incoming flight crew and warn them of any power lines, poles, antennas, trees, or other obstructions.

Mark each corner of the landing area with a highly visible device: a flag or surveyor's tapes by day and a flashing or rotating light at night. Use flares by day or night but only if there is no danger of fire. A beam of light should not be directed upward.

Put a fifth warning device on the upwind side to designate the wind direction.

If conditions are dusty or dry enough to create a fire hazard, have the area wet down, if possible.

Keep the patient and crew clear of the air downwash area. Spectators should be at least 200 feet away. EMT personnel should be at least 100 feet away during landing.

Assign one person to guide the pilot in. He should wear eye and ear protection and should stand near the wind direction marker with his back to the wind, facing the touchdown area, arms raised overhead to indicate the landing direction (Figure 42-8).

Give primary care to the patient and follow exactly the instructions of the pilot or crew members relating to the craft's operation. Never try to open a door or approach the tail of the aircraft without instructions and approval from the pilot and crew.

Be extremely cautious about the rotor blades. Remember that the tips can dip as low as 4 feet above the ground. Always crouch when approaching or leaving the helicopter (Figure 42-9a), and approach or leave only at the pilot's direction.

Never approach a helicopter until the pilot indicates it is safe. Never approach from behind the pilot. The pilot cannot see behind the craft, the tail rotor is spinning very quickly, and the pilot sometimes needs to move the tail boom without warning. If you have to go from one side to another, always cross in front of the craft, never behind it or underneath it.

Secure all loose items so that nothing will blow into the rotor blades when you are approaching or leaving a helicopter.

No one should smoke within 50 feet of the aircraft.

If the helicopter has to land on an incline, always approach from the downhill side, never from the uphill side (Figure 42-9b).

Never point spotlights up at a helicopter that is on its final approach at night.

In certain cases, a rendezvous with the helicopter may be arranged at a predesignated helipad. The advantage of helipads, such as those found at most hospitals, is that the site is already correctly designed for optimal landing of the aircraft. Terrain, size, markings, wind direction, and lighting are typically not concerns for the EMT on the ground in these cases.

SECURITY AND SAFETY

Operational Security Measures

The National Association of Emergency Medical Technicians (NAEMT) has established recommended guidelines to ensure better operational safety and security measures to avoid the possible use of emergency service vehicles in domestic terrorist attacks and to reduce the risk of an EMS vehicle being stolen or used in a manner that is not intended. The following are the recommended security measures:

Personnel

- Security briefings should be conducted at the beginning of each shift regarding any possible threats to the EMS crews or service. These briefings may be conducted as meetings, information sheets, postings, or supervisor briefings at the beginning of each shift.
- EMS crews should have the opportunity to be well informed and take part in the development of operational security measures and situation awareness. A greater degree of understanding by the field personnel is necessary.

Vehicle

- All EMS vehicles must be tracked at all times. That includes vehicles that are in service, out of service being repaired, and off service. It also includes reserve units and those units that are no longer in service and will be salvaged.
- EMS vehicles should never be left running or unattended with the keys in the ignition or in the vehicle.

Tracking of Vehicle Access

- Authorized persons must secure all off-service vehicles at stations or other locations to eliminate access and use by unauthorized persons. Random and routine vehicle audits should be conducted.
- A comprehensive key log must be kept to account for all keys that may allow for entry into restricted stations and areas in which a person may gain access to an EMS vehicle. If keys are not accounted for, measures should be taken to correct the security breach.
- Ensure that security measures are strongly enforced when the EMS vehicle is off the EMS premises for repairs or other work conducted by repair or installation facilities. These should include securing the vehicle indoors overnight when the facility is not open, not leaving the keys in the vehicle or in a place where there is easy access, not allowing the vehicle to leave the premises for any unauthorized travel when being repaired, and reporting any unusual interest by an individual related to an EMS vehicle.
FIGURE 42-8 Guiding the helicopter pilot in.
Carbon Monoxide in Ambulances

Another emergency situation that you may encounter while driving an older model ambulance is the buildup of carbon monoxide gas. Carbon monoxide (CO) is colorless, odorless, tasteless, and deadly. If an ambulance is not properly cared for, a CO level that is harmful to injured or ill patients and even to emergency personnel may build up. Any amount of CO over 10 parts per million above the ambient CO level in the air may be dangerous. Excessive amounts of CO may come from:

- The vehicle’s own exhaust gases
- Supplemental equipment that is powered by gasoline or liquid petroleum gas
- The exhaust gases of vehicles parked next to or traveling by the ambulance
- Greater outside air pressure, which forces the CO into the ambulance

Be aware of the symptoms of carbon monoxide poisoning. Low levels of carbon monoxide may cause yawning, dizziness, dimmed vision, headache, irregular heart rhythm, nausea, or vomiting. Extended exposure or high concentrations can lead to seizures, coma, and death. Review the information on carbon monoxide poisoning in Chapter 22, “Toxicologic Emergencies.”

If any of the indications of carbon monoxide occur, remove the patient from the ambulance and administer oxygen by nonrebreather mask. Resuscitate the patient, if necessary.

Prevent CO poisoning by:

- Having frequent engine tune-ups
- Having an adequate exhaust system that discharges beyond the side of the vehicle
- Keeping rear windows shut
- Making sure that doors shut tightly with proper gaskets and adjustments
- Covering any opening to the outside
- Not using ventilation exhaust fans or static roof vents
- Keeping the heater or air-conditioner on (They create continuous positive interior pressure.)
- Not using supplemental equipment that is powered by gasoline or liquid petroleum gas inside the ambulance

A bright light or water spray under pressure will help you identify possible spots where CO can enter. CO testers for the inside of ambulances are available. There are also color-change CO monitors that stick to the sun visor or dash and audible CO alarms.
**EMT SKILLS 42-1**

**Elements of the Daily Vehicle Inspection**

- **42-1A** Check tires for inflation, wear, or danger spots.
- **42-1B** Make sure all lights are functional.
- **42-1C** Check all belts and hoses.
- **42-1D** Check all fluid levels and keep them up.

**EMT SKILLS 42-2**

**En Route to the Receiving Facility**

- **42-2A** Ensure that the patient is secure.
- **42-2B** Change to on-board oxygen.
42-2C  Perform reassessment.

42-2D  Document your history and other assessment findings.

42-2E  Communicate with medical direction and the receiving medical facility.

42-2F  Make the patient comfortable and reassure him.

42-2G  Notify dispatch when you are en route and when you have arrived at the receiving medical facility.
EMT SKILLS

42-3

Post Run

■ 42-3A  Put all equipment in its proper place.

■ 42-3C  Complete an inventory of equipment and supplies. Replace necessary equipment so that the ambulance is fully stocked.

■ 42-3B  Make up the wheeled stretcher and lock it in place.

■ 42-3D  Clean and disinfect the patient compartment.

SUMMARY

A large number of crashes each year involve ambulances in which EMTs, patients, and others are severely injured or killed. Ambulance operation is a serious matter. When operating an ambulance, obey all laws, regulations, and ordinances as well as your standard operating procedures, policies, and local protocols. Always drive defensively and maintain complete control of the ambulance. Consider and anticipate changes in road conditions, weather conditions, and movements by other vehicles in traffic. The warning devices are to notify traffic of your approach and you must use them only for that purpose. Although you may have all of the warning devices in use, another driver may not recognize your approach, especially from behind. Be prepared for sudden and erratic movements by startled, distracted, or impaired drivers.

Ambulance operation usually follows a standard sequence of phases: prerun preparation, dispatch, en route to
the scene, at the scene, en route to the medical facility, arrival at the medical facility, en route to the station or response area, and post run. Always exercise the highest degree of competency and professionalism in each phase.

Air medical transport is sometimes needed to respond to and transport critically injured or ill patients to the medical facility. Follow your protocols for requesting air medical transport and what information to provide once they have been notified. On-scene emergency personnel must set up a landing zone that allows the helicopter to land and take off safely.

Emergency personnel have been severely injured and even killed while working in or near moving traffic. Exercise safety precautions to limit your exposure to traffic and make yourself very visible. Always remain alert and attentive to oncoming traffic. Use emergency vehicles to block and protect yourself and others who are at the scene.

Case Study Follow-up

**En Route to the Scene**
You’ve been dispatched to a 33-year-old female patient with labor pains at a highway rest area. You remember that during the patient compartment check you made sure the OB kit was stocked. As your partner drives, you look at your notepad and reconfirm the location of the call. You request a further update from dispatch on the nature of the call. “The mother believes she will have the baby before you arrive!” Emergency Medical Responders at the location give you a report on the radio: “It’s a girl!”

**At the Scene**
You notify dispatch when you reach the rest area. While looking through your vehicle’s front window, you begin the scene size-up. Your partner sets the parking brake and then puts the transmission in park. The vehicle is parked so you won’t have to back into traffic when leaving. The scene is safe. You put on your personal protective gear, turn on the patient compartment heat, and grab the OB kit. You take a deep breath and try to relax.

The Emergency Medical Responders tell you the patient’s name is Karen Austin and direct you to the sleeper cab of a semi-truck. You in fact have two patients, mother and child. You begin your primary assessment of the mother and baby. After providing initial OB care and treatment, you prepare them for transport. Both are covered with warm blankets and loaded into your warmed ambulance. The truck driver tells you he’s Tom Austin, the father, and wants to ride along. You say okay, but politely advise him that your agency requires that he ride in the front seat of the ambulance. You ask an Emergency Medical Responder for assistance en route to the receiving facility. She gladly agrees and jumps in the back.

**En Route to the Receiving Facility**
In the patient compartment, you complete your secondary assessment. Prior to leaving the scene, your partner makes sure all equipment and vehicle compartments are secure. He asks for assistance from a police officer in stopping traffic. He then notifies dispatch he is en route to the hospital with two patients. You calmly inform the mother where she will be transported. She is settled, and the baby is resting comfortably.

You’re still 30 minutes away from the nearest medical facility. You begin your reassessment. You reassess the mother’s and child’s mental status, airway, breathing, and circulation, and all of your medical interventions. You then tell your partner and the father that the mother and baby are doing fine. Your partner decides to continue driving at the posted speed limit. You radio a report on the condition of your two patients to the receiving facility.

**At the Receiving Facility**
As you arrive at the facility, your partner notifies dispatch. You are greeted at the door by emergency department staff. Mother and baby are immediately wheeled into a patient room. You continue to make sure they are kept warm. Next, you provide your oral report to both the emergency physician and the nurse.

Meanwhile, your partner has already started to clean and prepare the vehicle for your next run. After transferring the care of your patients to the hospital staff, you ask your partner if he wants help in resupplying the ambulance. He tells you to go ahead and write the prehospital care report while he gets clean linens and disinfects the cot.

You finish your report and leave a copy with the patient’s records. Your partner advises you the unit has been cleaned and resupplied. You ask emergency department personnel if they need any further information. They say thanks but everything seems all right. “Good job,” they tell you.

**En Route to the Station**
Your partner has already disposed of contaminated linen and supplies. The vehicle and reusable supplies have been disinfected according to your agency’s protocol. Both of you remembered to wash your hands. You advise dispatch you are available for another call and are returning to the station. You and your partner buckle your seat belts and decide to refuel.

**Post Run**
Once at the station, you recheck your supplies and finish cleaning the patient compartment floor. Also, you decide to wash the vehicle’s exterior. Your station phone rings. It’s Tom Austin calling from the hospital. The baby’s name is Sandra. You contact dispatch and let them know.
IN REVIEW

1. List some of the privileges that may be granted to an ambulance operator. List the qualifications necessary for using these privileges.
2. Explain when an ambulance operator should use a police escort.
3. List the major causes of intersection collisions.
4. Explain the problems use of a siren can pose for ambulance safety.
5. List the phases of an ambulance run.
6. List information an ambulance crew should receive from dispatch before beginning a run.
7. Describe the procedures you should follow in turning a patient over to a receiving facility.
8. Explain when cleaning and restocking of an ambulance after a run should begin, and why.
9. List the infection control procedures that should be followed.
10. Explain how you should mark a landing area for air ambulance use.

CRITICAL THINKING

You are dispatched to respond to a motor vehicle crash on a highway. It is raining lightly and the roadways are very slippery. You are informed by dispatch that the crash involves two vehicles with four patients. The police are on the scene and indicate that the patients appear to be critically injured. You know this highway to be very busy, especially at this time of day.

1. What emergency vehicle driving practices would you use to ensure a safe response to the scene?
2. What other resources may you request to respond to the scene?
3. What specific steps would you take to improve your safety while on the scene of the crash?
4. What personal protective equipment should you wear while on scene?
5. If a helicopter is requested, how would you prepare a landing zone?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • EMS Operations (Content Area: Vehicle Extrication)

**COMPETENCY** • Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

**OBJECTIVES** • After reading this chapter, you should be able to:

43-1. Define key terms introduced in this chapter.
43-2. Explain elements of dispatch information, including location and whether it is a motor vehicle collision or other type of emergency, that would indicate possible obstacles to patient access, extrication, and care, and discuss how you can plan for such situations.
43-3. Use scene size-up findings to anticipate and prepare for the following:
   a. Potential problems in accessing patients
   b. Need for additional resources
   c. Appropriate personal protective equipment
   d. Appropriate measures to improve scene safety
   e. Location of all patients
   f. Vehicle safety in a collision situation
43-4. Explain actions that may be required to gain residential access.
43-5. Explain actions that may be required to gain motor vehicle access, including the concepts of simple and complex access.
43-6. Describe the role of the EMT and basic considerations for caring for a patient entrapped in a vehicle.
43-7. Describe equipment and methods for stabilizing an upright vehicle, a vehicle on its side, and a vehicle on its roof.
43-8. Describe various methods of accessing, disentangling, and extricating a patient entrapped in a vehicle.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

| complex access p. 1185 | simple access p. 1185 |

---

**Case Study**

**The Dispatch**
EMS Unit 204—respond to Solzman Road just north of Pin Oak Court—vehicle crash with reported multiple injuries and entrapment. Time out is 2337 hours.

**Upon Arrival**
You find a small red vehicle sitting nose to nose with a large dump truck. The front of the automobile has collapsed and is underneath the front axle of the truck. The front bumper of the truck is even with the windshield of the automobile.

You can see two motionless young people in the front seat of the car with a considerable amount of blood coming from multiple facial lacerations. The dash is crushed down onto the patients, pinning them in the vehicle.

**How would you proceed?**
During this chapter, you will learn about your role as an EMT in patient rescue situations. Later, we will return to the case study and put in context some of the information you learned.
INTRODUCTION

By far the most common rescue situations encountered by the EMT are motor vehicle crashes. Patient rescue begins with the scene size-up. It includes stabilization of the scene as well as stabilization of the vehicle, gaining access, and safely extricating, packaging, and moving the patient. During the entire process, it is necessary to ensure the safety of the patient, bystanders, your partner, yourself, and any other emergency personnel on the scene.

Access and extrication are also issues at scenes other than vehicle crashes. Usually, you will find your patients in safe, easily accessible locations where gaining access requires no more than a knock on a door. However, there will be occasions when advanced rescue techniques must be used to get to and help a patient—for example, on a remote mountainside, from a raging river, or from entrapment under machinery or a collapsed building.

Obviously you cannot receive advanced rescue training from this or any other EMT text. You can, however, become familiar with the situations in which patients are found and the roles you can play in rescue. The primary role of the EMT in a rescue situation is gaining access to the patient as quickly as can be safely accomplished to perform patient assessment and emergency care, even as the rescue operation proceeds. In some situations, it may be necessary that you perform simple extrication to remove the patient from the vehicle. More complex extrication situations require advanced training and tools. Your two major priorities in a rescue situation are (1) to keep yourself and your partner safe and (2) to prevent further harm to the patient.

PLANNING AHEAD

Dispatch

As soon as you receive the call from dispatch, you must evaluate whether there are obstacles to patient access and extrication—in other words, whether the situation requires special rescue procedures. Begin with these questions:

- Is the patient ill or injured?
- What is the mechanism of injury?
- What is the location of the incident?
- What time of day is it?
- What is the weather?
- Is there a report of entrapment?
- Is there a report of a leak or a spill?

Most illnesses occur at home and offer little challenge to access and extrication other than an occasional locked door or protective pet dog. However, an incident involving trauma may offer considerable challenge. A trauma patient may be found anywhere under any circumstances. Based on the dispatch information, the EMT can begin to plan for access and extrication problems.

Location

Consider the location of the incident. For example, on a call to a fall in a parking lot at the local mall you may encounter heavy traffic. A cardiac emergency may be easy to handle at a residence, but on the 16th green of the local golf course or in the stands at the high school football game, it can be difficult. Access to a home may be easier than access to an industrial site.

Know your territory. Look around your community and begin to identify locations and occupations that may present access difficulties for EMS personnel. For example:

- Utility employees work above and below ground.
- Construction workers work everywhere from ditches to rooftops and around heavy equipment.
- Painters work off ladders and scaffolding, which may be placed on soft, unstable ground.
- Antennas and water towers need periodic maintenance.
- Industrial sites offer all these potential risks and problems and more.
- Some intersections are well known for serious collisions.

Excluding motor vehicle collisions, most injuries are the result of gravity. People either fall or something falls on them. Consider all the things that can fall on people—for example, a car on top of the weekend mechanic, a tree after a sudden storm, construction material at a new building site, or a few tons of dirt from a cave-in of a ditch or excavation.

People can crawl, climb, and walk to many locations that your ambulance and wheeled stretchers cannot traverse. Be prepared. Have strategies for gaining access in mind, and know the types of specialized rescue teams available through your system.

Motor Vehicle Collisions

Motor vehicle collisions present the most frequent rescue problems. Consider factors such as location and time of day to begin to mentally weigh the odds of patient entrapment and difficult access.

The numbers of accidents are greater during high traffic times, but with more traffic come slower speeds and less chance of entrapment and serious injuries. As traffic thins, speeds increase and so do the number of entrapments, serious injuries, and fatalities. A collision on a freeway holds a greater chance of entrapment than a collision in a parking lot.

The majority of examples discussed in this chapter concern vehicle collisions, because they are the rescue situation you will most commonly encounter as an EMT.

SIZING UP THE SCENE

Expect the unexpected. Do not rely solely on the information received from dispatch. It can be sketchy or inaccurate. Know your territory, and stay alert for potential hazards.
For example, when responding in industrial areas or to motor vehicle collisions involving common carriers and other commercial vehicles, stay alert for potential hazardous materials spills and releases. They present special challenges. Be sure your ambulance is equipped with binoculars, so you can assess the scene from a safe distance and position.

Scene size-up is a continual process. Even after you reach your patient, stay alert for changes in your surroundings. Wrecked vehicles can catch fire, an unsteady power line may fall, or the overturned container may begin to leak. Every scene is dynamic and must be approached cautiously and continually reviewed until it is stabilized.

**Perform a 360-Degree Assessment**

Once you are on the scene, perform a 360-degree assessment. You should perform this assessment prior to exiting the ambulance, if at all possible. However, to effectively perform the 360-degree assessment you must look at the front of the vehicle, at both sides, and at the rear. Also, inspect above and below the vehicle. The entire time, you will assess for potential hazards to yourself, your partner, other emergency personnel, the patient, and bystanders. Potential hazards include downed electrical wires; leaking fuels or fluids; smoke or fire coming from the vehicle or near or around the vehicle; and broken glass, jagged metal, and other sharp objects. While performing the 360-degree assessment, also attempt to identify trapped or ejected patients and potential mechanisms of injury.

**Evaluate the Need for Additional Resources**

Based on the initial information provided by the caller, the communications officer may have already dispatched additional resources to the scene, such as police for traffic control and crash investigation or the fire department or rescue services for extrication. Once on the scene, you may identify the need for other resources, such as the electric company for downed wires or the hazardous materials team for crashes involving hazardous cargo or spills. Consider the need for the following additional resources when responding to and assessing the scene:

- Extrication team or equipment
- Fire suppression
- Law enforcement
- Hazardous material team
- Utility company (electric, natural gas)
- Air medical evacuation
- Swift water rescue if vehicle is trapped in fast moving water

**Personal Protective Equipment**

The scene of a typical motor vehicle collision or other rescue situation is inherently hazardous. Materials such as shattered glass, sharp metal, flammable liquids, battery acid, and blood are commonplace. **Proper protective clothing and equipment must be used at every incident when such hazards are or may be present.**

The safety of any rescuer must never be jeopardized. Rescuers must always wear the level of protection needed for their particular role in the rescue process. The minimum level of protection for the EMT includes eye protection, disposable gloves, and any additional protection necessary to prevent direct contact with any blood or body fluid.

A major hazard to EMTs at vehicle crashes is being struck by a passing vehicle. Any time you are working on or near a roadway, it is necessary to wear a high-visibility safety vest to lessen your chances of becoming a victim yourself.

Your everyday work uniforms do not provide much protection from the glass and sharp objects usually present at collisions and other rescue scenes. Protective coveralls, for example, may protect you from a patient’s body fluids, but they may not protect you from hidden or flying debris. If you need to enter a wrecked vehicle to provide patient care, wear the appropriate protective clothing.

Full turnout gear, including coat, brightly colored and highly visible vest, bunker pants, and steel-toed boots, is required for personnel involved in the patient extrication process. Head protection, such as a standard fire helmet, will protect your head from impact. The ear flaps and a wide brim will help protect you from shattering glass and falling debris. In addition to goggles or safety glasses, the helmet’s face shield offers protection for the face and eyes. Heavy leather gloves worn over disposable gloves will help protect your hands from both sharp objects and body fluids.

Know your local protocols and standard operating policies, which may dictate additional precautions.

**Scene Safety**

As stated earlier, your safety is always the highest priority in any emergency. Focus on risk analysis, not risk taking. Never commit yourself to a situation that is not completely secure. Although it may be difficult to remember at times, the biggest difference between you and the average person is your training. Do not compound the emergency or risk other rescuers’ lives by becoming part of the problem.

If you are the first to arrive at the scene of an emergency, you are responsible for scene size-up and scene stabilization until police, fire, and other rescue personnel arrive. The list of hazards that you may encounter at motor vehicle collisions and other emergencies is much too lengthy to address in this chapter. However, common hazards include electrical lines and traffic. Unique hazards when you are working inside or around the vehicle include alternative-fueled vehicles, undeployed safety devices, energy-absorbing bumpers, and hazardous materials. Refer to Chapter 42,
“Ambulance Operations and Air Medical Response,” for safety methods to protect yourself when you are on scene in or near moving traffic. Also refer to Chapter 44, “Hazardous Materials,” for risks to and responsibilities of the EMT when hazardous materials are involved.

**Electrical Lines**

Hazards commonly found at collision scenes are downed electrical lines and damaged poles holding electrical lines and equipment. *Always assume a downed power line is electrically alive.* If you see that electrical lines are down near or in contact with the vehicle, the area must be secured to avoid accidental contact.

Often, the electrical distribution equipment supplying the power to the lines will have automatic resets. This is a method the power companies use to restore power when something such as a fallen tree branch causes a temporary short. When the power is automatically restored to the downed line, it can cause the line to whip and arc. Therefore, if a line is down and broken 75 feet from the pole, the area to be secured should be greater than 75 feet in all directions from the pole. If the power lines are in contact with the vehicle, *stay away.* Request special assistance from your local electric service company.

If patients are still in the vehicle, shout or communicate with them over your unit’s public address (PA) system. Advise them that the electric company is en route. Tell them to stay inside the vehicle, which is safer than attempting to get out. If patients were to climb out of the automobile, the electricity could pass from the vehicle and through them to the ground even before a foot touches the ground. Vehicle tires provide some insulation between the vehicle and the ground, but discourage the patients from touching any metal within the vehicle.

If the situation is immediately threatening to life, or if the electric company is unable to respond, rescue personnel specially trained in handling electrical emergencies may move the downed line using special equipment and techniques designed for that purpose. In the case of fire, the patients may have to be told to jump clear of the vehicle with their feet together, avoiding contact with the car and the ground at the same time. The proper way to move away from downed power lines is to shuffle away with small steps, keeping the feet together and on the ground at all times. (When separated feet touch the ground, a circuit is created—up one leg, through the body, and down the other leg—so feet must be kept together.)

**Control Traffic Flow**

Traffic must be controlled for scene safety. In most parts of the country, directing traffic is primarily the responsibility of the police. However, if this job falls to rescue personnel in your area, or if you must control traffic before the police arrive, special prior training in traffic direction and control is necessary. If the police are not on the scene, designate a person specifically to be responsible for traffic control to ensure that traffic is constantly being managed during the extrication.

In general, the safest method for traffic control at a serious vehicle collision is to stop all traffic and reroute it to different roads. This is not only for the safety of patients and bystanders but also for the safety of rescuers at the scene. If the regular flow of traffic must be channeled around the scene, it should be routed at least 50 feet from the wrecked cars (Figures 43-1a to 43-1d).

Even specially trained personnel must take extreme care when directing traffic away from an accident scene. Use fire apparatus and other emergency response vehicles as blockers to provide a safety zone. Position the ambulance so that the patient loading doors are angled away from the moving traffic. Always face the oncoming traffic and be attentive to erratic vehicle movement by drivers. Additional rescue personnel and warning devices such as flares, chemical lights, or reflective cones are needed. Watch for fluids spilled on the roadway, and do not place flares where they might contact or become contacted by a fluid spill. All those who are working in or near the traffic should wear adequate reflective clothing or high-visibility vests so that they can be clearly seen. Visual signals must be clear, so that approaching drivers can quickly understand exactly what they are being asked to do. *Flares or cones should begin far enough from the scene so that a car can safely stop before it hits the scene, even if the driver did not notice the flares or cones from a distance.*

Another consideration in vehicle positioning is substances leaking from a vehicle involved in a crash. Park the ambulance upwind to avoid being affected or overcome by potentially hazardous fumes. Also park the ambulance uphill if a potentially hazardous liquid is leaking from a vehicle so that the liquid will flow away from the ambulance.

**Alternative-Fueled Vehicle Systems**

Alternative-fueled vehicle systems are gaining much popularity as gasoline prices rise and people become more environmentally conscientious. Hybrid vehicles use a combination of gasoline and electricity to power the vehicle. High-voltage batteries and cables are used as an alternative fuel source. This poses a risk of electric shock to the rescuer if an electric discharge occurs or if the high-voltage cables are breached.

Vehicles may use other alternative fuels, such as natural gas or hydrogen. These fuels are stored in high-pressure containers that could pose a significant risk if a fire were involved or if the container were to be accidentally punctured during the extrication process.

**Undeployed Air Bags**

Air bag systems have evolved over the years from a single driver-side air bag to multiple air bags placed throughout the vehicle. Undeployed air bags pose a
Table showing stopping distances for different speeds:

<table>
<thead>
<tr>
<th>Posted speed (mph)</th>
<th>Stopping distance for that speed</th>
<th>Posted speed (in feet)</th>
<th>Distance of the farthest warning device</th>

- **FIGURE 43-1a** Flares are positioned according to a formula that includes the stopping distance for the posted speed plus a margin of safety.

- **FIGURE 43-1b** Flares positioned on a straight road. Approaching vehicles are moved into the correct lane before they reach the edge of the danger zone.

- **FIGURE 43-1c** Flares positioned ahead of a curved section of road. The start of the curve is considered to be the edge of the danger zone.

- **FIGURE 43-1d** Flares positioned on a hill. The flares slow approaching vehicles and make them turn into the correct lane before they reach the top of the hill.
safety risk to rescuers who enter the vehicle to assess, treat, or extricate the patient. Air bags are deployed with significant force by a controlled explosion from a canister device. If a rescuer is positioned in front of an undeployed air bag that suddenly deploys, the force of the air bag striking the rescuer could severely or mortally injure him. It is necessary to deactivate air bags before any type of extrication to avoid accidental deployment. Deactivation is usually done by simply disconnecting the car’s battery cables.

**Energy-Absorbing Bumpers**

Bumpers are designed to absorb low-velocity impacts to the front and rear of the vehicle. These bumpers, commonly referred to as “five-mile-per-hour bumpers,” use a piston-type system to absorb the impact of the collision. If the piston is pushed inward it is considered to be “loaded.” If a rescuer happens to be standing in front of the bumper when it springs back outward, it may cause serious injury.

**Locate All Patients**

Most incidents involve a single patient who is easily accessible. Always locate that patient before attempting to gain access. By doing so you will prevent further injury. For example, you can make sure the patient is protected with a blanket before a rescue team breaks a car windshield for emergency extrication. You may also be able to check if an injured or ill patient is behind a bedroom door before the rescue team forces it open.

Some incidents involve more than one patient, and they are not always easy to identify or find. In explosions, building collapses, trench or confined-space rescues, and hazardous materials incidents it is often difficult to locate patients. That is also true in high-impact, rollover, and off-road vehicle collisions. Look for patients both at the site of the emergency and in the immediate vicinity. Unrestrained automobile occupants, for instance, can be thrown great distances and hidden by uneven terrain, darkness, vegetation, and debris.

Look for clues to “missing” patients. Get information from witnesses and patients about others who may be hurt at the scene. An empty child’s car seat or a small sweater and coat in the back seat may be an indication that a child was involved in the incident. If in doubt, have the police contact relatives in an attempt to learn who might have been in the vehicle. Also ask bystanders if a patient walked away from the scene or if a passerby took a patient away. Before leaving the scene, a thorough search of the area for all victims must be conducted by emergency personnel. You may arrive on the scene to find no obvious crash or emergency at all. Take the time to look for signs that a vehicle might have left the road—for example, skid marks or damaged guard rails. (In one real-life incident, a car went off a freeway and under a chain-link fence without damaging or even displacing the fence!)

It can be frustrating to wait in a safe area while specialized rescue teams locate, extricate, and deliver patients to you. Realize that in difficult and complex rescue situations, a team effort is required to successfully perform a rescue. Follow directions from the scene commander, and provide emergency medical care to patients as necessary and as possible.

**Vehicle Safety**

If a fire engine company is not yet on the scene, remove the fire extinguisher from your vehicle and place it near the collision in case of fire.

After all hazards are addressed and the scene is secure, the vehicles involved must be properly stabilized for the safety of everyone at the scene. A vehicle is considered stable when it is in a secured position and can no longer move, rock, or bounce. Remember, even vehicles found on all four wheels and on a level surface need to be stabilized to minimize movement. This can be done by placing stabilizing chocks under the vehicle and deflating the tires.

If necessary, there are steps you can take to stabilize a vehicle without using special equipment. For example, if the vehicle is upright, resting on all four wheels, and safe to approach, you can shut off the engine. Then set the parking brake, and shift the automatic transmission to “park” or the manual transmission to any gear. Also employ cribbing and chocking for stabilization by placing firm objects such as a spare tire, pieces of wood, or logs in front of and behind a wheel to minimize vehicle movement. These steps usually will prevent a vehicle from rolling until rescue crews can properly and completely stabilize it.

Although rescue personnel may determine it to be necessary to disconnect the vehicle’s battery, the majority of electric current and associated hazards can be eliminated by simply turning the ignition off. Before disconnecting power, attempts should be made to lower the power windows, unlock power door locks, and move the power seat to a position that provides the greatest patient access.

If it is necessary to disconnect the car battery, the engine compartment must be accessed. Cut or use a wrench to remove the negative battery cable first. Remove the positive cable last.

*Note: If the positive cable is removed first, a spark may occur that could ignite acid fumes from the battery or gasoline spilled from the accident.*

If you determine that the vehicle is in an unstable and unsafe position and you cannot stabilize it with available equipment, do not enter it and do not put any weight in or on it. Wait for additional rescue personnel to properly stabilize the vehicle. (More information on vehicle stabilization is provided later in the chapter.)
GAINING ACCESS

There are two basic ways a rescuer can gain access to a patient. Simple access is access in which tools are not required. Complex access requires the use of tools and specialized equipment.

Fortunately, most incidents do not present access problems. However, when confronted with one, you must quickly evaluate the situation and decide if a simple or complex access procedure is necessary. If complex access is required, it is best to call for rescuers who have had specialized training. (Specialized training programs available for complex access include trench, high angle, and basic vehicle rescue.)

Residential Access

To gain access to a residence when the door is locked, first walk around the house to check for open windows or doors. Attempt to locate the patient by shouting through doors and windows and looking in windows. If you are able to converse with the patient, ask if a neighbor has a key. If you cannot speak to the patient, ask neighbors if they have a key or if they know someone who does.

You can evaluate the need for a rapid, forced entry based on dispatch information, what you observe at the scene, and your conversation with the patient. If you need to forcefully enter the scene (break into the house or apartment), have the police and fire department dispatched. If possible, wait for their arrival.

The easiest and least costly method of forceful entry usually is breaking a window. Breaking a pane of glass in or next to a door may permit you to reach in and unlock the door. Kicking the door in is not recommended, since you may be injured and it can cause costly structural damage. It is also more difficult to secure the residence afterward.

After police and fire personnel are on the scene, proceed with a forceful entry as follows:

1. Check all windows and doors for one that is unlocked or open. At the same time, look and shout through each window to try to locate the patient and check for hazards.
2. If a window is open but blocked by a screen, cut through the screen.
3. If you must break a window, choose a room in which there are no patients and a window through which you can see what is on the other side. Locate the smallest and least expensive window that will still allow you access.
4. If the patient is awake and responsive, inform him of what you are going to do.
5. Wear eye protection, heavy work gloves, and a coat.
6. Stand alongside the window to be broken (Figure 43-2).

7. Using an object like a flashlight or a tire iron, grasp one end firmly and strike the top corner of the pane nearest you. Do not reach above your head.
8. Clear the broken pieces of glass out of the frame before reaching in to unlock the window or door.

People are becoming more security conscious. In many urban areas and areas of high crime, for example, people often cover windows and doors with security bars. As a result, it is difficult to force entry into many homes and apartments. Specialized rescue techniques and tools are constantly being developed and refined. It is best to call on rescue companies within the fire department or other emergency services to gain access in these situations.

Motor Vehicle Access

By far, the most common access problems encountered by the EMT involve motor vehicle collisions. Throughout the process of gaining access, your main function is patient care. Once the scene is secure and you have decided that it is safe to approach the vehicle, walk around it once to identify mechanisms of injury, and approach facing the patient. (If you approach from the side, the patient may attempt to turn his head toward you, possibly aggravating a spinal injury.) If the patient is responsive, look directly into his eyes while you tell him not to move his head or neck. Tell the patient that focusing on any object directly in front of him will help lessen the chance of neck movement.

Simple Access

The door is always the simple access of choice because it is the largest uncomplicated opening into the passenger compartment of a car. Always start by testing the door handle to see if it will open. If the doors are
Locked, reach in any open window to unlock one of them. If all windows are intact and rolled up, say to one of the patients: “Without moving your head or neck, try to unlock a door or lower the window.” Be sure to state the instruction not to move the head or neck first. If you wait until the end of your request, he may move and injure himself further in his eagerness to help.

**Complex Access**

If none of these methods of gaining access work, the quickest means of gaining access is by breaking a window. The side windows in a modern automobile are made of tempered safety glass that will break into rounded pieces rather than sharp shards. (The windshield and back window are made of a different kind of safety glass with a layer of plastic between layers of glass.) When breaking windows or using rescue tools near patients or rescuers, cover them with a heavy blanket or tarp whenever possible.

To break a window in an automobile, tell the patient what you are going to do. Then:

1. Wear personal protective equipment. Heavy gloves and eye protection are necessary.
2. Locate the window farthest from the patient and, if time allows, cover it with contact paper or strips of broad tape to prevent the shattered glass from flying in on the patient. Or, if possible, cover the patient or have the patient cover himself before you break the glass—a procedure that is less time-consuming than taping the window.
3. Place a sharp tool such as a screwdriver, center punch, or other commercial window shattering device against a lower corner of the window and strike the tool with a hammer. Hold the tool with your hand resting against the car so your hand will not go through the window when it breaks. Rescue personnel often carry a spring-loaded punch. Available at most hardware stores, this tool can easily be carried in a pocket or equipment holster. It is used in much the same way as just described except that, when you place it against the lower corner of a tempered safety-glass window, you simply push until the spring causes the tip to punch, or you pull back on the spring and suddenly release the spring for the tip to punch and break the glass. Again, you must take care to avoid pushing your hand through the window. The spring punch model shown in EMT Skills 43-1 prevents the hand of the rescuer from pushing through the broken glass. In older model cars, a makeshift tool that can be used in an emergency is the car’s whip antenna. Snap off the antenna and hold it at one end along the metal of the door frame just below the window, allowing the opposite tip to touch the corner of the glass. Pull the tip away from the glass, causing the antenna to bow. When released, the tip of the antenna will strike the glass with enough force to shatter the window.

4. Carefully remove the broken glass, starting at the top and continuing until all has been removed. Broken correctly, although completely shattered, most tempered safety glass will remain in place even if it was not taped.

5. Attempt to unlock the door. If unsuccessful, cover the door edge with a blanket or tarp before crawling into the vehicle to gain access to your patient.

Other complex access methods require much more specialized training and equipment and will be discussed later in the chapter.

Once you gain access, evaluate the patient’s condition. At that time make the decision to perform rapid or normal extrication (as explained in Chapter 32, “Spinal Column and Spinal Cord Trauma”).

**EXTRICATION**

The purpose of extrication is to remove the patient as rapidly and safely as possible from wreckage—most commonly the wreckage of a vehicle collision—in which he is entrapped.

**The Role of the EMT**

The fundamental components of extrication include scene size-up, stabilization, gaining access, disentanglement, and patient removal. The role of the EMT in vehicle stabilization and patient extrication is that of patient care provider. The EMT may be responsible for gaining simple access to the patient prior to the rescue team’s arrival. However, in some cases, access to the patient is delayed because of the inability to gain simple access or because the vehicle is deemed to be unstable. Once specialized rescue personnel assure you that the vehicle is stable and the scene is safe to enter, you may approach the patient to perform an assessment and administer emergency medical care.

*Note: Patient care always precedes removal from the vehicle unless delaying removal would endanger the life of the patient, EMS personnel, or other rescuers.*

While always bearing in mind that your responsibility is seeing to the welfare of the patient, work with other rescuers. Cooperate in every way possible with personnel who are working to disentangle the patient. Help them make certain that the patient is removed from the vehicle in a way that minimizes risk of further injury.

In some EMS systems, EMS providers are both emergency medical care providers and rescuers. In those systems, a chain of command should be established to ensure patient care priorities.

**Caring for the Patient**

As in any emergency, your first priority is always your own safety. (You are no good to the patient if you become
another casualty.) Be sure the scene is safe, the vehicle is stable, and you are wearing the appropriate personal protective equipment before you try to reach the patient.

Basic considerations when dealing with a patient entrapped in a vehicle include the following:

- Maintain manual spinal stabilization at all times during the extrication process.
- Perform a primary assessment and manage any immediate life threats.
- Perform a controlled rapid extrication of the patient.
- Remove the vehicle from around the patient and not the patient from around the vehicle, if possible.
- Use adequate personnel.
- Use the path of least resistance that provides the least chance of further injury to the patient.

After gaining safe access to the patient, provide the same care you would provide to any trauma patient. Stabilize the cervical spine, complete the primary assessment, and provide critical interventions. Be sure you have, or have called for, sufficient personnel to help you provide proper care and to help you protect the patient from hazards.

Once you have access to the patient, establish a rapport. Remain with the patient throughout the rescue. Along with assessment, stabilization, and resuscitation efforts, you are responsible for assisting the patient through the extrication process and preparing him mentally and physically for disentanglement from the wreckage. Communicate with the patient and keep him informed of your actions and the actions of the rescue team. This communication is necessary for the safety of both you and the patient. Often, two EMTs need to be inside the vehicle during the extrication process—one to maintain manual in-line spinal stabilization and inform the patient of the actions of the rescue team, and another to assess the patient’s condition and treat potentially serious injuries.

Before a forcible rescue is initiated, its effect on the patient must be analyzed. The usual approach to rescue is to remove the vehicle from around the patient. However, when the condition of the patient or the scene dictates speed, the parts of the vehicle that will allow for rapid extrication while protecting the patient’s cervical spine should be removed first.

Use heavy blankets, a tarp, or a salvage cover to protect yourself, the patient, and other EMTs from the glass and flying debris that commonly result from disentanglement operations. During some extrication procedures, it may be necessary to place a solid object such as a backdrop between the tool activity area and the patient.

Continually monitor the patient’s condition and position in relation to the extrication tools and procedures. If there is a potential problem, relay this information to the person in charge of the extrication team. If the patient’s condition begins to deteriorate or otherwise becomes unstable, advise the rescue crew. They will change the approach to the incident and get the patient out as quickly as possible.

The patient entrapped by a vehicle collision is often in a highly agitated state. He will not be emotionally capable of handling the noise and confusion often associated with extrications and rescues. Even with a diminished level of responsiveness, the patient will be very frightened and may even attempt to move or crawl out of the vehicle.

To avoid this, it is very important that you prepare the patient for the rescue operation. Make him aware of the amount of time that the disentanglement might take and why it is necessary. Explain the activities, movements, and associated noises that will be encountered during the extrication process. Give the patient the opportunity to have some control over the process. For example, when the rescue crew asks you if you are ready for them to do a particular function, such as remove the door, check with the patient. Asking if he is ready to have the door or dash removed provides him with a feeling of control. If properly prepared, the patient will readily agree with each step of the extrication.

Stabilize and, if possible, immobilize the spine securely before you remove the patient from the vehicle by normal or rapid extrication procedures. The only exception to this rule is when there is an immediate threat to your patient’s life or your own, such as fire, that requires an urgent move without spinal protection.

### SPECIALIZED STABILIZATION, EXTRICATION, AND DISENTANGLEMENT TECHNIQUES

#### Stabilizing a Vehicle

Vehicle stabilization is carried out by specialized personnel using equipment such as wood cribbing and wedges, step chocks, air bags, hydraulic tools and rams, come-alongs, jacks, chains, and winches (Table 43-1).

#### Upright Vehicle

The way to properly stabilize an upright vehicle is to immobilize the suspension. The first step in this process is to position plastic step chocks under the vehicle parallel to each wheel (Figure 43-3 ■). Plastic chocks are lighter than wood chocks and are resistant to most of the fluids spilled at motor vehicle crashes. The chocks can be pushed in until they touch the undercarriage. The vehicle should not be lifted to place the chocks. If step chocks are unavailable, a box crib with wedges can function in much the same manner. Either procedure will prevent the vehicle from rocking.

The air should then be removed from the tires. A quick and easy way to deflate tires is to pull out the tire’s valve stems, using a pair of pliers. This will allow the air...
pulling device, cable, or chain from the undercarriage of the car to another vehicle or strong immovable object. Rescuers would then crib the length of the vehicle’s side where it has contact with the ground. Every void between the ground and the vehicle should be filled with box cribbing and wedges to minimize movement. The 12- to 18-inch space between the top of the door frame along the roof line and the ground should also be filled.

If additional support is needed on either side of the vehicle to prevent rollover, rescue struts can be placed from the ground to the undercarriage or roof (EMT Skills 43-2). If these struts are unavailable, 3- to 6-foot pieces of 4\texttimes{}4 cribbing can be used instead.

Vehicle on Its Roof

A vehicle that has landed on its roof usually is in one of two conditions. It will either be held up by its roof posts or, if one or more posts collapse, it may be resting on the hood, trunk lid, or both.

Since the roof posts are not designed to support the weight of the vehicle, the vehicle must be stabilized before you can get to the patient. Whether the posts have collapsed or not, the weight of the vehicle must be taken off the posts. This can be accomplished by building a box crib under the hood and trunk and using wedges to remove any remaining space.

Air bags under either the front or the rear of the vehicle can also be used to stabilize the vehicle. Low-pressure bags may be used by themselves because of their greater lift height. If high-pressure air bags are used, a box crib should be built to within a couple of inches of the surface of the vehicle. Rescuers would then slide the air bag into that space. When the air bag is inflated and one end of

Vehicle on Its Side

A vehicle on its side is inherently unstable and particularly dangerous to EMS personnel. Never attempt to enter such a vehicle before it is stabilized. A vehicle on its side is likely to roll onto its roof, thereby aggravating a patient’s existing injuries and posing a severe risk of injury to rescuers both in and around the vehicle.

The first step in stabilizing this vehicle, when the equipment is available, is to attach a stabilizing pole, to escape from the tires, neutralizing the vehicle’s suspension and virtually eliminating any movement. Sometimes, however, it may be desirable to be able to replace the air in the tires. If this is the case, air can be removed using a deflation tool or a valve stem removal tool. Valve stems would be cut and tires would be sliced only when it is absolutely necessary to use these methods to release the air.

![FIGURE 43-3](image) Plastic step chocks, as seen here, are strong and light and can be easily cleaned.
the vehicle begins to lift, the other end will settle onto the box crib and the weight of the vehicle will be totally removed from the roof posts.

Remember, even if the vehicle seems stable initially, opening or removing doors during patient extrication will reduce the strength of the post. Without proper stabilization, that could lead to collapse.

**Extricating a Patient**

Patient disentanglement is carried out by specialized personnel. The primary goal is to remove the vehicle from around the patient, thus ensuring that the patient’s injuries are not aggravated. Key factors in meeting that goal are that all personnel are familiar with extrication procedures and the incident command system (see Chapter 45, “Multiple-Casualty Incidents and Incident Management”) and that all personnel can communicate with other members of the rescue team.

The most common tool used in vehicle extrication and patient disentanglement is the power hydraulic tool. This tool, along with various attachments, can be used to spread, push, cut, and pull. The power hydraulic rescue tool creates tremendous forces from several thousand pounds of force to well in excess of 20,000 pounds. In order to prevent injury to rescuers and patients, it should be continually monitored for safety during use.

**“Rip and Blitz” Disentanglement**

A sequence of patient extrication called the “rip and blitz” is illustrated in EMT Skills 43-3. This is just one of a number of specialized procedures that can be carried out by highly trained and qualified personnel. The vehicle is cut from around the patient, minimizing movement and protecting the patient and rescuers at all times. An EMT is inside the vehicle with the patient, maintaining spine stabilization and continually reassessing the patient’s condition during the entire procedure until the patient is removed from the wreckage. The sequence is as follows:

1. An EMT enters the vehicle and establishes and maintains stabilization of the cervical spine as rescue personnel begin to stabilize the vehicle by placing chocks under the wheels (EMT Skills 43-3A and 43-3B).
2. Most electrical hazards can be avoided by simply turning off the ignition. To thoroughly minimize all risks, the battery cables should be disconnected or cut, always the negative terminal first, then the positive. This will reduce the risk of post-crash fire or unexpected air bag deployment. As an added precaution, the patient should be covered with a fire-retardant blanket (EMT Skills 43-3C).
3. Hydraulic spreaders are used to “pop” the rear door. Then the post between the front and rear sections of the passenger compartment—the B post—should be cut. A strap or rope should be attached to the rear door. As the cutter finishes the cut to the bottom of the B post, another rescuer uses a hydraulic ram or spreader to “rip” open the doors (EMT Skills 43-3D to 43-3G). (Keep in mind that the A posts are the front posts supporting the car roof. The B posts are the middle posts. C posts are at the rear.)
4. Next, the roof should be removed. The hydraulic cutters or a Sawzall (reciprocating saw) is used to cut both the A and C posts and the opposite-side B post, and a glass-cutting saw or Sawzall is used to cut across the bottom of the windshield. Care must be taken not to penetrate the passenger compartment with the cutting tool any farther than necessary. During the cutting process, one of the rescuers must monitor and control the cutting from a vantage point inside the vehicle. Hydraulic cutters then cut the roof from the vehicle (EMT Skills 43-3H and 43-3I).
5. “Jacking the dash” or performing a “dash roll” is very important when a patient is trapped by the dashboard. A relief cut should be made where the rocker panel meets the bottom of the A post. Hydraulic spreaders can then be used to push the dash off the patient. Some hydraulic spreaders have a spreading force of over 37,000 pounds and can spread up to 40 inches (EMT Skills 43-3J). Be sure to continually reexamine the patient’s position during this procedure to avoid causing further injury.
6. As previously stated, the whole purpose of cutting the vehicle from around the patient is to protect the patient from further injury of both the cervical spine and the lower spine. The proper way to remove an injured patient from a damaged vehicle is vertically, or in line with the spine. Having a patient, especially one complaining of pain, “spin” or rotate his body onto a backboard is unacceptable (EMT Skills 43-3K).

**Side-Impact or Head Protection Air Bags**

Special consideration must be given when cutting any posts in vehicles that have side-impact or head protection systems. These deployment systems may utilize high-pressure stored-gas cylinders to deploy the air bags, which can cause serious injuries to rescue personnel or patients if they are punctured by cutting tools.

**Other Methods of Access and Disentanglement**

Other methods commonly used for access and disentanglement are described in the next sections.

**Door Removal.** Sometimes all that needs to be done to access patients at a vehicle collision is opening or removing a door. Always check all doors and confirm that none are able to be opened normally prior to forcing entry.
A rescuer can force or “pop” a door with manual pry tools, hydraulic spreaders, and air chisels. Remember to protect yourself and the patient from flying debris by covering yourselves with a blanket during the procedure. If possible, place a solid object such as a spine board between the tool activity area and the patient. Keep the patient advised of reasons for the noise and any movement that may be encountered.

The front doors are most easily opened by prying at the latch site on the B post. All glass should be broken and removed on the side of the vehicle to be opened.

Often, when using hydraulic spreaders, there is not enough of a gap to fit the tip of the tool in near the latch. The rescuer must begin by widening the gap with a thinner hand pry tool (halligan or hux bar). Another method of widening the gap is by placing the tips of the partially opened hydraulic spreader vertically in the window opening of the door and forcibly enlarging this opening, which will cause the gap near the latch to widen. If the patient position allows clear access to the inside of the door, a third method is to place the partially opened tool over the door with one arm of the tool on each side of the door 6–12 inches from the latch. As the arms of the spreader begin to close, pinching the door, the gap near the latch will widen.

Once an opening has been created, the hydraulic spreader will be placed in the gap directly above or below the latch and begin to spread the arms. As long as the metal does not begin to rip, the rescuer should continue to spread the arms. If the metal begins to rip, the rescuer will stop, close the tool as needed, and get another grip nearer the latch.

Once open, the door may need to be removed completely to facilitate patient removal. With the proper technique, the hinges may be cut to remove the door completely. If this is not possible, the door may be removed by placing the tips of the spreader near each hinge and spreading the arms until the hinge fails. When any item is completely separated from the vehicle, such as when you remove the door, the object may suddenly be propelled several feet. This movement can be controlled but not prevented. Care must be taken to secure the object so it will not strike anyone when it becomes detached.

**Windshield Removal and Roof Rolling.** Although it is usually preferable to totally remove the roof from a damaged vehicle, occasionally it might be decided to just “flap the roof” (displace the roof and windshield of the vehicle) to facilitate patient removal. Since this procedure involves maneuvers close to the patient, it is very important that you and the patient are well protected from the tools and flying debris.

Before the rescuers displace the roof, the windshield must first be separated from the vehicle. Depending on the type of mounting found, either the mounting or the windshield is cut. Rubber mounts can often be cut with a razor knife and the windshield removed intact. Sometimes the windshield will be cut as described earlier in the “Rip and Blitz Disentanglement” section.

Next, the A posts and B posts must be cut. Normally, either a hacksaw, air cutting tool, or hydraulic cutting tool is used. Care must be taken to cut the A posts as close to the dash and the B posts as close to the door as possible. This will increase patient accessibility and minimize potential injury from the remaining post stubs. The roof is then creased just in front of the C posts using a long pry bar, pike pole, or other similar item. The roof can be grasped near the A post on each side and folded up and back toward the trunk.

After the roof is displaced, the stubs of the posts must be covered with duct tape or pieces of old 2 ½ fire hose to protect the patient and rescuers from any exposed sharp metal.

**Special Disentanglement Procedures**

No two vehicle extrications are exactly alike. Some can be quite complex. Very often, improvisation and common sense must prevail.

One complication occurs when a patient’s foot is caught under the brake pedal. In this situation, a rope pulling device or portable hydraulic tool can be used to force the pedal sideways around the steering column to free the extremity. This procedure involves using tools in very close proximity to the patient, who may have an injury to the trapped part that is causing considerable pain. Therefore, disentanglement must be accomplished with utmost care so as not to disturb the injury. Often the rescuer can simply grab the brake pedal with a hand and pull firmly upward away from the floor, lifting it enough to free the foot.

A patient also may be trapped in a way that requires the seat to be moved or removed, such as a patient in the backseat of a two-door vehicle or a patient with a leg trapped under the seat. Disentanglement may be accomplished by using the seat adjustment lever to gently move the seat. If greater movement is needed, it can be done slowly by using hand tools to remove the nuts securing the seat or quickly by forcing the seat using portable rams or spreaders or a come-along. If the seat is forced, the patient will receive a considerable jolt. If injuries dictate that such movement may be harmful, other options must be considered.

Extricating a patient who is trapped in a vehicle on its side involves some different techniques. Rapid access and removal are important because the patient in a vehicle on its side may be experiencing a tremendous gravitational pull on the spine. Access to the patient may be gained by removing the rear window. The best way to extricate the patient is to cut the upper posts of the vehicle and fold the roof down (EMT Skills 43-4).

Once the patient has been disentangled, you will remove him from the wreckage using normal or rapid extrication procedures as discussed in Chapter 32, “Spinal Column and Spinal Cord Trauma.”
**EMT SKILLS 43-1**

**Breaking an Automobile Window**

- **43-1A** Position the punch in the corner of the side window and pull back on the spring.

- **43-1B** Keeping the tip of the punch in place, let go of the spring to shatter the window.

- **43-1C** Starting at the top of the window, carefully push the broken glass away from the interior of the vehicle.

**EMT SKILLS 43-2**

**Stabilizing a Vehicle on Its Side**

- **43-2A** Rescue struts can be used to prevent a vehicle on its side from rolling over onto its top or back onto its wheels.

- **43-2B** For extra safety, rescue struts can be placed against both the underside and the top of a vehicle on its side.
While the EMT maintains spine stabilization from inside, rescue personnel will begin to stabilize the vehicle.

The first step in stabilizing the vehicle is to place chocks under the vehicle. Chocks should be pushed in until they touch the undercarriage; the vehicle should not be lifted up to fit the chocks into place.

The patient should be covered with a fire-retardant blanket. The air should be released from the tires and the battery should be disconnected. Always disconnect the negative terminal first.

Hydraulic spreaders are used to “pop” open the rear door.

Cut the B post at the top by the roof.

Cut the B post at the bottom by the floor.
Using a hydraulic ram or spreaders, “rip” the B post while pulling the doors open on the front hinges.

Hydraulic cutters are used to cut the roof from a vehicle.

Use as many people as necessary to safely lift the roof up and away from the vehicle.

Hydraulic spreaders are used to free the patient from entrapment by the dashboard.

To prevent further injury to the patient, it is best to remove him vertically out of the vehicle.
Extricating a Patient from a Vehicle on Its Side

To extricate a patient from a vehicle on its side, first cut the upper posts using a hydraulic cutter or other cutting tool. The windshield should also be cut.

Then fold the roof down to provide an adequate space from which to remove the patient.

### SUMMARY

Motor vehicle collisions account for the majority of incidents where an EMT must gain access to the patient. However, some medical patients may be in a confined area or in their own locked home to which the EMT would need to gain access. Extrication is the removal of a patient. You perform simple extrication every time you remove a patient from his home. Complex extrication is most often required at the scene of a vehicle collision when the patient is entrapped in tangled metal.

It is imperative that EMTs wear the proper personal protective equipment at the scene, to include high-visibility vests, while working on or near the roadway. If jagged metal and glass are present, EMS personnel should wear full turnout gear. Be sure to consider safety hazards such as downed electrical lines, traffic, and unstable vehicles. Also, it is necessary to locate all patients at the scene. Pay attention to scene clues that may indicate additional patients who are not immediately present or visible.

It may be necessary to gain immediate access to the patient to initiate emergency care. In a vehicle collision, this may be done by simply opening a door or shattering a window. Explain to the patient what you are doing. Once you have gained access to the patient, shift your attention to providing emergency care. The fire department may need to perform complex extrication maneuvers to remove you and the patient from the vehicle. Protect the patient and communicate with the extrication team to ensure that no further harm is done to the patient.

At times it may be necessary to gain access to a patient in a home behind a locked door. Contact the police or fire department and wait for their arrival, if possible, prior to gaining access. If you need to gain entry yourself, you may be able to shatter a small window in a door near the lock mechanism, then simply reach in, disengage the lock, and open the door. Do not kick in doors, since this may cause injury to you and excessive and unnecessary property damage.
Case Study Follow-up

Scene Size-up
You have been dispatched to a motor vehicle collision between a large dump truck and a small passenger vehicle. You see from your unit that this is a complex rescue situation. You have multiple patients with potentially life-threatening injuries. They are entrapped in the wreckage of what was, minutes before, a bright red sports car.

There are no other emergency personnel immediately responding, so you call for rescue crews and an additional ambulance for each additional patient. Before exiting the unit, you size up the scene, identifying real and potential hazards. You make a mental note of all necessary precautions—including personal protective clothing and equipment—to protect yourself, bystanders, and the patients from further injury.

You position your vehicle 100 feet from the wreckage—the minimum safe distance since there are no electrical lines down or other visible hazards—to provide easy access to your equipment while being out of the way of rescue operations. You review what you and your partner need to do:

- If the patient access is prevented or hampered, attempt to assess the patients’ condition based on the findings of whatever portion of the primary assessment you can perform.
- If you can, establish and maintain an airway, stabilize the cervical spine, and control any serious bleeding from outside the vehicle.
- Provide direction to other responding units as to what the situation is and what you need from them.

- Once the rescue crews arrive and the scene is secure, the incident commander and rescue crews will assess the situation and direct you in your assignment.
- If the incident requires complex rescue operations, a team approach using an incident command system with one commander is vital for success.
- Your attention should be given not only to the patients in the sports car. The driver of the truck may also be injured and many potential hazards must not be overlooked.

You and your partner arrive back at the station and discuss the extrication among a group of rescuers who were at the scene. It was a difficult experience for everyone. You were there when the teenager in the passenger side of the sports car died, well before extrication was completed and in spite of all your attempts to keep him alive. You know that the driver of the car, also a teenager, died in the ambulance after prolonged extrication and emergency medical procedures. Neither of the teenagers was wearing a seat belt. Both of them had been drinking. You are grateful to learn that the truck driver will recover.

The same questions are on the minds of everyone in the room. Is there anything we could have done better or faster? Is there any way we could have saved those kids’ lives? As you, your partner, and the other rescuers defuse the room, you feel reasonably reassured that you did everything you could. And you and the rescue crew have worked out some refinements in procedure that might make the next rescue a little faster, safer, and more effective.

IN REVIEW

1. Name your first priority in this and any other type of emergency situation.
2. Describe the role of the EMT in vehicle stabilization and patient extrication.
3. Identify the first step you should take upon arriving at the site of a motor vehicle collision.
4. Explain how you can locate all the patients involved in an emergency such as a motor vehicle collision.
5. Explain why it is important to approach a motor vehicle collision from the front.
6. Identify which process comes first—patient care or patient extrication—and describe the exceptions.
7. Describe how you can protect the patient from further physical injury during extrication.
8. Describe the minimum level of personal protective equipment required at a motor vehicle collision site.
9. Describe the steps that may be taken after you identify downed electrical lines at the scene.
10. Describe a ‘stable’ vehicle. Then name some simple steps that you can take to stabilize a vehicle in danger of rolling until rescue crews can properly and completely stabilize it.

CRITICAL THINKING

You arrive on the scene and find a vehicle that struck a pole in a head-on crash. The driver of the vehicle is not alert and is not responding when you call to him. The windows are all up and the doors are not opening.

1. Do you need to gain immediate access to the patient or should you wait for the extrication crew to arrive?
2. What methods could be used to gain immediate access to the patient?
3. Once access has been gained, what is your primary role?
4. How can you assist the extrication crew while providing care to the patient?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • EMS Operations** (Content Area: Hazardous Materials)

**COMPETENCY •** Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

**OBJECTIVES** • After reading this chapter, you should be able to:

44-1. Define key terms introduced in this chapter.
44-2. Explain the U.S. Department of Transportation placard system and the National Fire Protection Association symbols for identifying hazardous materials.
44-3. Explain the purpose of shipping papers and material safety data sheets.
44-4. List sensory indications that a hazardous materials situation may exist.
44-5. Identify resources that can be used in the identification and management of hazardous materials incidents.
44-6. Differentiate between the levels of hazardous materials training identified by the Occupational Safety and Health Administration.
44-7. Explain the general rules of hazardous materials rescue.
44-8. Discuss the components of hazardous materials incident management, including:
   a. Preincident planning
   b. Considerations in implementing the plan
   c. Establishing safety zones
   d. Emergency procedures, including decontamination, that should take place in each zone
44-9. Describe special considerations in responding to and managing patients exposed to or contaminated with radiation.
44-10. Differentiate between radiation sickness, radiation injury, and radiation poisoning.
44-11. List factors that determine the amount of risk posed to patients and rescuers by a source of radiation.
44-12. Describe the importance of being knowledgeable about terrorist attacks involving weapons of mass destruction.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

cold zone p. 1208  hazardous material p. 1197  hot zone p. 1206
safety zones p. 1206  warm zone p. 1206
INTRODUCTION

Billions of tons of hazardous materials are manufactured in the United States annually. More than 800,000 shipments transport more than 4 billion tons of hazardous materials within this country every year, including explosives, compressed and poisonous gases, flammable liquids and solids, oxidizers (substances that give off oxygen and stimulate combustion of organic matter), corrosives, and radioactive materials. Hazardous materials spills and other accidents are common problems (Figure 44-1 ■).

The EMT is not required to deal directly with hazardous materials. That takes specialized training. It is, however, important for you to know how to recognize and react to a hazardous materials emergency.

IDENTIFYING HAZARDOUS MATERIALS

What Is a Hazardous Material?

A hazardous material is defined as one that in any quantity poses a threat or unreasonable risk to life, health, or property if not properly controlled during manufacture, processing, packaging, handling, storage, transportation, use, and disposal (Table 44-1). Hazardous materials include chemicals, wastes, and other dangerous products. The principal dangers hazardous materials present are toxicity, flammability, and reactivity.

Hazardous materials can asphyxiate, irritate, increase the risk of cancer, act as nerve or liver poisons, or cause loss of coordination or altered mental status. They can cause skin irritation, burns, respiratory distress, nausea and vomiting, tingling or numbness of the extremities, and blurred or double vision. The acronym TRACEM can be used to remember the types of damage that can be caused by hazardous materials: thermal, radiological, asphyxiation, chemical, etiological, and mechanical (Table 44-2). The amount of damage depends on the dose, concentration, route of exposure, and amount of time the patient is exposed.

Accidental exposure to hazardous materials can be limited to a few victims, but an accident also can cause widespread destruction and loss of life. Therefore, the primary concern in any hazardous materials emergency is safety of the rescuer, the patient, and the public.

Placards and Shipping Papers

U.S. Department of Transportation (DOT) regulations require vehicles containing hazardous materials to be marked with specific hazard labels or placards (Figures 44-2 ■ and 44-3 ■). A vehicle driver must have shipping papers, which identify the exact substance, quantity, origin, and destination.

A placard is a four-sided, diamond-shaped sign used to designate hazardous materials in transit on roadways. The placard contains important information that can aid the EMT in determining the best course of action. Often, a placard will display a four-digit UN number (United Nations identification number) that can be

</table>

*This patient may require advanced airway management and assisted ventilation.*
used to identify the hazardous material. The color of a placard also indicates what class of hazard is contained within. A legend that indicates whether the material is flammable, radioactive, explosive, or poisonous is also commonly displayed.

The National Fire Protection Association (NFPA) has adopted an internationally recognized diamond-shaped symbol, which is divided into four smaller diamonds (Figure 44-4a ■), for use in marking hazardous materials located at fixed facilities. This system—the NFPA 704 system—identifies potential danger with the use of background colors and numbers ranging from 0 to 4. The blue diamond is a gauge of health hazard; the red, fire hazard; and the yellow, reactivity hazard. The white diamond is used for symbols that indicate additional information, such as radioactivity, oxidation, need for protective equipment, and so on. For example, a symbol that has a 1 in the blue diamond and a 4 in the red diamond would indicate a material that presents a relatively low health hazard but is extremely flammable. For another example of NFPA 704 labeling, see Figure 44-4b ■.

Shipping papers and material safety data sheets (Figure 44-5 ■) are also important. If you can find them, shipping papers will have the name of the substance, the classification (such as flammable or explosive), and

\[ TABLE 44-2 \] TRACEM: Types of Damage from Hazardous Materials

| T | Thermal: Heat sources, burning, radiant heat |
| R | Radiological: Nuclear fuels and by-products, nuclear bombs |
| A | Asphyxiation: Lack of O₂ due to chemical vapors, heavy gases |
| C | Chemical: Toxic or corrosive chemicals |
| E | Etiological: Biological hazards |
| M | Mechanical: Trauma from bullets, shrapnel, and so on |

Any tank, vehicle, train, or ship that carries hazardous materials must have a placard that identifies the substance.

\[ FIGURE 44-2 \] The U.S. Department of Transportation requires packages, storage containers, and vehicles containing hazardous materials to be marked with specific hazard labels.

\[ FIGURE 44-3 \] Any tank, vehicle, train, or ship that carries hazardous materials must have a placard that identifies the substance.
HAZARDOUS MATERIALS CLASSIFICATION

HEALTH HAZARDS
- 4: Can be lethal
- 3: Serious or permanent injury
- 2: Temporary incapacitation or residual injury
- 1: Significant irritation
- 0: No hazard beyond ordinary combustibles

HAZARDOUS MATERIALS

FLAMMABILITY HAZARDS
- 4: Rapidly or completely vaporize and burn readily
- 3: Ignite readily in ambient conditions
- 2: Ignite when moderately heated
- 1: Require preheating for ignition
- 0: Will not burn under normal fire conditions

INSTABILITY HAZARD
- 4: May detonate or have explosive reaction
- 3: Shock and heat may detonate or cause explosive reaction
- 2: Violent chemical change at elevated temperatures
- 1: Unstable if heated
- 0: Normally stable

SPECIAL HAZARDS
- Oxidizers OX
- Water Reactives W
- Simple Asphyxiants SA

FIGURE 44a NFPA 704 hazardous materials classification.

This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented solely by the standard in its entirety. The classification of any particular material within this system is the sole responsibility of the user and not the NFPA. The NFPA bears no responsibility for any determinations of any values for any particular material classified or represented using this system.)

Remember: You may not be able to see or smell the hazardous material. Some are odorless and colorless, while others have anesthetic properties and will deaden your senses. Never rely on your senses alone—sight, smell, taste, or touch—to detect a hazardous material. Always assume that the area surrounding a spill or leak is dangerous.

Resources

Several resources can assist you in proper identification of hazardous materials emergencies. They include printed materials, the American Chemistry Council (www.americanchemistry.com), and state and local agencies including specialized “hazmat” teams. Poison control centers also provide resources.

One concise print reference is a guidebook published by the U.S. Department of Transportation, Transport Canada, and the Secretariat of Communications and Transportation of Mexico called the Emergency Response Guidebook. The Emergency Response Guidebook is updated every four years in an effort to keep current with new transportation hazards. Compact enough to be carried with your usual equipment and supplies, the book lists more than a thousand hazardous materials, each with a four-digit UN identification number cross-referenced to complete emergency instructions. Hazardous materials emergency response information is also available electronically and in handheld PDAs. Other print materials are also available.

CHEMTREC (Chemical Transportation Emergency Center) is a public service division of the Chemical Manufacturer’s Association and another important resource. Officials at CHEMTREC can answer any question and advise you on how to handle any emergency involving
### Material Safety Data Sheets

#### I – CHEMICAL IDENTIFICATION

<table>

</tbody>
</table>

**Other Designations**
- EPA Reg. No. 5813-1
- Sodium hypochlorite solution
- Liquid chlorine bleach
- Clorox Liquid Bleach

**Manufacturer**
The Clorox Company  
1221 Broadway  
Oakland, CA 94612

**Emergency Procedure**
- Notify your supervisor  
- Call your local poison control center OR  
- Rocky Mountain Poison Center  
  (303)573-1014

#### II – HEALTH HAZARD DATA

- Causes severe but temporary eye injury. May irritate skin. May cause nausea and vomiting if ingested. Exposure to vapor or mist may irritate nose, throat and lungs. The following medical conditions may be aggravated by exposure to high concentrations of vapor or mist: heart conditions or chronic respiratory problems such as asthma, chronic bronchitis or obstructive lung disease. Under normal consumer use conditions the likelihood of any adverse health effects are low.

**FIRST AID:**
- **EYE CONTACT:** Immediately flush eyes with plenty of water. If irritation persists, see a doctor.  
- **SKIN CONTACT:** Remove contaminated clothing. Wash area with water.  
- **INGESTION:** Drink a glassful of water and call a physician.  
- **INHALATION:** If breathing problems develop remove to fresh air.

#### III – HAZARDOUS INGREDIENTS

<table>
<thead>
<tr>
<th>Ingredients</th>

</tr>
</tbody>
</table>

CAS# 7681-52-9

None of the ingredients in this product are on the IARC, NTP or OSHA carcinogen list. Occasional clinical reports suggest a low potential for sensitization upon exaggerated exposure to sodium hypochlorite if skin damage (e.g., irritation) occurs during exposure. Routine clinical tests conducted on intact skin with Clorox Liquid Bleach found no sensitization in the test subjects.

#### IV – SPECIAL PROTECTION INFORMATION

**Hygienic Practices:** Wear safety glasses. With repeated or prolonged use, wear gloves.

**Engineering Controls:** Use general ventilation to minimize exposure to vapor or mist.

**Work Practices:** Avoid eye and skin contact and inhalation of vapor or mist.

#### V – SPECIAL PRECAUTIONS

Keep out of reach of children. Do not get in eyes or on skin. Wash thoroughly with soap and water after handling. Do not mix with other household chemicals such as toilet bowl cleaners, rust removers, vinegar, acid or ammonia containing products. Store in a cool, dry place. Do not reuse empty container; rinse container and put in trash container.

#### VI – SPILL OR LEAK PROCEDURES

Small quantities of less than 5 gallons may be flushed down drain. For larger quantities wipe up with an absorbent material or mop and dispose of in accordance with local, state and federal regulations. Dilute with water to minimize oxidizing effect on spilled surface.

#### VII – REACTIVITY DATA

Stable under normal use and storage conditions. Strong oxidizing agent. Reacts with other household chemicals such as toilet bowl cleaners, rust removers, vinegar, acids or ammonia containing products to produce hazardous gases, such as chlorine and other chlorinated species. Prolonged contact with metal may cause pitting or discoloration.

#### VIII – FIRE AND EXPLOSION DATA

Not flammable or explosive. In a fire, cool containers to prevent rupture and release of sodium chlorate.

#### IX – PHYSICAL DATA

- Boiling point: 212°F/100°C (decomposes)
- Specific Gravity (H₂O = 1): 1.085
- Solubility in Water: complete
- pH: 11.4

**CHAPTER 44 • Hazardous Materials 1203**
Look for clues to potential hazardous materials, such as (a) signs and (b) storage tanks.

hazardous materials. They will even locate the shipper of the hazardous materials for appropriate follow-up. You can reach the CHEMTREC emergency response line around the clock, 7 days a week, by calling their toll-free number at 1-800-424-9300.

Chemtel, Inc. is another emergency response communications service that can be reached at 1-800-255-3924 in the United States and Canada. For calls outside the United States or Canada or for collect calls, the number is 1-813-979-0626. These resources and others, along with their phone numbers, can be found in the front section of the Emergency Response Guidebook. Also, your regional poison control center is a good source of information for hazardous materials incidents.

When contacting an organization, be prepared to provide the following information:
- Your name, callback number, and fax number
- Nature and location of product
- UN identification number or name of product(s)
- Name of carrier, shipper, manufacturer, consignee, and point of origin
- Type of container and size (rail, truck, housed, open)
- Quantity of material
- Local weather conditions
- Number of injuries and/or exposures
- Emergency services that are present or are responding

Accidents involving hazardous materials often occur at inconvenient locations, making communication difficult. It is critical that you make every effort to keep a phone line open.

Training Required by Law

Because of the frequency and potential impact of hazardous materials emergencies, two federal agencies—the Occupational Safety and Health Administration (OSHA) and the Environmental Protection Agency (EPA)—have developed regulations to enhance the safety of rescuers and bring about a more effective response. The regulations can be found in the OSHA publication “29 CFR 1910.120—Hazardous Waste Operations and Emergency Response Standards.”

The regulations identify four levels of training:
- **First Responder Awareness.** This level is for those who are likely to witness or discover a hazardous materials emergency. They are trained to recognize a problem but are not expected to take any action other than call for proper resources and prevent others from entering the scene. This level of training is commonly required for all operating EMTs.
- **First Responder Operations.** This level of training is for those who initially respond to hazardous materials emergencies to protect people, property, and the environment. They are trained in the use of specialized personal protective equipment and help to stop the emergency from spreading.
- **Hazardous Materials Technician.** This extensive level of training is for rescuers who actually plug, patch, or stop the release of a hazardous material.
- **Hazardous Materials Specialist.** Rescuers with this training have advanced knowledge and skills. They provide command and support activities at the site of a hazardous materials emergency.

Employers are responsible for determining and documenting the appropriate level of training for each employee. Because training addressed by OSHA usually has a fire-service focus, the National Fire Protection Association has published Standard 473, which deals with competencies for EMS personnel at hazardous materials
emergencies. Refer to the OSHA and NFPA standards for more information on training requirements. Most EMTs are trained to the First Responder Awareness level.

GUIDELINES FOR HAZARDOUS MATERIALS RESCUES

Note: Never attempt a hazardous materials rescue unless you have had the necessary specialized training (to the hazardous materials technician level or better) and have had the proper training in the use of self-contained breathing apparatus (SCBA) and chemical protective clothing. If you have had no training, radio immediately for help. While you are waiting for help to arrive, protect yourself and bystanders by keeping uphill, upwind, upstream, and away from the danger.

General Rules

One rule of a hazardous materials rescue is to avoid contact with any unidentified material, regardless of the level of protection offered by your clothing and equipment. In achieving that goal, there are three general priorities in an order that never changes:

1. Protect the safety of all rescuers and patients.
2. Provide patient care.
3. Decontaminate clothing, equipment, and the vehicle.

Another rule of hazardous materials rescue is to avoid risking your life or your health if the only threat is to the environment. In other words, if victims are not involved, do not enter the scene. Let specially trained environmental workers clean up the hazard.

At the First Responder Awareness level of training, your actions at a hazardous materials incident should include the ability to recognize that a hazardous materials incident has occurred, avoid contact with the hazardous substance, isolate the area, and notify the appropriate authorities or response agencies. These actions can be easily remembered using the acronym RAIN (Table 44-3).

Simply cordon off the area and evacuate bystanders. Even if there are patients involved, this is one situation in which you should not automatically begin rescue work. Generally accepted guidelines call for you to weigh the emergency according to your best judgment, determining whether the risk to rescuers is justified by the lives that can be saved. Consider the difficulty of the rescue, the flammability of materials, the possibility of explosion, any time or distance constraints, available escape routes, and the probability of patients surviving if they receive medical care. If you decide to begin rescue operations, act quickly—time is critical, but do not work so quickly that you endanger yourself or others or make patient injuries worse. The Emergency Response Guidebook can be of great assistance in your decision-making process.

As a first course of action, secure the scene and limit the exposure of rescuers and bystanders. Then make sure there is enough additional equipment, trained personnel, and whatever else you might need to handle the emergency effectively. Finally, make sure that every rescuer who enters the scene has adequate protective equipment: a positive pressure SCBA and a full suit of appropriate chemical protective clothing, at least two layers of gloves, boots, helmet, eye protection (preferably full-face protection), and lifelines (EMT Skills 44-1).

Use wide duct tape to seal off the protective suits at the wrists, ankles, neck, and other gaps or openings. You will need specialized suits if you are working in high temperatures or areas where you could be splashed with corrosive chemicals. Only responders trained to the First Responder Operations level or above should ever consider entering a dangerous hazardous materials scene.

Incident Management

Preincident Planning

The most essential part of hazardous materials rescue is effective preincident planning. Before a hazardous materials emergency ever develops, all agencies that would probably be involved in a rescue need to know how various forces will be mobilized to handle the emergency.

Generally, you should prepare for the worst possible scenario. That way, the community will be capable of handling any emergency that arises. Your plan should be specifically tailored to the individual circumstances in the community. However, the following should be included:

- One command officer, who is responsible for all rescue decisions, should be appointed. All rescuers should be aware of who the command officer is. If the command officer hands over the decision-making power to someone else, all rescuers should be notified of the change in command.
- There should be a clear chain of command from each rescuer to the command officer.
- There should be an established system of communications used throughout the emergency. The system should be one all rescuers are informed about, know how to use, and have access to.

</tr>
</tbody>
</table>
Receiving facilities should be predesignated. Choose facilities that are capable of handling large numbers of patients, have surgical capacity, and, if possible, have established decontamination procedures.

**Implementing the Plan**

The first priority in implementing a plan is to immediately establish an incident command system and a command post from which orders are given and to which information is directed. Then—to identify the best plan of action under the circumstances as quickly as possible—get the following information:

- Nature of the problem
- Identification of the hazardous material or materials involved
- The type and condition of containers
- Existing weather conditions
- Whether there is presence of fire
- Time that has elapsed since the emergency occurred
- What has already been done by people at the scene
- The number of patients
- The danger of victimizing more people

Smoke from hazardous materials fires presents an environmental hazard. It carries toxins and particles of hazardous materials through the air, widening the area of contamination. This “secondhand smoke” not only threatens the immediate safety of patients and rescuers, it also threatens long-term health, in some cases increasing risk of cancer and chronic effects involving the brain, liver, lungs, and kidneys.

*Unless you are a trained firefighter, do not attempt to extinguish the fires yourself.* Hazardous materials fires often require special techniques. (For example, some cannot be extinguished with water; in fact, water would make them worse.)

**Establishing Safety Zones**

As an early priority at the scene of any hazardous materials emergency, safety zones are established in which rescue operations and a specific sequence of decontamination procedures take place. Some EMS areas use the circular model for depicting safety zones (Figure 44-7). Remember: You may not be able to see or smell the hazardous material. Always assume that the area surrounding a spill or leak is dangerous and avoid entry unless you are wearing appropriate protective gear.

As an EMT, when decontaminating a patient, follow steps 1–9 of the decontamination procedure (Figure 44-8) the same as rescuers. After step 4, if the patient is experiencing life-threatening illness or injury, move the patient to the ambulance and transport immediately. Do not complete steps 5–9 in this case.

**Hot Zone.** The hot zone, also known as the exclusion zone, is where contamination may actually be present. It generally is the area that is immediately adjacent to the accident site and where contamination can still occur. To help limit the spread of contamination, a single point at which all rescue personnel enter and exit the hot zone is established. An emergency exit is designated to be used in case the scene deteriorates rapidly (in case of an explosion, for example). Never smoke, eat, or drink in the hot zone, because you would risk inhaling or ingesting the hazardous material.

The hot zone should be restricted. Only as many trained rescuers as absolutely necessary should enter it. Bystanders never allowed.

**Warm Zone.**

Area surrounding the contamination zone. Vital to preventing spread of contamination. Personnel must wear appropriate protective gear. Lifesaving emergency care is performed.

**Cold Zone.** Normal triage, stabilization, and treatment performed. Rescuers must shed contaminated gear before entering the cold zone.

*FIGURE 44-7 Establishing safety control zones at the site of a hazardous materials emergency.*

To the accident site and where contamination can still occur. To help limit the spread of contamination, a single point at which all rescue personnel enter and exit the hot zone is established. An emergency exit is designated to be used in case the scene deteriorates rapidly (in case of an explosion, for example). Never smoke, eat, or drink in the hot zone, because you would risk inhaling or ingesting the hazardous material.

*The hot zone should be restricted. Only as many trained rescuers as absolutely necessary should enter it.* In areas with a specialized hazmat team, only members of that team should enter the hot zone. Bystanders should never be allowed in the hot zone. If necessary, cordon off the whole area and appoint people to keep bystanders away.

The only work done in the hot zone is hazard assessment, control of the release or hazard, and rescue performed by trained personnel who are wearing appropriate protective equipment.

**Warm Zone.** The warm zone, also known as the contamination reduction zone, is immediately adjacent to the hot zone. While the hazardous materials may not actually be in the warm zone, there is still danger of contamination from the patients and rescue personnel who
NINE-STEP DECON PROCEDURE*

<td>Identify personnel and complete exposure records. Transport personnel to hospital, if needed, or to a fixed decon facility for Steps 5 through 9.</td>
</tr>
</tbody>
</table>

**FIGURE 44-8** Nine-step decontamination procedure.
have exited the hot zone. For that reason, all personnel in the warm zone must wear appropriate protective gear.

The warm zone is vital in preventing the spread of contamination. All supplies used in the warm zone must remain there until fully decontaminated. All water used in this area must also be contained here. Rescue work done in the warm zone consists of lifesaving emergency care, such as airway management and immobilization. All initial decontamination efforts take place within the warm zone.

**Cold Zone.** The cold zone, also known as the support zone, is immediately adjacent to the warm zone. Before entering the cold zone from the warm zone, rescuers should shed all contaminated protective gear and patients should be as fully decontaminated as possible. By design, the cold zone should not contain any contamination, but since contamination can still enter the cold zone, you should continue to exercise caution and take measures to protect your equipment and vehicle.

By the time patients enter the cold zone, life-threatening problems should have been initially managed. Continue emergency care. Triage patients to determine the order of care, perform necessary treatment, and stabilize patients prior to transport (see Chapter 45, “Multiple-Casualty Incidents and Incident Management”).

## Emergency Procedures

Anyone entering the warm zone or the hot zone must be properly trained and wearing appropriate protective equipment. The type of protective equipment needed is dictated by the type of hazardous material being dealt with and the rescue scene itself.

Initial (gross) decontamination should be performed at the entry to the warm zone. The patient should be removed from the actual accident site while any necessary management of immediate life threats is performed. Initial decontamination always involves the use of copious amounts of water, and may also include the use of a simple soap. The patient’s clothing, tools, and equipment should be left in the hot zone.

A primary assessment of patients is also performed in the warm zone. Protective equipment must be worn in the warm zone. Once the immediate life threats are managed, complete decontamination is performed. Following thorough decontamination in the warm zone, a physical assessment is performed. Treat the patient’s major injuries, immobilize the spine as appropriate, splint where needed, and move the patient to the cold zone.

All of the protective equipment is removed before entering the cold zone. In the cold zone, take a set of vital signs and history and prepare the patient for transport.

Take precautions to protect your equipment and vehicle during transport, since there may still be some contamination on the patient. Prior to transport, cover the benches, floor, and other exposed areas of your vehicle with thick plastic sheeting. Secure the sheeting with duct tape. Patients should be fully decontaminated before being placed into a helicopter. A contaminated patient in such a closed, tight space could affect the breathing or vision of the air transportation team, resulting in a crash. Contamination of an aircraft can take it out of service for several days.

All clothing and equipment used in the hot or warm zones must be left at the scene so it can be properly contained. Any contaminated equipment or clothing must be sealed in plastic bags or in metal containers with tightly fitting lids. All corpses at the scene need to be decontaminated fully before being transported to a morgue. This must be performed by appropriately trained rescuers.

If you are accidentally exposed to hazardous materials during the rescue, decontaminate yourself thoroughly (Figure 44-9). Contamination occurs most easily in areas of your body where skin is thin or usually moist such as under the arms and in the groin. Wash with mild detergent, such as Dawn or a similar grease-cutting detergent, or with green soap and plenty of running water. Green soap is preferred for hazmat decontamination because it is known to be nonreactive and does not contain additional chemicals such as perfumes or stabilizers that can interact with hazardous substances. Irrigate exposed skin for at least 20 minutes or until any localized burning or discomfort stops. Seek medical attention, document the emergency, and report it to your employer.

---

**FIGURE 44-9**  (a) Testing hazard levels at a spill. (b) Rescuer in decontamination process.
All rescuers should have a thorough medical examination and medical surveillance to treat any exposure-related injuries or illnesses. Some do not manifest for hours or even days after exposure. Following a hazardous materials emergency, watch yourself for signs of exposure. Seek medical help immediately if you develop headache; nausea or vomiting; abdominal cramps or diarrhea; difficulty breathing; dizziness; lack of coordination; blurred vision; excessive salivation; irritation of the skin, eyes, nose, throat, or respiratory tract; or any other unusual symptoms.

Following rescue, decontaminate your equipment and vehicle by washing them thoroughly inside and out. Caution: If you fail to clean them thoroughly, the result may be chronic chemical exposure. The clothing under your protective gear also needs decontamination. However, do not take clothing home to launder, since it may contaminate your family and the general sewer system.

Radiation Emergencies

Exposure and Contamination

In a radiation accident, the patient may suffer from exposure, contamination, or both. Exposure occurs when the patient is in the presence of radioactive material without any of the radioactive material actually touching his clothing or body. The exposure he receives may be harmful to him, but the patient does not become radioactive and does not pose any threat to rescue personnel. (Remember, however, that the source of the radioactivity may pose a threat to rescuers who come close enough to it.)

Contamination occurs when the patient has come into direct contact with the source of radioactivity or with radioactive gases, liquids, or particles. The radioactive material is present on the patient’s clothes or skin, which poses a hazard for the rescuer as well as the patient. The contaminated patient is considered a risk to emergency personnel.

Guidelines for Radiation Emergencies

Remember two major principles about radiation-related accidents: (1) protect yourself and others from contamination as your first priority and (2) no EMT should ever attempt to decontaminate a radiation patient. If you suspect a patient is contaminated by radiation, you have two choices:

- **Wait for a Radiation Safety Officer (RSO),** an expert specifically trained under federal government provisions to handle such situations. The RSO in your area is probably employed by the county or state health department and will respond to the scene when possible.
- **If an RSO cannot come to the site,** you can transport the patient to the hospital for decontamination by experts there. To transport, place the patient in a body bag up to the neck, cover the hair completely with a cap or towel, and use disposable wipes to clean the face. Put the disposable wipes in a plastic bag, seal it, and take it to the hospital with you.

*Time is the critical factor in managing radiation emergencies.* Trained personnel should remove the patient from the source of radiation as quickly as possible before you begin emergency care. Increase distance between yourself and the source of radiation. Depending on the type of radiation, provide shielding between the patient and the source of radiation. Alpha rays can be stopped by clothing. Beta rays can be stopped by aluminum or like materials. Gamma rays require lead shielding.

Procedures for Radiation Emergencies

Limit your stay in a contaminated area to as little time as possible. Keep as far away from the source as you can and involve as few rescuers as possible. (Exposure to radiation is cumulative and is determined by an inverse square relationship. That is, if you are twice as close, you will receive four times the exposure. If you move twice as far away, you cut your exposure by four times.)

Remember the priorities for hazardous materials emergencies listed earlier in this chapter: (1) protect the safety of all rescuers and patients; (2) provide patient care; and (3) decontaminate clothing, equipment, and the vehicle. Keeping these priorities in mind, follow the guidelines for scene safety, patient care, and personal decontamination that are outlined next.

**Scene Safety.** First establish scene safety. Follow these guidelines:

1. As you approach the accident scene in your vehicle, visually survey the area for the radiation symbol on the sides of vehicles, machinery, or containers involved (Figure 44-10). Determine the location of a possible source of radiation. Be alert for the presence of other hazardous materials as well. If you determine

**FIGURE 44-10** Radiation hazard labels.
that radiation is a possibility, park your vehicle upwind of the accident to reduce the chance of radiation particles being blown to your location. Do not park near any liquid spills or near any transport vehicle that may be leaking. Do not park near any container that might have been cracked or damaged in the accident.

2. As soon as you suspect radiation and before you enter the suspected area of contamination, and if trained to an appropriate level, put on a positive pressure self-contained breathing apparatus plus protective clothing. Leave no skin or hair exposed. Wear several layers if you can, with an outer layer of tightly woven protective clothing. Seal all openings with duct tape. Wear a pair of protective gloves under a pair of heavy work gloves. Wear a pair of shoes covered by two pairs of paper shoe covers under a pair of heavy rubber boots.

**Personal Protection.** Protecting yourself from exposure to radiation includes consideration of the following factors:

- **Time.** The less time spent near the radiation source, the less radiation exposure.
- **Distance.** The farther you are from the radiation source, the lower the radiation dose.
- **Shielding.** The denser the material between you and the radiation source, the greater the protection. SCBA and protective clothing or simple examination gloves may be all that is required to adequately shield yourself from the radiation. In some cases, lead shields are required. Increasing the time and distance factors can reduce the amount of shielding needed.
- **Quantity.** Decreasing the amount of radioactive material in the area will decrease exposure. Remove the patient from the radioactive material or remove the radioactive material from the patient.

**Patient Care.** Emergency care for a patient with radiation exposure must center on the patient’s immediate life threats and injuries and not on the radiation itself. Remove the patient from the source of radiation as quickly as possible. Conduct a primary assessment and a secondary assessment and manage injuries or medical conditions as you normally would. Consult with medical direction and the poison control center when radioactive contamination is a concern.

**Personal Decontamination.** After providing the necessary patient care, transport, and transfer of the patient to the hospital, turn your attention to your own personal decontamination. Report and document your exposure to the radiation source and follow the recommendations of the hospital or local protocol for personal decontamination.

**Vehicle/Equipment Decontamination.** Any equipment that you used to care for the patient—including blankets, towels, bandages, cots, stretchers, or equipment used in transportation—must be checked for radiation contamination before it can be used again. Authorities at the hospital or medical center can arrange for an equipment check.

The vehicle used to transport the patient needs to be washed inside and out before it is placed back in service. Any radioactive dust must be removed from the vehicle. Pay special attention to the tires and other contact points. You may need to use a commercial decontamination solution on your equipment (never use one on the skin). Follow local protocol.

If equipment or tools cannot be completely decontaminated, they will need to be disposed of. Signs of incomplete decontamination include debris adhering to the equipment, discoloration, corrosion, and stains.

**Problems Caused by Radiation**

Radiation is a general term that describes energy transmission. There are three general kinds of problems caused by radiation: radiation sickness, radiation injury, and radiation poisoning.

Radiation sickness is caused by exposure to large amounts of radiation. Symptoms start anywhere from a few hours to days following exposure to the radiation and, depending on the dose, can last anywhere from a few days to seven or eight weeks. In fact, the amount of time between radiation exposure and the onset of symptoms is a relatively reliable indicator of how much radiation a person has absorbed. Common signs and symptoms include nausea and vomiting, diarrhea, hemorrhage, weight loss, appetite loss, malaise, fever, and sores in the throat and mouth. Radiation sickness also affects the immune system, lowering resistance to disease and infection.

Radiation injury is a local injury that is generally caused by exposure to large amounts of less penetrating particles, such as beta particles. General signs and symptoms include hair loss, skin burns (Figure 44-11), and generalized skin lesions.

Radiation poisoning occurs when the patient has been exposed to dangerous amounts of internal radiation. The result is a host of serious diseases, including cancer and anemia.

![Figure 44-11]( Radiation burn.)
While a victim of a radiation accident is not "contagious" or infectious and generally will not endanger a rescuer, you are at risk of becoming contaminated if the patient still has radiation particles on his skin or clothing. Always put on full protective gear as soon as you recognize a radiation accident.

Protection from Radiation
As you approach the scene of an accident, protect yourself and other rescuers if you know ahead of time that radiation sources are present. Immediately contact the Radiation Safety Officer or Emergency Management Agency within your jurisdiction.

The following factors determine the amount of radiation damage that you may sustain during a rescue if an unshielded radiation source is present in the vicinity:

- The amount and type of personal shielding you use
- The strength of the radiation source
- Your distance from the radiation source
- The type of radiation
- How long you are exposed
- How much of your body is exposed

You can reduce your risk. The best approach is to divide the rescue work among many rescuers, with teams composed of as few rescuers as possible. The Federal Nuclear Regulatory Commission recommends that an individual in an emergency situation, while engaged in activities deemed necessary for the preservation of life, be exposed to no more than a one-time whole-body dose of 25 roentgens. This means that if the Geiger counter at the patient’s location indicates 50 roentgens per hour, then a new team of rescuers should move in and relieve the first team after 30 minutes.

Another approach to reducing risk is to shield the radiation source itself (not you or the patient). For example, the best protection against gamma rays (one type of radiation that is extremely dangerous) is lead, preferably 1–2 inches thick. If lead is not available, any material that has thick mass (such as bricks, concrete, or several feet of dirt) will do.

Know your community’s plan for hazardous materials emergencies. Know how to reach your Radiation Safety Officer. Always wear your protective gear, including a self-contained breathing apparatus, as soon as you suspect the involvement of radiation. Never smoke in an area where radiation has contaminated the air, and do not eat food that comes from a contamination site. (Smoking and eating are the two most common ways to become internally contaminated.)

Terrorist Attacks Involving Weapons of Mass Destruction
The threat of a terrorist attack has heightened the awareness of a need to better prepare EMTs to respond to incidents involving weapons of mass destruction (WMD) including nuclear devices, biological agents, and chemicals. The more common chemicals that could be used by a terrorist are listed in Class 2 Toxic and Flammable Gases, Class 6 Toxic and Infectious Substances, or Class 7 Radioactive Materials (review Table 43-1). It is recommended that EMTs and other EMS personnel enroll in a counter-terrorism class. See also Chapter 46, “EMS Response to Terrorism Involving Weapons of Mass Destruction.”
Hazardous Materials Protective Equipment

■ 44-1A  Assisting with a self-contained breathing apparatus (SCBA).

■ 44-1B  An airtight seal must be achieved when putting on the mask.

■ 44-1C  The hazmat suit must be sealed at the wrists and ankles.

■ 44-1D  Hazmat team, fully suited.

■ 44-1E  Using sensors to detect hazardous materials.
SUMMARY

A hazardous material is a substance that in any quantity can pose a threat or risk to life, health, or property. Hazardous material is identified by placards and shipping papers. Do not use your senses in an attempt to identify the hazardous material since some may be odorless and colorless. There are several resources available to responding emergency personnel to assist in the identification of the hazardous material and to determine the threat to life, health, and property. It is important that emergency responders are trained at some level of hazardous material response. Most EMS personnel are trained to the First Responder Awareness level. This primarily is designed to provide information to keep the EMS personnel safe at the scene. Awareness-level responders should always adhere to the RAIN principles (recognize, avoid, isolate, notify).

General priorities of hazardous materials scene management are to protect the safety of rescuers and patients; provide patient care; and decontaminate clothing, equipment, and the vehicle. Preincident planning is a key in getting all of the responding emergency personnel to work together effectively.

Three zones must be established at the scene: hot zone, warm zone, and cold zone. Only those with specialized protective equipment are allowed in the hot or warm zone. EMTs without specific hazardous materials operations or technician training must stay in the cold zone. The patient will be delivered to you in the cold zone once decontamination has occurred.

Case Study Follow-up

Scene Size-up
You have been dispatched to a multiple-vehicle accident involving a tanker truck and passenger vehicle. In addition to the injuries to the patients caused by the impact, you realize that the tanker may pose a possible hazardous materials emergency. As your partner decides on a safe place to park—uphill, upwind, and away from the potential danger—you pull out your Emergency Response Guidebook.

From your present safe position, you note the size and shape of the tank and, with binoculars, search for some form of identification. You finally recognize one—a “Flammable Liquid” placard. Using your guidebook, you find that danger can come from fire or explosion and you realize that everyone at the scene needs to make sure they don’t accidentally start one with an open flame, heat, or sparks. Continuing to size up the scene, you look for signs of damage to the container. You spot a small leak and vapors.

You report to incident command. Just as you exit your vehicle, the fire department arrives and begins to set up an entry and decontamination area.

Primary Assessment
You observe the patients as they begin to walk toward the EMS unit. Your general impression is of a male and female in their 40s, neither of whom looks very steady. They were exposed to the vapors, so they are probably dizzy.

Over the loudspeaker, incident command instructs the patients to stop where they are. Their clothes are contaminated, and they must strip. They don’t need much convincing. They can smell the vapors. The patients are soon in the decontamination area being washed down, with rescuers holding manual in-line stabilization.

Once the patients have been decontaminated and are in clean clothes, you and your partner complete the primary assessment while an Emergency Medical Responder continues to hold manual in-line stabilization. Both patients are talking coherently and so you conclude that they are alert and have open airways. Their breathing rates are slightly rapid but adequate. Pulses for both are present, strong, regular, and slightly rapid. Skin color, temperature, and condition are normal. There is no bleeding. Because you are concerned about toxic inhalation, you provide both patients oxygen by nonrebreather mask at 15 lpm. You conclude that neither patient is a high priority for immediate transport and you can continue with the secondary assessment at the scene.

Secondary Assessment
You and your partner perform a secondary assessment on both patients. Neither appears to have been injured, but since the mechanism of injury was significant (the collision with the truck), you apply cervical spine immobilization collars and immobilize each patient to a long spine board. You take vital signs—all are within normal ranges for both patients—and gather a history. The only symptom either patient reports is dizziness. Neither reports any allergies. The female is taking no medications; the male is taking a medication for high blood pressure. Neither has any pertinent past medical history except for the blood pressure problem. Their last meal was lunch at a fast food restaurant just before the collision. Events leading to the present problem are obvious to all.

continued
**IN REVIEW**

1. List clues that tell you a hazardous material may be present at an accident scene.
2. Name the first thing an EMT should do after recognizing that hazardous materials might be involved in an accident.
3. Explain what qualifies the EMT to attempt a hazardous materials rescue.
4. List specific actions you can take to protect bystanders.
5. If you have had no specialized training, explain what you should do while waiting for expert help to arrive.
6. List the resources available to the EMT at the site of a hazardous materials emergency.
7. Explain what you can do to protect yourself, others, and your vehicle from contamination.
8. List the “safety zones” and describe what work should be done in each.
9. List the information that is necessary for trained personnel to decide on a course of action at a hazardous materials emergency.
10. Name the required elements of an incident management plan.

**CRITICAL THINKING**

You are called to the scene for a factory worker who has collapsed in a storage area. As you arrive on the scene, the foreman tells you that the storage facility contains a large number of hazardous chemicals in containers. He states that a leaking chemical container was found in the storage area. He is not sure if the patient was exposed to a leaking chemical or if he suffered some other medical problem. As you look around the corner, you note the patient is not moving and is lying in a prone position. No odors or vapors are noted in the area.

1. What would be your first action?
2. How would you manage the scene?
3. Would you call for any additional resources? If so, who?
4. When would you begin your emergency care for the patient?

Another ambulance arrives at the scene. Both ambulance crews cover the stretchers and other items in the ambulance with thick plastic. Each patient is loaded onto a plastic-covered wheeled stretcher and transferred to one of the ambulances for transport.

**Reassessment**

Since your patient is stable, a reassessment is needed only every 15 minutes. Transport time is relatively short, so you have time to perform only one reassessment en route. You repeat the primary assessment, the secondary assessment, and vital signs measurements. You check that the patient is still securely immobilized and that oxygen is flowing adequately. You arrive at the hospital without any change in the patient’s condition. You and your partner transfer the patient to the care of the emergency department personnel, complete your oral and written reports, and then proceed to decontaminate yourselves and the ambulance.

**Case Study Follow-up continued**
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • EMS Operations** (Content Area: Multiple-Casualty Incidents)

**COMPETENCY •** Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

**OBJECTIVES **• After reading this chapter, you should be able to:

45-1. Define key terms introduced in this chapter.
45-2. List situations that might result in multiple trauma casualties and situations that might result in multiple medical casualties.
45-3. List aspects important to effective management of an MCI.
45-4. Explain the purposes for establishment of the National Incident Management System (NIMS).
45-5. Describe the purposes and desirable features of the incident command system (ICS).
45-6. Identify responsibilities that may be assigned to EMS (units that might be established) at a multiple-casualty incident.
45-7. Describe the principles of a triage system.
45-8. Describe and contrast primary triage with secondary triage.
45-9. Given a scenario with multiple patients, categorize patients according to a color-coded triage system.
45-10. Explain the principles and assessment categories used in START triage.
45-11. Explain why JumpSTART was developed for triage of pediatric patients, contrast JumpSTART with START, and explain how to identify a "child" for triage purposes at the scene of an MCI.
45-12. Explain the important principles of a patient-tagging system to be used during triage.
45-13. Explain the interrelationship of triage and treatment within the treatment unit at an MCI.
45-14. Discuss the logistics of staging and transport at an MCI.
45-15. Discuss common issues with communications in MCI and disaster situations.
45-16. List measures that can be taken to reduce rescuer stress during and after an MCI response.
45-17. Describe requirements of effective disaster assistance.
45-18. Anticipate psychological reactions of disaster victims and describe ways in which EMS providers can assist disaster survivors.

**KEY TERMS **• Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

Case Study

The Dispatch
EMS Unit 105—respond to the Firebird Raceway—we have reports that two race cars have crashed through a fence into a bleacher full of people. Initial reports indicate as many as 10 dead and 40 critical injuries. Time out is 1612 hours.

Upon Arrival
While en route to the scene, you request dispatch to activate the multiple-casualty incident plan. Dispatch advises you they are contacting appropriate emergency response agencies from the call-up list and that area hospitals have been notified.

Upon arrival, you see two demolished vehicles in the midst of a collapsed bleacher. Bystanders are helping the injured. People scream for your help. You estimate there are at least 50 injuries. Since you are the senior EMT, according to your multiple-casualty incident plan you are the incident manager for EMS operations.

How would you begin your assessment and emergency care in this multiple-casualty incident?

During this chapter, you will learn about the roles and responsibilities of an EMT during a multiple-casualty incident. Later we will return to the case study and apply the principles you have learned.

INTRODUCTION
This chapter provides an overview of how to organize and provide emergency medical care when there is an event that involves a number of patients: a multiple-casualty incident, or MCI. The number of patients required to declare an MCI varies with the jurisdiction and the availability of resources. MCIs may range from a vehicle collision with several injured passengers to a major disaster such as a hurricane, flood, earthquake, bombing, building collapse, or airliner crash. For a more advanced understanding of MCIs and disaster response, you must regularly practice your community’s MCI or disaster response plan.

In this chapter you will learn the fundamentals of MCI response, but these fundamentals must be adapted to your own region. You will learn about the incident management system, EMS units, triage, components of a disaster response plan, and—most importantly—how to get the right patient to the right hospital in the right amount of time.

MULTIPLE-CASUALTY INCIDENTS
A multiple-casualty incident (MCI)—sometimes called a mass casualty incident or a multiple-casualty situation (MCS)—is any event that places excessive demands on personnel and equipment. Typically, an MCI involves three or more patients. A multiple-patient incident with three patients may be routine in a large metropolitan area, but three critically injured patients can quickly overwhelm a small community or rural area with limited resources and personnel.

Motor vehicle crashes, gang-related violence, or apartment fires are just some of the situations in which you may encounter multiple patients. But MCIs do not always involve trauma patients. Your MCI plan should prepare you to manage the multiple-patient incident involving food poisoning, toxic gas inhalation, and in some parts of the nation, refugee influx.

In any MCI, the key to effective emergency care is to call for plenty of help. Make sure that you call for enough, or more than enough, rescuers with advanced lifesaving skills as soon as you encounter the incident. Remember: It’s better to call too many rescuers than too few.

Getting help, however, is only one aspect of managing the multiple-casualty incident. Effective management of MCIs consists of getting enough help, positioning vehicles properly, giving appropriate emergency medical care, transporting patients efficiently, and providing follow-up care at receiving facilities.

NATIONAL INCIDENT MANAGEMENT SYSTEM
In February 2003, President George W. Bush signed Homeland Security Presidential Directive #5 (HSPD5), which authorized the Secretary of Homeland Security to develop and administer the National Incident Management System (NIMS). NIMS provides for a consistent approach to managing disasters by all responders to the incident that may include emergency response personnel and local, state, and federal government agencies and employees. The incident command system (ICS), which provides a standardized approach of management for mass casualty incidents, is a subset of the NIMS.

NIMS provides for two main components: flexibility and standardization. These two components are the keys to managing any disaster and ensuring cooperation and operability between various agencies. Every agency that may respond to a disaster was required to become NIMS-compliant through the completion of training in basic incident command systems and the National Incident
Management System by September 2006. This training is intended to ensure that all responders comprehend and employ the same terminology and have a standardized knowledge of the incident command system. However, this is only the beginning of NIMS compliance. Agencies and responders must also participate in preparedness standardization. The components of preparedness standardization are planning, training, mutual aid agreements, and preparedness exercises involving multiple response agencies. Preparedness standardization is intended to lessen the confusion as to who is in charge in multiple-casualty incidents, to facilitate the building of working interdepartmental relationships, and to provide responders experience in the incident management system.

These are the building blocks that provide a strong foundation for effective management of a multiple-casualty incident or a disaster. Relationships built during training and preparedness exercises assist in eliminating unrealistic expectations of responders and agencies. (After-action reviews following Hurricane Katrina [Figure 45-1]—which devastated New Orleans and the Gulf Coast in 2005—revealed that, when everything else seemed to fail, the relationships that had been developed during the preparedness phase did work to the advantage of the responders and agencies. These relationships led to resolutions of issues that were initially not apparent.) Completing training exercises in a controlled environment provides experience to responders and leads to the certification and qualification that is necessary to manage a disaster or multiple-casualty situation. The training exercises help identify and resolve problems with the disaster and multiple-casualty plans before an event actually occurs.

NIMS is the template—the gold standard—in incident management systems and command. When implemented, it helps prevent disaster response and management from becoming their own disaster and allows responders to do the greatest good for the greatest number of people affected by the incident.

Incident Command System

The incident command system (ICS) is an incident management concept that has become the standard for on-scene management of disasters and multiple-casualty incidents. As a standardized command system used among all of the responding agencies, ICS allows flexibility within the structure of the system to meet the needs of the incident regardless of the complexity and type of incident. The purpose of ICS is to use best management practices to ensure:

- The safety of the emergency responders and others
- The achievement of tactical objectives
- The efficient use of resources

Features of ICS that make it a desirable and effective system are as follows:

- *Common terminology is used, including standardization of titles for facilities and positions. Plain English
is used for all communication. Codes or agency-specific jargon has been eliminated. This lessens confusion and promotes straightforward communication among responders and agencies.

- Common designations are assigned to all organizational resources including personnel, facilities, equipment, and supplies to avoid confusion and increase operational effectiveness between responders and agencies.
- Manageable spans of control are used to maintain control of the incident.
- Incident facilities are identified by common terminology with specific activities and functions performed at each facility. Also identified are which members of the ICS can be found at each facility. Incident facilities include the incident command post, staging areas, base camp, helibase, and helispots. Only the facilities needed to manage the incident will be established.
- Distinct titles are used. Only the incident commander is called “commander” (Figure 45-2). Section leaders or heads are called “chiefs.” The incident commander is responsible for coordinating all aspects of the incident. The incident commander must have the necessary training, experience, and expertise to serve in this capacity. The highest ranking officer is not always the incident commander. With standard terminology, it is clearly understood what position each person holds and what duties he is expected to perform.
- Incident action plans (IAPs) identify the objectives to be accomplished during the incident. IAPs are used to issue assignments, plans, procedures, and protocols. The results of the objectives are documented and reported so that they can be used in further planning.
- An integrated communications approach is organized so that information can be transferred within the command structure and outside of the command structure.
- Accountability applies at all levels and within all functional areas. Knowing in advance who is accountable to whom provides an orderly chain of command and makes it easier for responders to check in, regardless of their home agency. Each responder is assigned to only one designated supervisor, the person to whom that responder is accountable.

The incident command system has several designated sections. They are:

- Command
- Finance/administration
- Logistics
- Operations
- Planning

Incident command is typically assumed by the most experienced and senior member of the first emergency service arriving on the scene. Thus, it may be the most senior EMT on the EMS unit that is initially assuming incident command. Incident command can be transferred to the most qualified individual; however, this transfer must be done in a highly organized and informed manner.

Upon arrival at the scene, the initial action of scene size-up and triage may be conducted until additional resources arrive. When additional resources arrive, the incident commander will begin to organize and delegate the responsibilities of the various established branches depending on the scale of the multiple-casualty incident. In a unified command structure, police, fire, and EMS would each be represented and would establish one unified command. Each service would then likely be established under the operations section and retain its autonomy. The unified incident commanders of the three agencies would work together in one command post to solve problems and direct the management of the incident.

The incident commander can choose to establish a number of branches within the structure. These branches are managed by branch directors, who report to a section chief. As an example, the EMS branch director would be responsible for managing all triage, treatment, and transportation of patients within his operation. He would report to the operations chief, who in turn would report to the incident commander. In a large-scale multiple-casualty incident, the EMS branch director would typically assign a unit leader referred to as the leader or supervisor to the triage unit, treatment unit, transport unit, staging unit, and morgue unit (Figure 45-3). Each unit may also be referred to as an area, sector, or section. Each leader would supervise the activity within his unit to ensure effective and efficient management of patients and casualties. As an EMT working in any of these areas, you would report to the unit leader, who reports to the EMS branch director.

The responsibilities of the EMS units might include:

- Triage unit. This unit sorts patients by criticality and assigns priorities for emergency care and transport.
- Treatment unit. Emergency care is provided to patients in this unit. This is done based on the priority assigned to the patient by the triage unit.
- Transport unit. In this unit, patients are moved to ambulances or helicopters for transportation to a medical facility, and communications are organized to notify the receiving medical facilities.
- Staging unit. Ambulances, helicopters, and additional equipment are held in this area until they are ready to transport a patient.
assigned to a particular task. Sometimes a supply unit is established as part of or separately from the staging unit to gather and distribute supplies and equipment required by all units.

- Morgue unit. Deceased casualties are moved to this unit where they are held and processed.

As a responding EMT, you will report to the incident commander and wait for an assignment. You would likely be assigned to the operations section that deals with emergency care of the patients. If qualified, you may be assigned as a section chief or a unit leader. In a smaller-scale incident, the command structure for EMS would typically include the incident commander, the operations section chief, and the triage, treatment, and transport unit leaders (Figure 45-4).

**Triage**

During the early phases of an MCI, you may be directed to assist in triage. Triage is a system used for sorting patients to determine the order in which they will receive medical care or transportation to definitive care. Basically, triage determines which persons need immediate emergency care in order to survive their injuries, which patients will live with a delay in emergency medical care, and which patients will die regardless of the emergency care provided. Triage is one of the first functions performed at the scene of a multiple-casualty incident and has a direct effect on all other aspects of the operation (Figure 45-5).

**Primary and Secondary Triage**

There are typically two phases or types of triage that are conducted at the scene of a multiple-casualty incident. Primary triage occurs immediately upon the arrival of the first EMS crew.

This triage is usually conducted at the actual site of the incident, provided the scene is safe. For example, primary triage in the case of a bus rollover would be conducted inside the vehicle, provided the bus is properly stabilized and free of safety hazards. The primary triage is done quickly and provides a basic categorization of the severity of the patients involved in the incident.
Once the patients are moved from the scene to the triage unit, the secondary triage occurs. The secondary triage is designed to reevaluate the patient categorization, during which the patient may be upgraded to a higher priority, downgraded to a lower priority, or kept at the same priority status. This occurs as the patient is brought into the triage unit and the triage unit leader performs the reassessment of the patient to categorize him for treatment and transport. During the treatment phase, the patient is retriaged and may be recategorized as a higher or lower priority.

Typically, the most knowledgeable and experienced EMT arriving on the scene will perform the initial triage of the patients; however, all EMS personnel must be trained to triage patients at a multiple-casualty incident. All EMS units must carry the necessary triage equipment to allow for prompt recognition of priority status of patients.

The patients are usually tagged as red, yellow, green, or black with colored ribbon or tape for easy recognition by rescue crews for removal of patients according to priority. The person performing primary triage is also responsible for providing an initial report back to the EMS commander, who may be one of the first-arriving EMTs acting in the position at this time, regarding the estimated number of patients and resources needed at the scene.

The universally recognized triage categorizations by color are:

<table>
<thead>
<tr>
<th>Color</th>
<th>Category</th>
<th>Priority Status</th>
</tr>
</thead>
<tbody>
<tr>
<td>Red</td>
<td>Immediate care and transport necessary</td>
<td>Priority 1 (P-1)</td>
</tr>
<tr>
<td>Yellow</td>
<td>Delayed emergency care and transport</td>
<td>Priority 2 (P-2)</td>
</tr>
<tr>
<td>Green</td>
<td>Minor injuries and ambulatory patients</td>
<td>Priority 3 (P-3)</td>
</tr>
<tr>
<td>Black</td>
<td>Deceased or fatal injuries</td>
<td>Priority 4 (P-4)</td>
</tr>
</tbody>
</table>

The START triage is performed primarily to initially categorize patients for priority movement to the triage unit. It should not take you more than 30 seconds per patient to complete. The three basic categories...
assessed in START, easily remembered by the mnemonic RPM, are:
- Respiratory status
- Perfusion status
- Mental status

**Ability to Walk (Ambulatory or “Walking Wounded”)**

Upon initial triage, any patients who are already up walking around the scene and those who indicate that they are able to get up and walk should be collected and moved to a safe area. Any patient who is able to walk, despite the injuries he has suffered, is considered to be a lower priority initially and is tagged “green.” A green tag, ribbon, tape, or other identifier is placed on each ambulatory patient. These patients are then moved to one site and confined there. Do not allow them to continue to walk around the scene. These patients will be reevaluated in the triage unit but will be the last to be treated in the treatment unit and moved from the scene to the hospital.

**Respirations**

Begin assessing the nonwalking patients by looking, listening, and feeling for respiratory effort. If the patient is breathing and the respiratory rate is greater than 30 respirations per minute, tag the patient as “red” and move on to the next patient. If the respirations are less than 30 per minute, move on to assess perfusion. If there are no respirations present upon assessment, open the airway. Upon opening the airway, if the patient begins to breathe, determine the respiratory rate. If the respiratory rate is greater than 30 per minute, tag “red” and move on. If the patient’s respirations are less than 30 per minute,
and he is breathing, assess his perfusion status. If the respirations are shallow or inadequate and require assistance, tag “red” and move on to the next patient. If you open the airway in the patient who is not breathing and he has no respiratory effort, tag the patient as “black” (deceased) and move on to the next patient.

**Perfusion**

Perfusion status is determined by assessing the capillary refill and radial pulse. If the capillary refill is less than 2 seconds and the radial pulse is present, go to the neurological assessment. If the capillary refill is greater than 2 seconds or the radial pulse is absent, tag the patient “red” and move on to the next patient. Keep in mind that a 2-second capillary refill time is subject to many factors, including age, sex, and environmental considerations; therefore, the radial pulse may be a better indicator in assessment of perfusion.

**Mental Status**

The last component to assess is the mental or neurological status of the patient. At this point, if you are assessing the neurological status of the patient, he will have had a respiratory rate less than 30 per minute with adequate respirations, a radial pulse, and a capillary refill of less than 2 seconds. Ask the patient to squeeze your fingers. If the patient obeys your command, tag him “yellow” and move on to the next patient. If the patient is not alert, does not obey your commands, or is unresponsive, tag him “red” and move on to the next patient.

**JumpSTART Pediatric Triage System**

The START triage system does not take into account the physiological differences between adult patients and young children. Therefore, the START triage system may be applied erroneously to these young patients. Often, the EMT may overtriage a child patient, expending an unnecessary amount of time triaging or providing extensive initial care because of the EMT’s own insecurities when dealing with pediatric patients.

In order to facilitate triage in young children, Dr. Lou Romig developed JumpSTART, a triage system specifically for pediatric patients (Figure 45-7 ■). Dr. Romig now recommends that JumpSTART be used on any patient who appears to be a child and that START be used on any patient who appears to be a young adult or older. The lower end of the age range is used to capture those children who are usually able to walk. Infants (less than 12 months) have significant physiological variations in vital signs; therefore, the JumpSTART system is not designed for them.

Infants less than 1 year of age could be triaged using JumpSTART; however, more screening may be necessary. If all of the criteria point to the “delay” category, and there are no obvious external injuries, the infant may be categorized as “ambulatory.” If the patient looks like a young adult, use the START system. If the patient looks like a child, use JumpSTART.

The reason for the use of JumpSTART in pediatric patients is primarily some physiological differences in young children as compared to adults. In the adult patient, respiratory failure due to a traumatic event usually occurs after severe blood loss with circulatory failure or severe head injury. Thus, an adult patient in respiratory arrest has more than likely suffered a significant amount
of cardiac damage from hypoperfusion and hypoxia that makes his condition beyond saving.

In a child, it is usually the opposite. The child will typically go into respiratory arrest, followed by circulatory failure and cardiac arrest. Respiratory arrest in a young child may occur rapidly after shorter periods of hypoxia. The child could be apneic (not breathing) and the pulse could be present because the child has not yet become extremely hypoxic. During this period, opening the airway and providing ventilation to the child may stimulate spontaneous ventilation until more emergency care can be provided. This brief provision of ventilation to the child is considered the “jumpstart” for the child to start breathing on his own.

JumpSTART uses the same categories as START. You would assess the following:

- Respiratory status
- Perfusion status
- Mental status

The JumpSTART triage system should take no more than 15 seconds to perform on each pediatric patient.

JumpSTART Ambulatory Assessment

Any patient who is walking around the scene should be directed or escorted to the “green” area for secondary triage. Children who are developmentally unable to walk and are still at the scene will be screened using the JumpSTART system. If they do not meet any of the “immediate” criteria, they should be tagged as “green” and moved to that area for further assessment and treatment.

Children with special needs should be considered the same as the developmentally unable to walk and should be triaged at the scene the same as the very young child who can’t walk yet.

JumpSTART Breathing Assessment

If the child is breathing, assess the respiratory rate. If the breathing is between 15 and 45 breaths per minute, assess the pulse. If the patient is breathing spontaneously and the breathing rate is less than 15 per minute, greater than 45 per minute, or irregular, tag the patient “red” and move on to the next patient. If there is no breathing or it is very irregular, open the airway using a manual maneuver. If the airway maneuver causes the patient to begin to breathe spontaneously, tag the patient “red” and move on to another patient. If there is no breathing after opening the airway, check for a peripheral pulse. If the pulse is absent, tag the patient “black” and move on to another patient. If a pulse is present after opening the airway and finding no breathing, provide 15 seconds of mouth-to-mask ventilation (about five breaths). If the patient remains apneic (no breathing), tag the patient as “black” and move on to another patient. If breathing is restored after the “jumpstart,” tag the patient “red” and move on to the next patient.

JumpSTART Perfusion Assessment

If the peripheral pulse is palpable, assess the mental status. If no peripheral pulse is present, tag the patient “red” and move on to the next patient. The pulse should be checked in the least injured extremity. Capillary refill assessment is not performed.

JumpSTART Mental Status Assessment

Conduct a quick assessment of AVPU. If the child is alert, responds to voice, or responds to pain by localizing it, withdrawing from it, or trying to push it away, the patient is tagged “yellow” and placed in the delayed category. If the child is unresponsive to all stimuli or responds to pain with incomprehensible sounds or inappropriate movement (does not localize pain, or no purposeful flexion or extension), tag the child “red” and move on to the next patient.

Patient Tagging

Patient tagging or identification (Figures 45-8 and 45-9) is critical to the successful initial triage of every patient. Tagging the sick or injured helps arriving EMTs quickly and efficiently identify treatment priorities. The tagging system should be easy to understand, standardized, and easily affixed to the patient:

- **Highest Priority/Red/Immediate.** The highest-level priority, “red,” is assigned to patients with the most critical injuries who may be able to survive the incident with quick treatment and transport. Notice that most of the red category abnormalities are correlated with the primary assessment. The red category is the same as the START/JumpSTART “immediate” category.

- **Second Priority/Yellow/Delayed.** The second-level priority, or “yellow,” is assigned to patients who are suffering severe injuries; however, some delay in treatment should still provide the patient a good chance of survival. The yellow category’s abnormalities would more closely correlate with those findings and life threats identified in the rapid trauma assessment. The yellow category is the same as the START/JumpSTART “delayed” category.

- **Lowest Priority/Green/Minor.** The lowest-level priority, or “green,” is assigned to injuries in which delay in treatment will not reduce the patient’s chance of survival. Fractures and soft tissue injuries without life-threatening bleeding commonly fall into this category. The green category is the same as the START/JumpSTART “minor” category.

- **Black/Deceased.** The final category, “black,” is reserved for those patients who will not survive, even with treatment, or who are already dead. For example,
Airway and breathing difficulties
Uncontrolled or severe bleeding
Decreased mental status
Severe medical problems: poisoning, diabetic and cardiac emergencies, etc.
Severe burns
Shock (hypoperfusion)

Primary Triage (Adult)
Breathing spontaneously after opening the airway
Respiratory rate > 30/minute
Capillary refill > 2 seconds
Doesn’t obey commands

(Pediatric)
Breathing after opening airway and after 5 rescue breaths
Respiratory rate < 15 or > 45/minute
No palpable pulse
Inappropriate posturing or unresponsive

Secondary Triage
Airway and breathing difficulties
Uncontrolled or severe bleeding
Decreased mental status
Severe medical problems: poisoning, diabetic and cardiac emergencies, etc.
Severe burns
Shock (hypoperfusion)

Primary Triage (Adult)
Unable to walk
Respiratory rate < 30/minute
Capillary refill < 2 seconds
Obeys commands

(Pediatric)
Unable to walk, if age-appropriate
Respiratory rate > 15 or < 45/minute
Palpable pulse
Alert or responds to verbal or painful stimuli

Secondary Triage
Burns without airway problems
Major or multiple bone or joint injuries
Back injuries with or without spinal cord damage

Primary Triage (Adult & Pediatric)
Able to walk
No breathing

(Pediatric)
Able to walk, if age-appropriate

Secondary Triage
Minor burns
Minor bone or joint injuries
Minor soft tissue injuries

Secondary Triage
Obviously dead
Will not survive

During an MCI, emergency personnel may respond from many miles and across many jurisdictions. If patients are to receive definitive care and transportation, then EMS personnel must have a universally understood triage identification tag system (Figure 45-10). The issue in triage and multiple-casualty incidents is to maximize the limited resources to do the most good for the most people. That is why patients in cardiac arrest at a mass casualty are immediately tagged as “black” or deceased. Realistically, it would require three EMTs to attempt to resuscitate a cardiac arrest patient. It makes no sense to use those three EMTs on a patient whose chance of survival is extremely low while neglecting others who could be effectively treated by those same three EMTs.

**Treatment**

A treatment unit or area should be designated close to the area where ambulances arrive. It should be on high ground and, if possible, covered and lighted. It should be safe from falling debris, a safe distance and upwind from the incident, and clearly marked. Use a tall flag if you have one. Depending on the size and scope of the MCI, it may be necessary to have more than one treatment unit.

a patient who has suffered a massive head injury with brain matter oozing from an open wound to the head has suffered a fatal wound and will not survive. It makes no sense to expend resources on a patient who has no chance of survival. The START/JumpSTART “deceased” category correlates to the black category.
Treat only salvageable patients. If color-coded triage tags, cards, or ribbons are used, the same colors should be used on color-coded flags that are erected at the triage units. Position patients in rows as they await treatment.

Since the dead are the last to be transported, establish a morgue unit. The morgue unit leader would coordinate the removal of bodies to the morgue with the coroner’s office or its representative. You should become familiar with your local plan for dealing with the dead.

If you are working in the treatment unit, a key concept to remember is to provide only necessary care to manage non-life-threatening injuries. For example, immobilize patients to long boards instead of trying to splint each individual extremity injury. Give a patient who is able a 4 × 4 dressing and ask him to apply direct pressure to a bleeding wound—his own or someone else’s. Once the highest-priority patients have been stabilized, move to the second-priority patients.

The triage, treatment, and transport unit leaders should remain in constant communication with each other regarding transport availability and needs. Become familiar with and follow local protocol.

Staging and Transport

Once patients have been properly assessed and cared for in the treatment unit, the triage process continues. Working closely together, the treatment, staging, and transport unit leaders make decisions regarding patient transport priorities.

To begin the process of transporting priority patients to the appropriate medical facility, a staging unit (Figure 45-11) is set up. A staging unit leader monitors, inventories, and directs available ambulances to the treatment unit at the request of the transport unit leader.

Patients should be moved from the triage unit to the treatment unit in order of their priority. Immobilize all patients before moving them, if necessary, and place them in rows according to their triage category.

Remember that triage is ongoing. Many patients’ categories will change as their conditions improve or deteriorate.
The transport unit leader ensures that ambulances are accessible and that transportation does not occur without the direction of the incident commander or operations section chief. The transport unit leader also coordinates patient transportation with the triage unit leader and communicates with the hospitals involved. The transport unit leader must consider the following when making decisions on where to transport each patient:

- Distribution of patients to each medical facility
- Surge capacity of each hospital or medical facility
- Need for transport to a specialty medical facility such as burn unit or pediatric emergency department
- Need for constant coordination and communication

To effectively transport patients of a multiple-casualty incident:

- As the highest-priority patients are stabilized (airway managed, life-threatening bleeding controlled), begin transport. Before and during transport, one or two triage leaders (depending on the number of patients) should move along the rows constantly, monitoring patients for a change in status.
- High-priority patients should be transported first, immediately after treatment; these serious patients should be evenly distributed among available hospitals.
- Before leaving the incident, EMTs should receive specific instructions from the transport unit leader or staging unit leader on how to leave the area (preferred route) and to which hospital to take the patients.
- If the routing in the area is complex, the staging leader should provide EMTs with marked maps to the appropriate hospital.
- As each ambulance leaves, the transport unit leader should radio the hospital that the ambulance is en route, briefly describing the injuries involved and giving an estimated time of arrival. Individual EMTs should not try to communicate with the hospital unless an emergency develops during transport. Individual ambulance communication will jam lines and cause confusion.
- When the only patients left at the site are ambulatory, consider loading them onto a bus that has been brought to the site for this purpose. Five to ten personnel carrying essential equipment (oxygen masks, suction equipment, emergency kits, and portable radio) should board the bus, and a fully equipped ambulance with its crew should lead the bus slowly and safely to an outlying hospital that has little or no patient load. If a patient on the bus suddenly deteriorates during the trip to the hospital, EMTs on board can handle the situation and, if necessary, call for intercept by another ambulance.

**Communications**

Effective communication between emergency responders is one of the most difficult aspects of a multiple-casualty incident. As an EMT, you can expect a variety of MCI communication difficulties. Upon your arrival at the scene of an MCI, oral communications between emergency responders may initially appear chaotic. Tasks are not always clear, and duties may not have been assigned.

Once an incident command system and mobile command center are established, the state of confusion will diminish. Throughout an MCI, you may also find radio communications of any kind difficult. Communication “dead spots,” frequency unavailability, and channel gridlock are a few of the more common radio communications problems you will encounter. These kinds of difficulties are mentioned to prepare you for the “real world” of patient care during an MCI. Don’t let communication difficulties distract you from your patient care. Plain English should be used in all communications at a multiple-casualty incident to avoid any miscommunication.

**Follow-Through**

When all patients have been moved from the incident scene, emergency personnel should go to hospitals to assist hospital personnel. However, the incident manager and an assistant should remain at the scene to supervise cleanup and complete restoration.

Once you arrive at the hospital, instructions for care and treatment will come from the facility’s incident manager. Depending on the size and nature of the MCI, some facilities may need your help, while other hospitals may have enough personnel to manage the MCI without your assistance. If your services are not needed, you should prepare your vehicle and equipment for other EMS calls. Update your dispatch center regarding your status and availability for response to additional calls.

**Reducing Posttraumatic and Cumulative Stress**

Psychological stress is acute at the scene of a multiple-casualty incident. Rescuers, too, react to disaster, often the same way patients do. Common are fears regarding personal safety, crying, anger, guilt, numbness, preoccupation with death, frustration, fatigue, and burnout. **Approximately two-thirds of all rescuers suffer long-term reactions.** Most rescuer reactions peak within about 1 week and then diminish. Approximately half of rescuers have recurrent dreams and repeated recollections of the disaster for weeks or months afterward. In some cases, the rescuer may not react at all, then react weeks or months later. Methods to reduce emergency personnel stress should be a part of the postincident standard operating procedures.

Any rescuer who breaks down or becomes hysterical during the incident operation should be removed immediately to a hospital; a rescuer who is injured or becomes ill during rescue operations should be treated
immediately and transported so that other rescuers can continue their work.

To reduce stress on yourself and other rescue personnel who report to you:

- Try not to get overwhelmed by the immensity of the incident. Carefully evaluate injuries and determine which patients should be cared for first. Then set about administering the aid, caring for patients one by one. This will help you maintain some calm and feel that you are making progress.
- As each rescue worker reports to the staffing area for assignment, he should be instructed to rest at regular intervals, maybe as often as once every 1 to 2 hours (Figure 45-12 ■). Follow local protocol. During rest periods, the rescuer should return to the staffing area (preferably an area that is away from the hub of the disaster), sit or lie down, have something to eat or drink, and relax as much as possible.
- If rest periods are effectively rotated, there will always be enough rescue workers to carry on disaster assistance, and the entire team will be rested and relieved periodically.
- Make sure that each rescue worker is fully aware of his exact assignment. Have a well-designed plan that enables you to fully utilize your personnel, and clearly explain to each worker what his responsibility is.
- Several workers in the staffing area should circulate among the rescue workers and watch for signs of physical exhaustion or stress. If one of the workers appears to be having problems, he should immediately be required to return to the staffing area and rest for a longer period than usual. After resting, a less stressful task should be assigned, possibly in another area of the disaster site.
- Make sure that rescue workers are assigned to tasks appropriate for their skills and experience. If there is a question about whether a certain worker can manage a task, don’t take the chance.
- Provide plenty of nourishing food and beverages; encourage rescue workers to eat and drink whenever necessary to keep up their strength.
- Encourage rescue workers to talk among themselves; talking helps relieve stress. This is a form of defusing that may be helpful at the scene of the incident to reduce stress. Discourage light-hearted conversation and joking, however—some patients as well as workers may be offended by it, increasing the stress level at the scene.
- Make sure that rescuers have the opportunity to talk with trained counselors after the incident. If your team has access to organized stress debriefing processes, make sure that all rescuers who worked on the disaster take advantage of this process.

**DISASTER MANAGEMENT**

In general, a disaster is a sudden catastrophic event that overwhelms natural order and causes great loss of property or life.

In a disaster, there is a great disparity between casualties and resources. It exceeds the capabilities of available management resources and may disrupt the community, the medical establishment, or both. It may be designated a disaster because of the overwhelming number of patients involved, or because just a few patients are so severely injured.

Disasters may be natural—such as hurricanes, earthquakes, floods, and tornadoes—or man-made—such as airline crashes, fires, toxic gas leaks, and nuclear accidents. The National Incident Management System and incident command systems apply to natural disasters.

Requirements of Effective Disaster Assistance

You think, “It can’t happen to me!” Yet, disasters do happen. Effective disaster assistance begins with emergency responders promoting the need for individual and community disaster preparedness. In general, effective disaster assistance requires:

- Preparation of the entire community; community members at large trained in basic life-supporting first aid and simple rescue procedures
- Careful preplanning
- The ability to quickly implement a plan
- Effective communications among responders
- The application of triage skills
- The ability to organize quickly and utilize fully all emergency personnel
- The ability to adapt the plan to meet special conditions, such as inclement weather or isolated locations
• A contingency plan that provides for shelter and transportation of people in an entire area, such as an entire community or county
• Doing the greatest good for the greatest number
• A plan that avoids simply relocating the disaster from the scene to the local hospital

Warning and Evacuation

In some cases, such as a hurricane or tornado, you may learn that a disaster is approaching and may have time to evacuate local residents. If you can conduct an orderly evacuation, you can prevent further injury, preserve life, and possibly protect property.

Relocation should, as much as possible, keep people in their natural social groupings. Make every effort to provide home-based relocation instead of relocating people to hospitals and clinics if they are not injured.

Alerts for the evacuation must be repeated often and with clarity. You must convince people that a disaster is really about to occur and that there is a substantial threat to their safety. At a minimum, the evacuation and warning message must contain the following information:

• The nature of the disaster and its estimated time of impact on the area; if possible, a description of the expected severity
• Safe routes to take out of the area
• Appropriate destinations for those who evacuate, indicating where food and shelter will be available

Use whatever means you have available to spread the message frequently and with urgency—by radio, television, roving police cars with loudspeakers, public address systems in buildings, and short-wave radios. Make sure that each message contains all pertinent details concerning the nature and impact of the disaster, how people should evacuate, which routes are safest, and where people should meet for assistance after evacuation.

Disaster Communications Systems

Critical to any successful rescue effort is an efficient communications system that includes a backup system in case the primary system fails. The specific system that you choose will depend on your area and requirements, but the following general guidelines apply to any disaster communications system:

• Establish details of the system ahead of time. The communications network should be a part of your disaster drill. Decide what radio frequency and kind of system you want, who will be responsible for operating it, and what equipment will be used.
• Appoint only one person at the scene of the disaster who will communicate to those outside the disaster area. It is usually best to use the disaster control chief. That person should be aware at all times of what is going on and can be a source of reliable information to the outside.
• The person who is designated to communicate should stay in touch with local hospitals and rescue units who may be called on to respond to the disaster. Make sure ahead of time that the person will have access to appropriate equipment to keep in touch with the outside.
• Area-wide communications are vital. They give people warning of an impending disaster and help people receive information regarding the status of family members, friends, and the community as a whole.
• Since it may be impossible to restore immediate telephone service to an area, establish a central location where people can register concerning their whereabouts, safety, health status, and so on.
• Make sure that information regarding road conditions, alternative routes, and closed roads is constantly monitored and communicated, especially in the case of a weather-related disaster.
• Constantly monitor and link all hospitals, trauma centers, burn centers, and clinics in the area so that you can determine which can receive more patients and when those patients can be transported to the specific facility. The status of hospitals will change constantly throughout and after the disaster; therefore, keep communications open.
• Do not allow emergency vehicle operators or EMTs who are en route to the hospital to communicate via radio to the hospital unless an emergency occurs en route. The person designated to take care of communications will contact the appropriate hospital as the ambulance leaves the disaster scene.
• If the disaster area is large, individual rescue workers should be equipped with portable radios so they can communicate with their commands.
• Include a recorder or some other device that will allow you to record and later reassess crucial communications.

The Psychological Impact of Disasters

Faced with the grim physical injuries that can accompany a disaster, it is difficult to remember that the psychological injuries can be severe—even among those not physically injured. The overwhelming reaction to disaster is a reaction to the loss of either life or property.

Almost all people experience fear; many also feel shaky, perspire profusely, become confused, and suffer irritability, anxiety, restlessness, fatigue, sleep disturbances, nightmares, difficulty concentrating, moodiness, suspiciousness, depression, nausea, vomiting, and
diarrhea. Survivors of a disaster often experience fear, anxiety, anger, guilt, shock, depression, denial, feelings of isolation, and vulnerability. All these reactions are normal. As soon as people begin working to remedy the disaster situation, their physical responses usually become less exaggerated, and they are able to work with less tension and fear.

**Helping Disaster Patients**

At high risk for severe emotional reactions are children, the elderly, those in poor physical or emotional health, individuals with disabilities, and those with a past loss or crisis.

The reactions of children depend on their age, individual disposition, family support, and community support:

- **Preschoolers** tend to cry, lose control of bowel and/or bladder, become confused, and suck their thumbs.
- **Elementary-age children** suffer extreme fears about their safety and show confusion, depression, headache, inability to concentrate, withdrawal, poor performance, and the tendency to fight with their peers.
- **Preadolescents and adolescents** may show the same reaction as elementary-age children, coupled with extreme aggression and stress that is severe enough to disrupt their lives.

While each disaster presents individual problems, the following general guidelines apply to any disaster:

- The families of patients need and deserve accurate information—something that is too often overlooked in the rush to begin emergency medical care. As soon as possible, assign several rescue workers to gather information and disseminate it to local radio and television stations so that psychological stress to other family members may be lessened.
- Reunite families as soon as possible. Emotional stress will be lessened once the patient is with family members, and family members may be able to provide you with critical medical history that may increase your ability to care for the patient.
- If the disaster involved a large number of people, group the patients with their families and neighbors. This will help reduce feelings of fear and alienation.
- Encourage patients to do necessary chores. Work can be therapeutic and should be used to help the patients get over their own problems.
- Provide a structure for the emotionally injured, and let them know your expectations. Tell the patient exactly what is happening—that he is suffering a temporary setback and will probably recover rapidly, and that meanwhile, you expect certain minimal tasks to be performed. For instance, direct the emotionally traumatized with basic commands such as “Let’s walk to the treatment unit.”
- Help patients confront the reality of the disaster. Help them work through their feelings. Encourage them to talk about the disaster and its long-term effects. Arrange for a group discussion where patients can exchange ideas as soon as physical needs are taken care of. If you sense that any patients are not facing reality or that expectations are much worse than reality, help them adjust their views.
- Don’t give false assurances. The patient needs help in facing problems and deciding how he will react to them, but he will need to face facts sooner or later. If the patient finds that you have lied, he may resist any further outside help, and the recovery period will probably be extensive.
- A patient may refuse offers of help because of cultural upbringing, threats to self-image, or an inaccurate concept of the seriousness of the situation. Explain that by accepting help no one is in any way admitting weakness. Make sure it is understood that the help (and, therefore, the patient’s dependency) is only temporary and that as soon as things are under control the patient may be needed to help someone else.
- Identify high-risk patients: the elderly, children, the bereaved, those with prior psychiatric illness, those with multiple stresses, those with low or no support systems, those from low socioeconomic backgrounds, and those with severe injuries. Target these people for immediate crisis intervention care.
- Identify people who are in a unique position to help people in need, and recruit them for psychological emergency care.
- Arrange for all those involved in the disaster—including rescuers—to get good follow-up care and support.
SUMMARY

Response to a multiple-casualty incident (MCI) requires standardized preplanning and training in order for the incident to be managed effectively and efficiently. The National Incident Management System (NIMS) has been established to standardize many aspects of disaster and MCI response and activities. Part of the NIMS structure is an incident command system (ICS) that clearly identifies the authority and responsibilities for activities occurring at a disaster or MCI. There is only one designated incident commander at the scene. The incident commander may establish finance/administration, logistics, operations, and planning sections and chiefs as necessary. The section chiefs, in turn, can establish units and unit leaders. Most often in an MCI, EMS and chiefs as necessary. The section chiefs, in turn, can establish units and unit leaders. Most often in an MCI, EMS units and unit leaders. Most often in an MCI, EMS units and unit leaders.

Triage is a system of sorting patients based on the criticality of their injuries. The START triage system is commonly used to triage adults and young adults, while JumpSTART is used for children. Once triage has occurred, the patients are tagged according to their priority. Red identifies the highest-priority patients, yellow the next priority, and green the lowest priority. Patients tagged with a black tag are either already deceased or have mortal injuries with no chance of survival. Patients are moved into and out of the treatment unit based on their triage designation.

Multiple-casualty incidents and disasters could prove to be very stressful to emergency responders. Be sure to recognize signs of stress and seek assistance, if necessary.

Case Study Follow-up

Scene Size-up

You have been dispatched to the Firebird Raceway, where two race cars have crashed into a bleacher. As you arrive at the raceway, you perform a quick scene size-up. Raceway officials have extinguished the fires caused by the race cars. However, many people have been seriously burned. You decide the scene is safe to enter. You see bystanders are trying to give aid to the injured on the unstable bleachers. Using your vehicle’s PA system, you direct the bystanders off the bleachers. You tell them rescue personnel will be here in moments.

Your local plan has predesignated you the incident commander during an MCI or disaster. You estimate at least 50 patients and begin to establish a mobile command center within a safe range of the crash. Next you and your partner, Judy Eibers, put on unit leader identification vests and set up the incident command center flag.

You confirm with dispatch the nature of the event, the precise location, and your best estimate of the total number of patients. You also request at least 20 ambulances. Because many of the patients appear entangled in the metal bleachers, you request at least 10 rescue units with medium to heavy extrication equipment. This may be more equipment and vehicles than you need, but you know it is better to have too many resources than not enough.

In preparation for arriving vehicles, equipment, and personnel, you establish an extrication unit, a treatment unit, a transport unit, a staging unit, a supply unit, and a triage unit.

Using your vehicle as the mobile command center, you contact incoming units and begin assigning a leader to each unit.

Triage

While you are busy communicating with incoming emergency personnel, Judy has started initial triage, using the START system. Using a bullhorn, she directs those patients who are able to walk (green, or priority 3) to a safe area away from the bleachers. She counts at least 10 people who are able to walk away. She knows that, for now, these patients have adequate airways and circulation. Additional EMTs arrive and set up a treatment unit. You have the red, priority 1 patients, many of whom have severe burns and airway problems, moved to the triage/treatment unit first.

Supply and Extrication Units

While the initial triage phase continues, you work closely with the supply and extrication leaders who have been assigned to determine the amount of medical materials and extrication equipment necessary to render care. The supply and extrication leaders then direct personnel and equipment to where the need is greatest during the initial triage phase.

Triage and Treatment Units

The initial triage is complete. You next work closely with Vinnie Lorenzo, the secondary triage leader, to further separate the triaged patients into treatment groups based on the priority tags attached to each patient. Unfortunately, there have been 10 deaths.

Vinnie has a total of 30 patients in the treatment unit. Harriet Lerner, the treatment leader, directs the EMTs to the red-tagged patients. In the red, priority 1 treatment unit, there are five patients with inadequate airways and severe burns. Harriet consults with the supply unit
Case Study Follow-up continued

leader to request more blood pressure cuffs, bandages, and oxygen. The remaining 25 patients are classified as yellow, priority 2 patients and are moved to the priority 2 treatment unit. Some of these patients are suffering from burns without airway problems. Many have multiple bone and back injuries, with or without spinal cord damage.

Staging and Transport
The staging leader, Harold Walters, has been working closely with Harriet Lerner of the treatment unit to determine the number and priority of patients in need of transport. Harold has kept a record of the number of available ambulances and EMS personnel. Meanwhile, the transport leader, John Bukowski, has consulted with the receiving hospitals to determine the number of available beds and to make sure the hospitals have called in additional medical personnel.

John Bukowski contacts Harold Walters and requests three ambulances respond to the red, priority 1 treatment unit. All five patients with severe burns and inadequate breathing are then transported to the appropriate hospitals. Because of heavy radio communications, EMTs transporting priority 1 patients do not contact the hospital. John provides patient information and estimated times of arrival. Once the priority 1 patients are released to hospital personnel, the ambulances return to the hospital. John provides patient information and equates breathing are then transported to the appropriate hospitals. The staging leader, Harold Walters, has been working closely with Harriet Lerner of the treatment unit to determine the number and priority of patients in need of transport. Harold has kept a record of the number of available ambulances and EMS personnel. Meanwhile, the transport leader, John Bukowski, has consulted with the receiving hospitals to determine the number of available beds and to make sure the hospitals have called in additional medical personnel.

John Bukowski contacts Harold Walters and requests three ambulances respond to the red, priority 1 treatment unit. All five patients with severe burns and inadequate breathing are then transported to the appropriate hospitals. Because of heavy radio communications, EMTs transporting priority 1 patients do not contact the hospital. John provides patient information and estimated times of arrival. Once the priority 1 patients are released to hospital personnel, the ambulances return to the hospital. John provides patient information and equates breathing are then transported to the appropriate hospitals.

John next requests 13 more ambulances from Harold Walters, the staging leader. Harold directs the ambulances to the yellow, priority 2 treatment units in a staggered sequence so as not to overload the treatment areas. Priority 2 patients are transported to the appropriate area hospitals.

Again, transporting EMTs do not contact the receiving hospitals. Maintaining only essential communications, John Bukowski has informed the receiving hospitals of only the number of patients and each patient’s chief complaint.

Finally, John requests five ambulances from Harold Walters in staging to transport the remaining 10 green, priority 3 patients. Harold directs the ambulances to the priority 3 treatment unit. As incident manager, you keep a skeleton crew of EMTs to assist in cleanup and scene restoration. You direct remaining EMS personnel to the receiving hospitals to assist in further patient care.

Thoroughly exhausted from managing the MCI at Firebird Raceway, you take time to have something nourishing to eat and rest for a bit. An MCI is an incredibly stressful experience. Both you, as incident manager, and the EMTs providing direct patient care will inevitably be plagued by doubts and second-guessing in the time following the MCI: “Did I make the right triage decision?” “Should I have started CPR?” “How should I have dealt with the mother begging me to care for her dying child?” You know that the best way to minimize these doubts, and the stress they cause, is to routinely practice your MCI plan. Then, when the unexpected happens, as it did at Firebird Raceway, you know how to get the right patient to the right hospital in the right amount of time.

IN REVIEW

1. Name the criteria for determining that an emergency is a multiple-casualty incident.
2. List the responsibilities of an incident commander.
3. Define the role of the EMT in a multiple-casualty incident or a disaster operation.
4. Name the five basic units of an incident command system and describe their responsibilities.
5. Explain how to perform the primary assessment of a patient during initial triage.
6. Identify the appropriate triage level (in a system with three levels of triage) for each of the following: (a) a patient with inadequate breathing, (b) a patient who is in cardiac arrest with insufficient EMS personnel to provide care, (c) a patient found with a suspected fractured forearm, and (d) a patient with a laceration to his back.
7. Explain the reasons for using a patient identification or tagging system and give the criteria for a successful patient identification system.
8. List guidelines for effective transport of patients in a multiple-casualty incident.
9. List at least five ways for reducing stress on EMTs during a multiple-casualty incident or disaster operation.

CRITICAL THINKING

You are responding to the scene of a natural gas explosion in a residential neighborhood. You are the first EMS unit to arrive on scene. You report to the incident commander and he indicates that so far approximately 30 patients have been identified. He designates you as the EMS branch director.

1. What responsibilities would you have as the EMS branch director?
2. What units would you establish?
3. How should triage be conducted?
4. What patients would be moved into the treatment unit first and moved out of the treatment unit first?
5. How would you manage all of the responding EMS units?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • EMS Operations (Content Area: Terrorism and Disaster)

COMPETENCY • Applies knowledge of operational roles and responsibilities to ensure patient, public, and personnel safety.

OBJECTIVES • After reading this chapter, you should be able to:

46-1. Define key terms introduced in this chapter.
46-2. Explain the mnemonics CBRNE and B-NICE and describe the characteristics of the various types of weapons of mass destruction.
46-3. Explain the importance of preplanning a response to terrorism involving weapons of mass destruction.
46-4. Discuss the components that should be included in a plan for responding to terrorism involving weapons of mass destruction.
46-5. Recognize indications that a response may involve terrorism with weapons of mass destruction.
46-6. Describe the EMT’s role when responding to terrorism involving weapons of mass destruction.
46-7. Describe types of injuries that may occur from conventional explosives and incendiary devices.
46-8. Discuss the effects of exposure to and explain the appropriate medical care for each of the following types of chemical agents:
   a. Nerve agents
   b. Viscants
   c. Cyanide
   d. Pulmonary agents
   e. Riot-control agents
   f. Toxic industrial chemicals
46-9. Give examples of biological agents in each of the following categories and the appropriate medical care for exposure to biological agents:
   a. Pneumonia-like agents
   b. Encephalitis-like agents
   c. Biological toxins
   d. Other agents
46-10. Differentiate between the characteristics of the following types of radiation:
   a. X-ray and gamma radiation
   b. Neutron radiation
   c. Beta radiation
   d. Alpha radiation
46-11. Differentiate between primary exposure and fallout associated with a nuclear explosion.
46-12. Explain blast injuries and thermal burns as mechanisms of injury from nuclear explosions.
46-13. Differentiate between a nuclear weapon and a radiological dispersal device (RDD, or “dirty bomb”).
46-14. Discuss assessment and care of patients affected by nuclear detonation and radiation injuries.
46-15. Explain issues of personal protection and patient decontamination in connection with chemical, biological, and radiological/nuclear weapons exposure.
Terrorism involving weapons of mass destruction (WMD) is a realistic threat that all EMS providers must be prepared to manage. Weapons of mass destruction—biological, nuclear/radiological, incendiary, chemical, and explosive—as well as unconventional weapons such as airplanes—can cause widespread, indiscriminate death and destruction. The best way to manage an attack is to be informed and prepared and to understand your limitations. The goal of emergency medical services is to successfully manage the patients affected by the attack.

The term *weapons of mass destruction* typically conjures thoughts of chemical, biological, and radiological/nuclear threats. However, conventional bombs, explosives, and incendiary devices are the most commonly used terror devices worldwide. An example is the Oklahoma City bombing in 1995. Unconventional weapons, such as the use of commercial airliners as in the attack on the World Trade Center and Pentagon on September 11, 2001, must also be considered. EMS providers must be prepared to deal with any type of WMD attack.

**Weapons of Mass Destruction**

Weapons of mass destruction (WMD) are intended to cause widespread and indiscriminate death and destruction. The mnemonic CBRNE is a useful way to remember the types of weapons of mass destruction: chemical, biological, radiological, nuclear, and explosive. Another useful mnemonic is B-NICE: biological, nuclear/radiological, incendiary, chemical, and explosive. These lists reflect the types of weapons or agents that might be employed in a terrorist attack. Because each of the agents has its own characteristics, this chapter introduces the EMT to these critical threats.

The destructive power of the weapon used to carry out the attack is dependent on the agent and the delivery method. A small amount of a chemical agent may kill hundreds or thousands of people if it is spread over a densely populated area, with minimal or no physical damage suffered to the structures in that area. On the other hand, a nuclear device that can fit inside a footlocker may have the power to obliterate ten city blocks and cause damage to many more. The subtle and gradual nature of biological weapons that can be spread by contact with a person or an infected object leads to potentially huge numbers of possible deaths.

Nuclear and conventional bomb detonations last for only a brief moment and have immediate effects on the individuals involved in the attack. The fallout from a nuclear weapon may last for days to weeks, and it may have long-lasting effects. Chemical agents may take a few minutes to begin to show the effects, and those effects may last from minutes to hours. Biological weapons are the most insidious and may take hours to days to cause widespread and indiscriminate death and destruction.
for the onset of effects, and the duration may be days to weeks. The destructive power of conventional explosives is the lowest, yet they have the highest likelihood of being used as the primary weapon. Nuclear weapons carry the highest destructive capabilities, but because of the complexity of developing the devices and the special materials needed to build them, they have the lowest risk of use. Chemical and biological weapons have both a moderate likelihood of use and a moderate to high destructive power.

The greatest amount of structural damage is caused by nuclear weapons, which also carry a high risk of environmental contamination. Chemical and biological weapons cause minimal damage to structures; however, chemical weapons have a high impact on environmental contamination, whereas biological weapons have only a minimal effect on the environment. Do not underestimate the destructive power of weapons that do not produce massive structural damage. Conventional weapons, and unconventional ones such as jetliners, will cause a significant amount of damage. Response to such dramatic events may require such resources as heavy and confined-space rescue, whereas chemical and biological weapons may require more involvement from epidemiologists and other public health officials but less involvement of rescue personnel (Figure 46-1).

Detection of weapons of mass destruction may also pose a problem. Biological agents, radiation, and even many chemical agents are typically colorless and odorless. They cannot be detected by human senses and are identified only after the clinical signs and symptoms become apparent. The subtle and silent nature of the agents leads to a delayed response. Until the deployment of such weapons is identified or their effects are recognized, response cannot begin. Combinations of weapons are also possible. Radiological dispersal devices (RDDs), also known as dirty bombs, are made by combining a conventional explosive with radioactive material. Detonation results not only in physical damage from the blast but also in a spread of the radioactive material, causing additional complications to the scene.

The general prehospital approach to an incident involving weapons of mass destruction is similar to that for any disaster involving mass casualties. The principles of the response are relatively the same with some additional considerations. All local, regional, and state disaster agencies should develop WMD disaster plans that are readily functional. This is important because prehospital providers often don’t know the exact nature of a disaster when it first unfolds. A common approach to a disaster—whether it is caused by human accident, nature, or terrorist intent—serves to prepare the EMT for all of the possibilities. This general method of dealing with disasters and special situations is often termed the all-hazards approach.

**PREHOSPITAL RESPONSE TO TERRORISM INVOLVING WMD**

Terrorist attacks involving weapons of mass destruction can wrest you from your everyday, customary responsibilities to an incident that involves mass numbers of people over a prolonged period of time while working with limited resources. Response to a terrorist attack involving weapons of mass destruction requires specific planning and preparedness.

Planning for a WMD incident must encompass several aspects of preparation and response. Consider that incidents may require special protective equipment in large quantities to support not only the triage and treatment aspects of the incident but also the extrication, decontamination, and cleanup phases. Transportation of mass numbers of patients to a multitude of medical facilities may be required with sufficient personnel to provide both transportation and en-route care. Communications may be destroyed or disrupted as a result of the attack, and hospitals and other medical facilities may be destroyed or severely damaged, creating secondary treatment and transportation problems.

**Supplies and Equipment**

It is unrealistic to think that a single EMS agency will have the equipment necessary to manage a WMD incident. Rather, it is necessary to establish a community response to the disaster (Figure 46-2).

Each type of WMD incident requires different types of specially trained personnel, equipment, and supplies. For example, nerve agents may require massive amounts of certain drugs along with a large number of ventilators. Chemical incidents may require special personal protective equipment such as self-contained breathing apparatus or hazardous materials suits. Large explosions with structural collapse may require heavy rescue equipment, specially trained search and rescue teams, electronic detection devices, and trained search dogs.

A plan must be in place that will allow the communications center immediate access to the individuals.
who are capable of deploying the equipment, supplies, and personnel. Mutual assistance agreements must also be in place to allow for neighboring departments to provide equipment, supplies, and personnel.

Medical Direction

There will be a multitude of EMS providers from a variety of systems responding to a multiple-casualty incident involving weapons of mass destruction. The response of providers from several areas may pose a problem with medical direction and the use of protocols from a different jurisdiction. A plan should address how medical direction will be provided to EMS personnel at the scene as well as how to confirm the credentials of EMS personnel from outside the area.

The communications system should not be relied on to provide on-line medical direction, since it will likely become overloaded. One possibility is to make all protocols standing orders in a case involving weapons of mass destruction. This would clear communications channels to allow for scene updates, incoming patient reports, and on-line orders for special medical treatment requests, such as medical personnel to perform a field amputation of an extremity of a trapped patient.

The protocol should address treatment for specific agents used in weapons of mass destruction. Triage protocols should ensure that minor injuries and walking wounded patients do not proceed to the nearest hospital. The closest hospitals should be reserved for the more seriously injured.

Provider Preparation

As an EMS provider, you must be aware of the personal risks and dangers associated with responding to a WMD incident. Personal safety is the first priority for all EMS personnel. As an example, coming into contact with sarin, a nerve agent, could result in immediate death or permanent disability. The presence of biological agents may not be immediately apparent, but in rare circumstances they may cause the slow, agonizing death of an EMS responder.

Understanding the threats and the potential consequences is vital. Rushing onto the scene of an explosion may cause the deaths of many rescuers, which may be the secondary objective of the terrorist. This was seen in the World Trade Center attacks of September 11, 2001, where hundreds of firefighters, law enforcement officers, and EMS personnel were killed or injured as a result of the secondary effects of the attack. In some past incidents, secondary explosive devices were even planted and detonated with the specific purpose of injuring and killing rescue personnel and others who rushed to the scene.

In regard to patient care, you must be aware of the various agents that can be used as weapons of mass destruction and the signs and symptoms of the conditions that result from exposure. (See the discussion of specific agents and findings associated with these agents later in this chapter.) You should have specific guidelines on triage and management of these patients. As always, your personal safety is your first priority and requires that you be informed of the potential dangers to your health when you enter the scene, both during and after the incident.

Responding to the Scene

One of the most important aspects of a WMD incident is recognition. The earlier the incident and the weapon are recognized, the earlier you can protect yourself and contact the necessary resources to respond.

These incidents employ the same incident command system as does any multiple-casualty incident. If a chemical agent is involved, it is also similar to a hazardous materials incident. Thus, you may be required to establish an EMS command center if you are one of the first-arriving EMS crews on the scene, and you will be required to function within the incident command system throughout your time at the incident.

Be wary of the possibility of secondary explosions when conventional weapons are used. Booby traps may be used to injure and kill responders. Subsequent attacks may occur to inflict more damage, as in the 2001 World Trade Center attacks.

Issues of Scene Safety

There is a significant difference between the effects of conventional, chemical, and most biological weapons as compared to the death, injury, and mass destruction of nuclear weapons. Conventional, chemical, and most biological weapons cause a relatively small region of impact, yet place an extreme strain on the EMS system and medical care. On the other hand, the medical facilities and personnel are primarily intact after the attack.
By contrast, a large nuclear weapon will cause concentric rings of complete destruction, severe devastation, and areas of limited damage, with death and injury superimposed. Access to the scene is severely limited by the mass physical destruction. The nuclear weapon destroys emergency services, health care services, and facilities within the rings of the impact. Shelters, medical supplies, food, and clean water are also destroyed. Electrical equipment, including computers and radios, may be destroyed even when located relatively far from the center of the detonation, which may leave the entire response area without effective communication. About 1 hour after the detonation, radioactive fallout will begin to occur and will last for days to weeks. A sizable nuclear event will require extreme measures to evacuate, care for, and support the injured.

Chemical and biological weapons present a danger that is much more difficult to recognize and identify as compared to the nuclear or conventional blast. Chemical weapons may release gases or aerosols that are only recognized upon exposure or shortly thereafter. If numerous patients present with similar signs and symptoms with an unexplainable or unidentifiable cause, a chemical weapon should be suspected. Consider the environment to be toxic and unsafe. With chemical weapons, the patients will often complain of the following:

- Respiratory distress
- Dyspnea
- Cough
- Burning chest
- Burning eyes

If excessive salivation, loss of bowel and bladder control, and tearing are noted, suspect a serious chemical exposure. Inspect the scene for dead or incapacitated animals or insects. Odors of bitter almond, peaches, mustard, garlic, onions, or fresh-cut grass or hay may also be indications of deadly chemical weapons.

The exposure to a biological weapon will typically have occurred days before the first signs or symptoms appear. The contamination source may not be identified for days to weeks after the patients present with signs and symptoms. Biological weapons may also affect the EMS crews, hospital personnel, other rescue personnel, and their families. As an example, a patient exposed to and ill from smallpox who seeks medical treatment from EMS and is transported to a medical facility will contaminate the EMS crew and hospital personnel well before identification of the biological agent can be made. This may cripple the personnel in the systems that normally respond to these incidents. When presented with a patient with a suspected communicable disease, use a HEPA or N-95 mask, gloves, eye protection, and gown. Alert medical direction prior to transport to the medical facility so that the staff may prepare for immediate patient isolation.

When accessing the scene of a suspected chemical, biological, or nuclear weapon, approach from upwind. If the area is large or entry is limited, the best approach is from the side. Avoid confined spaces such as subways, basements, buildings, or low-lying areas. Chemical or biological agents may be harbored in these areas for longer periods of time because of poor ventilation. Entry must be made only by responders with specialized training and with the proper personal protection equipment, including self-contained breathing apparatus.

The target of terrorists is typically an area that is heavily populated or one that would have a great impact on the population. These areas might include airports, subways, schools, churches, government buildings, and large gatherings such as fairs, sporting events, and festivals.

If a WMD incident is suspected, stay away from the scene until the nature of the weapon is identified and you are able to take the necessary personal protection. Once the incident is recognized, employ the incident command structure to begin a careful and organized response to the scene. Similar to a hazardous materials incident, sectors of operations should be established. Coordinating efforts with law enforcement is necessary because of the increased security needs related to this type of incident. The individuals responsible for perpetrating the incident may be among the sick or injured; therefore, the EMT must be able to provide adequate care while maintaining a high index of suspicion. If a suspected perpetrator is located, law enforcement should be contacted immediately.

Whenever possible, all responders should enter the scene from a single staging or mobilization point in order to maintain security. An escape plan should be determined and communicated to all responders on the scene, with a predesignated responder collection point having been chosen so that all personnel can be accounted for if evacuation becomes necessary.

**Role of the EMT at the Terrorist Incident Involving WMD**

Upon arrival at the scene of a WMD incident, you may be required to fill one of three possible roles. If you are the first unit to arrive, you must establish incident command, quickly size up the scene, evaluate the need for additional resources, and begin to communicate the essential information to the communications center to organize an adequate response.

The scene size-up is of utmost importance, as it allows you to gather as much information as possible regarding the incident so that other incoming responders can be adequately warned of dangers. Perform a 360-degree assessment of the scene, keeping in mind all of the signs and characteristics of a terrorist-WMD incident. An estimate of the number of patients should be made, and multiple-casualty incident plans and protocols should be implemented as soon as possible.

If you are the second or third unit in, you may be asked to take on a sector-leader or officer role, such
as triage, treatment, supply, or transportation officer. If you are in a unit that arrives after all sector officers have been assigned, you will likely be assigned to the triage or transportation sector to provide care and transportation of injured victims.

Regardless of your role, the overall goal is ensuring that the most good is done for the most people. Utilize triage principles when faced with challenging decisions. Patients must be protected from harm, informed of your actions, and cared for to the best of your ability despite the difficult situation.

CONVENTIONAL WEAPONS AND INCendiary DEVICES

Conventional explosives and incendiary devices remain the most widely used weapons of mass destruction by terrorists. EMS providers must be familiar with the effects of the various devices and the necessary treatments for their victims.

Explosives

Explosives work by igniting special fuels that burn extremely rapidly, causing hot gases to displace air in a violent fashion, creating a shock wave or a blast. The blast moves out in all directions at supersonic speed. This shock wave is what causes blast injury. As victims get farther from the explosion, the severity of blast injury will greatly diminish. Barriers may offer some protection from the shock wave and lessen injuries. If a blast occurs in a closed room or space, the effects of the blast are amplified.

Primary, Secondary, and Tertiary Effects

The blast of an explosion is considered to be the primary effect. The secondary effects result from flying debris, shrapnel, and other projectiles. Flying debris can cause significant penetrating injury or blunt trauma. Flames and hot gases present in explosions also lead to secondary-effect injuries (Figure 46-3).

The patient may be propelled by the blast or shock wave. As the body strikes the ground or other objects, blunt trauma may occur. The injuries produced by the propulsion are referred to as tertiary effects.

Body Position

Body position plays a role in determining the extent of the blast injury. Victims who are standing or lying perpendicular to the blast will suffer the greatest amount of injury, whereas victims lying directly toward or away from the blast will suffer the least amount of injury. If you know that a blast is imminent, drop to a prone position facing away from the detonation. This will reduce the shrapnel and blast injuries.

Types of Injuries

A wide variety of injuries may result from explosions and incendiary devices. The more common injuries are as follows:

<table>
<thead>
<tr>
<th>Area/Type</th>
<th>Effects</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lungs</td>
<td>Lung injury may occur from primary blast effects, since the lung is an air-containing space. Look for evidence of lung injury such as altered mental status, dyspnea, blood-tinged sputum, respiratory distress, chest pain, and stroke-like signs and symptoms. Be careful if positive pressure ventilation is needed, since it may convert a pneumothorax into a tension pneumothorax. Also, the blast may have caused injury to the alveolar-capillary wall, and positive pressure ventilation may force small air bubbles into the vessels, creating air emboli.</td>
</tr>
<tr>
<td>Abdomen</td>
<td>Blast injury may cause bleeding to the bowel or may allow a lacerated bowel to leak its contents into the abdominal cavity. If the victim is close to the detonation, he may suffer an evisceration. In this case, manage the evisceration (refer to Chapter 35, “Abdominal and Genitourinary Trauma”) and transport rapidly.</td>
</tr>
<tr>
<td>Ears</td>
<td>The eardrum may rupture from the blast. The delicate bones inside the ear may fracture or dislocate. The patient may experience temporary or permanent hearing loss.</td>
</tr>
</tbody>
</table>
The threat from a hijacked gasoline tanker or sabotaged natural gas pipeline should be considered when thinking of potential incendiary devices of mass destruction.

Incendiary-device burns are assessed in the same way as typical thermal burns. The same burn-depth classification system and rule of nines are used to determine extent of injury. The general management is the same as for a thermal burn (see Chapter 29, “Burns”). Be sure to pay particular attention to the airway and ventilation. Dress the burned areas.

<table>
<thead>
<tr>
<th>Area/Type</th>
<th>Effects</th>
</tr>
</thead>
<tbody>
<tr>
<td>Crush injuries</td>
<td>Crush injuries may occur as a result of structural collapse. The weight of the debris on the patient may create excessive compression forces, causing a crush syndrome. In addition, the structural collapse may inflict direct blunt and penetrating injury, while dust and smoke can cause respiratory and eye injuries. Crush syndrome is associated with entrapment for 4 hours or more. The crushed tissue will produce harmful by-products. Once the pressure to the crushed area is relieved, the accumulated by-products are released into the systemic circulation, causing serious problems.</td>
</tr>
<tr>
<td>Shrapnel injuries</td>
<td>Shrapnel may cause penetrating injury to the solid organs, hollow organs, connective tissue, and bone. Each may experience a different effect from the missile. Solid organ tissues are rapidly compressed and stretched. Contents of ruptured hollow organs will leak out into surrounding cavities. Connective tissue injuries are frequently limited to the shrapnel pathway because of their resiliency. Bones will fracture when struck by shrapnel.</td>
</tr>
</tbody>
</table>

## Incendiary Devices

**Incendiary devices** create different injury patterns from conventional explosives. Incendiary devices include napalm, thermite, magnesium, and white phosphorus. Many are designed to be used against equipment, with the exception of napalm, which is used against personnel. The devices are designed to burn at extremely high temperatures. The primary injury is a burn.

A terrorist could possibly use any number of common flammable chemicals to make an improvised, yet devastating, incendiary device. Gasoline, propane, and natural gas are transported and stored around the United States in tremendous volumes. Virtually every community has tons of these chemicals within their boundaries at any given moment. The threat from a hijacked gasoline tanker or sabotaged natural gas pipeline should be considered when thinking of potential incendiary devices of mass destruction.

Incendiary-device burns are assessed in the same way as typical thermal burns. The same burn-depth classification system and rule of nines are used to determine extent of injury. The general management is the same as for a thermal burn (see Chapter 29, “Burns”). Be sure to pay particular attention to the airway and ventilation. Dress the burned areas.

## CHEMICAL AGENTS

Chemical weapons are among the most feared weapons of mass destruction. However, with proper training and equipment, it is possible to operate safely and effectively in a contaminated environment and perform basic emergency care. Terrorist groups can manufacture chemical agents with relative ease; therefore, it is imperative that EMS providers be familiar with the chemicals that are likely to be used and the necessary patient management.

### Properties of Chemical Weapons

Most chemicals for military use are stored in munitions (shells, rockets, and bombs) as a liquid. When the munition explodes, the liquid is converted to an aerosol, or tiny droplets of liquid suspended in the air. Alternatively, a bomb may be attached to a liquid chemical agent canister that will break open and spread the chemical upon detonation of the bomb. Terrorists can acquire such munitions or design their own. They can also release the liquid chemical, perhaps enhanced with an aerosol device, into a closed building or simply into the air. Some riot-control agents are stored as solids, but become an aerosol once deployed.

Some chemical agents, such as hydrogen cyanide, chlorine, and phosgene, may be in the form of a gas in warm weather. Nerve and mustard agents typically remain a liquid at the same warm temperature but will evaporate similarly to a puddle of water. The tendency of the chemical agent to evaporate is called *volatility*. A volatile liquid evaporates easily and creates a dangerous breathable vapor. A characteristic of agents that do not evaporate quickly and tend to remain as a puddle for long periods of time is referred to as *persistence*. These chemicals remain concentrated and dangerous to touch for days to weeks. As a general rule, the warmer the ambient temperature the greater the evaporation and creation of dangerous breathable vapors; the colder the temperature the greater the persistence and danger from contact for a prolonged period following deployment.

Chemical agents in the form of aerosolized liquids or solids, vapor, or gas can enter the body through the respiratory tract (lungs), skin, and eyes. Entry through the lungs is by far the most critical, since a large quantity of chemical can be absorbed and dispersed throughout the body by this route, causing severe systemic effects.

Liquid agents are primarily absorbed through the skin and eyes. They may cause both severe local effects, such as chemical burns, and serious systemic effects. Accidental ingestion of chemical agents in contaminated food is possible, yet rare.

### Types of Chemical Agents

There are six major types of chemical agents:

- Nerve agents
- Vesicants
- Cyanide
- Pulmonary agents
- Riot-control agents
- Toxic industrial chemicals (TICs)
The pulmonary system is affected in two ways:

- Respiratory failure occurs as a result of the paralysis of respiratory muscles (diaphragm, intercostals, and abdominal).
- Copious (excessive) airway secretions lead to airway obstruction, while bronchoconstriction obstructs the lower airways.

The patient may be in respiratory distress or arrest. He may be drooling or may be found with a large amount of secretions in the oropharynx. You may also hear wheezing on auscultation of the lungs if he is moving air on respiration.

Other signs and symptoms include miosis (pinpoint pupils), rhinorrhea (runny nose), excessive salivation, tearing in the eyes, blurry vision, nausea and vomiting, diarrhea, sweating, and loss of bladder control. The mnemonic SLUDGE (salivation, lacrimation, urination, defecation, gastric distress, emesis) is used to remember the signs and symptoms. Initially, the vital signs may show tachypnea (rapid breathing), tachycardia (rapid heart rate) or bradycardia (slow heart rate), and a normal blood pressure. As the patient’s condition worsens, you may see apnea, tachycardia, and hypotension (low blood pressure).

**Emergency Medical Care.** Initial care for nerve agent exposure should be directed at establishing an airway and, for inadequate breathing or apnea, providing positive pressure ventilation at 12 ventilations per minute in the adult. It may be necessary to suction the airway to clear the large amount of secretions. Position the patient in the lateral recumbent (coma or recovery) position. Monitor the airway and breathing status closely.

Administration of an antidote is the next step. Two drugs are used to counteract the effects of the nerve agent: atropine and pralidoxime (Protopam). Many EMS systems carry this nerve agent antidote in auto-injector form, either as a two-injector set known as the Mark I kit (Figure 46-4 ■), or as a single-injector containing both drugs known as the DuoDote. EMS providers must take all necessary precautions to protect themselves against these nerve agents (Figure 46-5 ■). However, it may be necessary to administer the antidote to themselves, their peers, or patients who have been affected by nerve agents. Standing orders for the approved use of these antidotes should be considered for addition to the disaster plan. These nerve agent auto-injectors function in exactly the same

### Nerve Agents

Nerve agents are among the most deadly known chemicals (Table 46-1). These agents are extremely potent and are relatively easy to make; therefore, they are a significant threat and a deadly weapon in the hands of a terrorist. In most weather conditions, nerve agents are in liquid form. When released, the volatile agents become both a vapor and a liquid hazard.

Nerve agents block the action of an enzyme called acetylcholinesterase (AChE). Acetylcholinesterase is found in the plasma of the blood, red blood cells, and nervous tissue. Its function is to stop the action of acetylcholine (ACH), a neurotransmitter. When nerve agents block the action of acetylcholinesterase, acetylcholine is allowed to accumulate. The most severe effects will be to the nervous tissue. With the body’s AChE being inactivated by the nerve agent, the skeletal muscles, smooth muscles, glands, and nerves remain in a steady “on” state, with uncontrolled and uncoordinated contraction of muscle fibers. This will be apparent in movements that are jerky. Seizures may also occur. The muscles eventually fatigue, stop working, and begin to die. Death usually results from inadequate breathing resulting from respiratory muscle failure.

**Signs and Symptoms.** The signs and symptoms depend on the amount of exposure, the dose, and the route. The larger the dose with direct respiratory inhalation of the nerve agent vapor, the quicker the onset and severity of the effects (Table 46-2). The most significant effects are on the nervous system, airway, and respiratory system. Large doses interfere with the brain’s ability to function and will result in a rapid loss of consciousness, seizures, and apnea (lack of breathing). Lower doses may result in difficulty concentrating, inability to sleep, impaired judgment, and depression.

**Table 46-2** Signs and Symptoms of Nerve Agent Exposure
blistering, burning, and tissue damage on contact. The eyes, skin, and lungs are the organs most commonly affected. The onset of signs and symptoms may provide a clue to what agent was used. Mustard agents cause little initial discomfort but lead to severe damage in a matter of hours. Lewisite and phosgene oxime produce immediate discomfort and redness on contact.

Vesicant agents, with the exception of phosgene oxime, are thick, oily liquids. They have low volatility and tend to be persistent. In warm temperatures, vesicants pose a significant threat of vapor exposure. Mustard gas has a characteristic odor of onions, garlic, or mustard. Phosgene oxime smells like newly mown grass or hay.

**Signs and Symptoms.** Vesicants were once referred to as “blister agents” because of their effects on the skin. These agents may have contact and systemic effects, depending on the exposure and the agent. Signs and symptoms of vesicant agents may include the following:

- Burning, redness, blistering, and necrosis of the skin (wheals or hives in the case of phosgene oxime)
- Stinging, tearing, and development of ulcers in the eyes
- Shortness of breath, coughing, wheezing, and pulmonary edema when inhaled
- Nausea and vomiting
- Fatigue

It may take 2–24 hours for mustard exposure to produce signs and symptoms. Eye damage may occur within 1–2 hours after exposure.

**Emergency Medical Care.** The most important emergency care that can be provided for vesicant exposure is immediate irrigation. Treatment during the first few minutes after exposure is crucial to preventing damage. Irrigate with water or a chemical decontamination kit. Continue to irrigate the areas of exposure. Manage the blistering as chemical burns. Apply a dry, sterile dressing once the area has been adequately flushed. Patch eye injuries after adequate flushing has occurred.

**Cyanide**

Cyanide is a rapid acting agent that disrupts the ability of the cell to use oxygen, leading to severe cellular hypoxia and eventually death. It used to be referred to as a “blood agent,” but its effects are on the cell and not the blood. Cyanide is relatively easy and inexpensive to produce.

Cyanide is absorbed by inhaling the vapor or by ingestion of contaminated food or water. Once in the body, the cyanide acts quickly. It targets the brain and heart. If a large concentration is inhaled, the patient may lose consciousness within 1 minute and die within 6–8 minutes. Even moderate exposure can lead to death. Low-dose exposures will lead to illness, but the patient would likely recover.
Signs and Symptoms. Low concentrations of cyanide exposure cause milder signs and symptoms and a slower rate of onset. Signs and symptoms of cyanide exposure may include the following:

- Anxiety
- Weakness
- Dizziness
- Nausea
- Muscular trembling
- Tachycardia
- Tachypnea
- Pale, cyanotic, or normal color skin
- Seizures
- Apnea
- Unresponsiveness

Signs and symptoms that appear to be initially mild may progress and eventually lead to death. The classic cherry-red skin and lip color is an unreliable and very late sign. The pulse oximeter may provide a false sense of reassurance, since the blood is being oxygenated well, yet the cell cannot use the oxygen.

Emergency Medical Care. Cyanide treatment must be initiated early to be effective. Manage the airway and provide positive pressure ventilation if the respiratory rate or tidal volume is inadequate. If an adequate respiratory rate and tidal volume are present, administer oxygen by a nonrebreather mask at 15 lpm. An antidote may be necessary to save the patient. It consists of a nitrite, such as amyl nitrite or sodium nitrite, and sodium thiosulfate. In 2006, the U.S. Food and Drug Administration (FDA) approved the injectable drug Cyanokit (hydroxocobalamin) for the treatment of cyanide poisoning, whether the cyanide has been inhaled or ingested. These agents work to remove the cyanide from the patient’s system.

Pulmonary Agents

Pulmonary agents include phosgene (CG), other halogen compounds, and nitrogen-oxygen compounds. They act primarily to cause lung injury and are commonly referred to as “choking” agents. Large amounts of phosgene are produced for chemical processes. Phosgene is transported as a liquid, but it rapidly converts into a gas that tends to settle in low-lying areas. It produces the odor of newly mown hay. The other pulmonary agents, like chlorine, have similar characteristics and are treated the same as phosgene.

Phosgene directly attacks the airway and lung tissue. The smaller airways and alveoli are the most susceptible to injury. The damaged airways and alveoli will leak fluid, leading to pulmonary edema and inflammation. This leads to hypoxemia and, potentially, respiratory failure.

Signs and Symptoms. Relatively small concentrations of phosgene irritate the mucous membranes of the mouth, eyes, nose, and throat. The initial signs and symptoms may reflect this irritation. Pulmonary edema may take several hours to develop after exposure. The mild symptoms may be a key indicator that the patient can progress to severe hypoxemia from pulmonary edema in a few hours. Exertion may worsen the condition. The typical signs and symptoms are as follows:

- Tearing
- Runny nose
- Throat irritation
- Dyspnea
- Wheezing
- Cough
- Crackles
- Stridor
- Secretions

Emergency Medical Care. The priority in pulmonary agent exposure is to manage the airway and ensure the patient is breathing adequately. Tracheal intubation may be needed if airway obstruction is evident. Activate ALS response for advanced airway care. Suction secretions, if necessary. If the respiratory rate or tidal volume is inadequate, begin positive pressure ventilation. Be sure to administer high concentrations of oxygen when ventilating. If the patient has adequate breathing, apply a nonrebreather mask at 15 lpm. Calm the patient and do not allow him to exert himself. If the patient is wheezing, a beta2 agonist can be administered.

Riot-Control Agents

As noted earlier, some riot-control agents are solids that become an aerosol when deployed. Thus, “tear gas” is not a gas but an aerosolized solid. The most recent type of riot-control agent is derived from the capsicum family of peppers.

Signs and Symptoms. Tear gas and capsicum-based “pepper spray” cause extreme irritation of the eyes, nose, mouth, skin, and respiratory tract. It may cause involuntary eye closing from the severe irritation or temporary blindness. The irritation usually lasts approximately 30 minutes after exposure.

Emergency Medical Care. Emergency medical care is primarily supportive and should focus on removing the patient from the contaminated environment and irrigating the eyes with water or saline. If the patient is wearing contact lenses, remove them. If the patient presents with signs of respiratory distress, provide oxygen therapy via a nonrebreather mask at 15 lpm. If the patient is wheezing and has a metered-dose inhaler, administer the MDI according to your protocol. If the pain from skin exposure is prolonged, decontaminate with soap and water. Do not use bleach.

Toxic Industrial Chemicals

Any toxic chemical can potentially be exploited by a terrorist and used as a chemical weapon. Millions of tons
other uncomplicated method of dispersal that, while attacks through the U.S. Postal Service demonstrate an- 

eristics throughout the nation or the world. The anthrax hub and result in widely dispersed emerging epit- 

emer with members of the general public. This technique with a highly contagious agent to come in close contact 

population by using one or more individuals infected 

erly occurring diseases. The only difference is that, as 

munatory agents; that is, they primarily attack the respiratory tract. Examples include chlorine, phosgene, and methyl isocyanate (the chemical that killed thousands in Bhopal, India). Others act like cyanide, including salts of cyanide and related compounds called cyanogens. Insecticides act similarly to nerve agents. It is important to utilize special resources to identify the exact chemicals involved, and this requires the expertise of a trained hazmat team. (Refer to Chapter 44, "Hazardous Materials.")

**BIOLOGICAL AGENTS**

**Biological agents** are made up of living organisms or the toxins produced by the living organisms and are used to cause disease in a target population. Diseases caused by these agents are no different from the naturally occurring diseases. The only difference is that, as weapons of mass destruction, the harm they cause is intentional. Biological agents lend themselves to use as weapons of mass destruction because small amounts can cause widespread disease and mass casualties. It may take several days to detect a biological assault. Viruses, bacteria, and fungi can be used to form the biological agents.

To be effective as a WMD, the biological agent must reach the intended target. This is usually accomplished by spraying a liquid agent through a nozzle. Delivery can be accomplished by an airplane that can achieve widespread distribution of the agent. Wind speed and direction, rain, and sunlight can each have an effect on the delivery. High winds can disperse the agent and carry it over a long distance. Rain and sunshine will usually decrease the effectiveness of the agent. Ideal conditions for delivery are night and very early morning.

Far less effective but nearly as frightening is a simpler method of introducing a biological agent into the population by using one or more individuals infected with a highly contagious agent to come in close contact with members of the general public. This technique could take place in an airport or other transportation hub and result in widely dispersed emerging epidemics throughout the nation or the world. The anthrax attacks through the U.S. Postal Service demonstrate another uncomplicated method of dispersal that, while ineffective at producing massive casualties, resulted in widespread fear and disruption of people’s lives in several locations.

The respiratory tract is the most common and efficient portal of entry for most biological agents. The size of the biological agent is also important. A particle that is between 1 and 5 microns in size can get lower in the respiratory tract and into the lungs. If it is too large, the particle will fall out of the air, or will stay in the upper respiratory tract and be less effective. If the particle is too small, it will be exhaled back out. The mucous membranes of the mouth, nose, and eye are also portals of entry. Biological agents can be ingested in contaminated food and water.

Most biological weapons are intended to kill the victims. They can be extremely potent weapons of mass destruction. Small amounts of these potent agents can lead to a horrible death. The biggest potential threat from biological agents comes from their ability to spread, much as natural infectious diseases do. Epidemics can race through unsuspecting and unprotected populations, infecting and killing thousands, if not millions. Fortunately, only a few agents possess this chilling capability to a strong degree: smallpox, Ebola, and plague.

The key to recognition of a biological attack is to distinguish the number and timing of the cases from the isolated case of an expected illness. This may be difficult to do when other, naturally occurring incidents of mass food poisoning or epidemic meningitis occur. It is necessary to identify the commonality between those who are ill, such as a shared meal, living quarters, or water source. Because a biological incident may evolve slowly, initially occurring as individual cases throughout the community, the usual EMS notification and first response to the disaster may not occur. Instead, doctors’ offices, emergency departments, and public health agencies may be the first to detect the outbreak. Traditional hazmat approaches of containment and isolation may be impractical when a single source cannot be located. Instead, a public health response may be more effective.

**Specific Biological Agents**

Several biological agents can be used as weapons of mass destruction and pose a serious threat. They are categorized into four groups:

- **Pneumonia-like agents** (presenting with fever and rapidly progressing dyspnea)
- **Encephalitis-like agents** (presenting with fever and altered mental status)
- **Biological toxins**
- **Other agents**

**Pneumonia-Like Agents**

Pneumonia-like agents include anthrax, plague, and tularemia. The common symptoms are cough, shortness
of breath, fever, and malaise (a general feeling of illness). The specific findings for each are as follows:

### Pneumonia-Like Agents

<table>
<thead>
<tr>
<th>Agent</th>
<th>Specific Findings</th>
</tr>
</thead>
<tbody>
<tr>
<td>Anthrax</td>
<td>Incubation period is 1–6 days. Fever, malaise, fatigue, nonproductive cough, mild chest discomfort with progressing dyspnea, diaphoresis, stridor, cyanosis, shock, and death can occur within 24–36 hours.</td>
</tr>
<tr>
<td>Plague</td>
<td>Incubation period is 2–3 days. Headache, hemoptyesis (coughing up blood), severe dyspnea, high fever, stridor, cyanosis, and death from respiratory failure, circulatory collapse, and bleeding disorder.</td>
</tr>
<tr>
<td>Tularemia</td>
<td>Chest pain that worsens with breathing, headache, malaise, nonproductive cough, and weight loss.</td>
</tr>
</tbody>
</table>

Additional agents presenting with fever and pneumonia include *Q* fever and *glanders*.

### Encephalitis-Like Agents

Encephalitis-like agents cause symptoms that resemble the flu, to include headache, fever, and malaise. These diseases are much more lethal than flu. They have a tendency to affect the brain and spinal cord; therefore, they are referred to as encephalitis-like agents.

The two most common encephalitis-like agents are smallpox and Venezuelan equine encephalitis. Common signs and symptoms are headache, fever, and malaise. The signs and symptoms are as follows:

### Encephalitis-Like Agents

<table>
<thead>
<tr>
<th>Agent</th>
<th>Specific Findings</th>
</tr>
</thead>
<tbody>
<tr>
<td>Smallpox</td>
<td>Sudden onset of malaise, fever, headache, vomiting, and backache. Vesicular rash in same stage of development appears in 2–3 days.</td>
</tr>
<tr>
<td>Venezuelan equine encephalitis</td>
<td>Sudden onset with malaise, fever, severe headache, rigor, nausea, vomiting, cough, sore throat, and diarrhea, with recovery within 1–2 weeks.</td>
</tr>
</tbody>
</table>

Other agents with similar signs and symptoms include *brucellosis* and the *Eastern and Western equine encephalitis*.

### Biological Toxins

Biological toxins are potentially the most significant threat of all the biological agents. Toxins are not living organisms but are products of living organisms. For this reason, toxins cannot be transmitted from one infected individual to another. This does not lessen the threat of these agents, however. Biological toxins are among the most dangerous compounds known to man.

The five most significant biological toxins are botulinum, ricin, staphylococcus enterotoxin 13 (SEB), epsilon toxin of clostridium perfringens, and trichothecene mycotoxins (T2). The signs or symptoms of the agents are as follows:

### Biological Toxins

<table>
<thead>

<td>Staphylococcus enterotoxin 13 (SEB)</td>
<td>Fever, chills, headache, body aches, and nonproductive cough will occur 3–12 hours after inhalation. Shock and death may occur at high doses.</td>
</tr>
<tr>
<td>Epsilon toxin</td>
<td>Cough, wheezing, and shortness of breath occur within 6 hours of exposure. Respiratory failure and death follow shortly from high exposure. Liver damage can also occur.</td>
</tr>
<tr>
<td>Trichothecene mycotoxins (T2)</td>
<td>Pain, itching, redness, and lesions on the exposed skin, nose, and throat; runny nose and sneezing; skin may slough; nasal discharge; dyspnea; wheezing; chest pain; and hemoptyesis (coughing up blood).</td>
</tr>
</tbody>
</table>

### Other Agents

Other biological agents include cholera, brucellosis, and viral hemorrhagic fevers. Viral hemorrhagic fevers include the Ebola and Marburg viruses and the agents dengue and yellow fever. These agents are very lethal and result in a 5–50 percent death rate in infected individuals. Cholera is still seen in epidemic proportions in developing nations. The dehydration associated with cholera can easily lead to death. The signs and symptoms of these agents are as follows:

Emergency Medical Care for Biological Agents

The care for biological agents is primarily supportive. Recognition is extremely important to advanced management of the patient. In a WMD incident where biological weapons are used, a large number of patients can be expected. Contacting the necessary resources, including public health officials, early is crucial in providing the needed antibiotic and antitoxin treatments to reduce the number of deaths from exposure.

Only a few of the biological agents are highly contagious and can be passed from an infected individual to another person. Smallpox, plague, and Ebola are all typically contagious. Isolate these patients, as best you can in the field, from those who are not affected. Response personnel should use personal protective equipment, including a HEPA respirator; head and face protection; and impervious boots, gloves, and bodysplash protection.

The priorities in patient care include securing an adequate airway and ensuring that the patient is breathing adequately. If the breathing is adequate, administer oxygen by a nonrebreather mask at 15 lpm to any patient with mild to moderate respiratory distress. For patients who are breathing inadequately, provide positive pressure ventilation. Respiratory support is especially crucial in botulinum poisoning, since the cause of death is respiratory failure. If the respirations can be supported, the patient’s chance of survival is good.

The use of antibiotics and antitoxins is imperative in the management of patients exposed to biological agents. It is important for the EMS provider to recognize a patient who may be in need of such treatment, summon the necessary medical personnel, and continue to assist with the treatment.

The best protection against biological weapons is prevention. A key to prevention is proper immunization and prophylaxis. Immunization involves taking substances related to the biological agent to develop a resistance or antibodies. Prophylaxis is taking antibiotics prior to exposure or during the incubation stage. Several effective immunizations and prophylaxis strategies are available and their use should be incorporated in the EMS response plan to a disaster.

NUCLEAR WEAPONS AND RADIATION

Nuclear weapons have been in existence since the United States developed the first atomic bomb in the 1940s. Nuclear weapons can cause extensive death by a variety of mechanisms and lead to severe destruction of buildings and other structures in the detonation area. There are three primary mechanisms of death or injury associated with nuclear detonation: radiation, blast, and thermal burns.

Radiation

When an unstable (radioactive) atom breaks apart, it releases energy in the form of rays and particles that travel at high speeds (nuclear radiation). It differs from other types of radiation (light, heat, sound) because it can change the structure of molecules it passes. These rays and particles damage the cells of the human body. The cells may die, repair themselves, or go on to produce damaged or mutated cells.

X-ray radiation and gamma radiation are the same type, although they are created by different processes. This is the most penetrating type of radiation and can travel long distances. This is the type of radiation that is generated in the reactor of a nuclear power plant, by a nuclear bomb, and through the decay of radioactive particles, as in fallout. Gamma radiation is the major external hazard and, to a lesser extent, internal hazard associated with a nuclear detonation or a reactor accident.

Neutron radiation is a powerful and very damaging particle that penetrates several hundred meters of air and easily passes through the body. Since it occurs infrequently outside of the nuclear chain reaction, its greatest threat to life occurs in close proximity to an active nuclear reactor or bomb explosion.

Beta radiation is a low-speed, low-energy particle that is easily stopped by 6–10 feet of air, clothing, or the first few millimeters of skin. It is a common product of fallout decay and is a serious threat from ingestion of contaminated foods and inhalation of airborne particles. Thus, it poses a great internal hazard.

Alpha radiation is a heavy and slow-moving particle that travels only inches in air and is stopped by clothing or the outer layer of the skin. It is a very serious internal contaminant because it causes a great amount of damage along its short course of travel. As in beta radiation, alpha radiation can be ingested or inhaled.

Radiation Exposure

There are two types of radiation exposure associated with a nuclear explosion: primary exposure and fallout.

Primary Exposure. Primary exposure is the primary radiation injury that occurs during or shortly after
the detonation. The rising fireball draws the radioactive materials upward and away from the ground very quickly. The exposure only occurs for the first minute immediately after the detonation. Neutron and gamma radiation travel 1,000–2,000 meters through the air, so exposure is limited to the blast proximity. Thus, most injury and death in the nuclear blast is caused by the blast and burns and not from primary radiation. An exception is a small radiological dispersal device where the radiation doses are strong enough to cause illness or injury well beyond the blast radius.

In the case of a radioactive reactor accident involving radioactive materials where detonation does not occur, gamma radiation is the most serious hazard. This can result in severe and life-threatening injuries to persons near the radiation source. The radioactive source strength, duration of exposure, shielding, and distance from the source directly affect the potential for injury and death.

**Fallout.** Fallout is the second form of radiation exposure. Fallout is radioactive dust and particles that may be life threatening to people far from the epicenter of the detonation. As the superheated products of nuclear detonation and surrounding debris are drawn up into the atmosphere, they are bombarded with nuclear reaction by-products, energized, and then distributed by wind. The closer the detonation occurs to the ground, the greater the updraft of particles, resulting in more fallout.

The radioactive material may be scattered anywhere from a few miles from the detonation site to around the world. The most immediate danger from fallout occurs within 48 hours and within close proximity to the blast. It contains intense ionizing radiation, since it has had very little time to decay, therefore making it the most hazardous.

Radiation injuries are different from burn injuries. The radiation travels through the body tissues and may alter some cell structures. The most common structure in the cell that is damaged is the DNA. The cells that are most sensitive to radiation injury are bone marrow, blood, bowel, skin, and nervous and cardiovascular tissue.

**Blast Injuries**

The nuclear detonation causes a rapid heating of air surrounding the nuclear ignition and an explosively expanding gas cloud. As the cloud movement reaches the speed of sound, it creates a shock wave, followed by a blast of wind. The shock wave and wind blast produce typical shock wave injuries as found in conventional weapons, although the intensity is much greater the closer the victims are to ground zero. The windblast may reach 160 miles per hour, displacing personnel and collapsing structures, leading to crush injuries and entrapment. The blast effects to the victims are reduced the farther they are from ground zero.

**Thermal Burns**

The mechanism that causes most deaths and injury associated with nuclear detonation is the thermal burn. A tremendous amount of thermal energy is released from the nuclear reaction and travels unimpeded through the air to its target. The heating is of very short duration, but it is extremely intense. Anything in close proximity to the detonation is incinerated. The heat energy is fairly easy to shield yourself against. Any opaque object captures the energy. White or light clothing will reflect a great deal of the energy. Flame burns may result from ignition of clothing and building materials. Often the burns of a patient far from the detonation seem very serious; however, they may be only superficial burns.

Eye injuries may be associated with the brilliant light flash. The patient may be blinded for a few seconds or minutes or longer. The retina can be permanently damaged if the person looks directly at the detonation and focuses on the intense light.

**Radiological Dispersal Devices**

A radiological dispersal device (RDD, also called a “dirty bomb”) is a conventional explosive attached to radioactive materials. Such a device has none of the immense blast power of a nuclear weapon, since it cannot sustain a nuclear chain reaction. Instead, it gains its destructive power first by the blast of the conventional explosive, and second by the spread of radioactive material all around the blast site. Thus, the primary mass destruction threat of such a device is to contaminate a wide area with radioactive materials. Such a hazard could induce radiation illness in many persons while seriously contaminating the local environment.

**Assessment and Care for Nuclear Detonation and Radiation Injuries**

The closer the patient is to the detonation, the more severe the injuries expected.

**Assessment**

As the energy travels away from the blast center, it quickly dissipates. This is viewed as concentric circles of injury and destruction. In the innermost circle of destruction, the buildings will be flattened and burned and no people will be found alive. The next circle will contain massive destruction to all structures. Most people will suffer lethal injuries from radiation, the blast wave, and burns. Some victims may survive if they are shielded from the heat and flying debris; however, they may die from a building collapse. The next circle has more survival with those patients exposed to the flash suffering from burns.
The shock wave and radiation may cause serious injury, but thermal burns are the greatest cause of death. As the circles move farther from the site, the injuries and death from the radiation and blast wave are reduced, but burns remain the major cause of injury and death.

When assessing patients, it is important to realize that this is a multiple-casualty scene. The multiple-casualty incident management plan will be activated. Assessment and triage will be done quickly, using the same criteria as in other multiple-casualty incidents. Identify the time after exposure that the patient complains of any radiation-related signs and symptoms.

Radiation injury will cause the following signs and symptoms:

| Bone marrow and blood cells | Nausea, fatigue, malaise, clotting disorders, and possible uncontrolled hemorrhage |
| Bowel | Nausea and vomiting, loss of appetite, diarrhea, fluid loss, malaise, and dehydration |
| Skin | Reddening (erythema) |
| Nervous and cardiovascular systems | Rapid onset of incapacitation, cardiovascular collapse, confusion, burning or “on fire” sensation with high doses |

### Emergency Medical Care

Victims of a nuclear incident will include patients suffering thermal burns, blunt trauma and pressure injuries from the explosive blast, and radiation exposure. Emergency medical care provided to these patients is primarily the same care provided to patients suffering such injuries from any cause.

Your primary concern is for your own and the patients’ safety. Move the patients so that they are perpendicular to the wind direction. Be careful, since the wind direction shifts frequently. If transportation of the patients is not possible, shelter them from the radioactive contamination by putting as much distance and substance as possible between them and the radioactive material. If fallout is expected to be a hazard, a shelter should be constructed for protection. It takes 2 inches of steel, 6 inches of concrete, 8 inches of earth, or 22 inches of wood to serve as protection.

Manage the airway and ventilatory status of the patient. Be cognizant of upper airway burns. If necessary, perform tracheal intubation if you are permitted or summon ALS to provide intubation for patients with upper airway burns. If the patient is breathing adequately and shows evidence of trauma or respiratory distress, apply a nonrebreather mask at 15 lpm. If the patient is breathing inadequately, begin positive pressure ventilation. Pressure injuries to the lungs may have caused severe damage leading to swelling, fluid accumulation, and possible pulmonary emboli. Be aware of the potential for a pneumothorax to occur.

Manage burns as you would normally manage a thermal burn. Use sterile dressings and sterile burn sheets to cover the burned areas. Manage blunt trauma as you normally would in a trauma patient.

Radiation exposure injury will occur hours after the exposure. The damage is typically diffuse throughout the body. Keep all wounds clean to reduce the incidence of infection, since the radiation may affect the body’s immune system and make the patient more susceptible to infection. Irrigate contaminated wounds and apply sterile dressings.

In an area of nuclear fallout or radioactive contamination, it is possible to prevent one of the long-term effects of the radiation by taking iodine tablets. If proper doses are taken before or immediately after the radiation exposure, future thyroid cancer risk can be reduced. This prophylactic measure should be considered in every EMS response plan to such a situation. It is important to remember that iodine only protects against one of the many harmful effects of radiation and its use does not reduce the need for proper shielding, personal protective equipment, decontamination, and long-term monitoring.

### PERSONAL PROTECTION AND PATIENT DECONTAMINATION

In chemical, biological, and radiological/nuclear weapons exposure, it is necessary for you to use personal protective equipment to reduce your risk of exposure and subsequent illness or death. This may involve wearing specialized suits, gloves, boots, and breathing apparatus (Figure 46-6). You must understand the agent you are dealing with in order to take the necessary precautions.
The same principles you use in dealing with hazardous materials can be applied to a chemical, biological, or nuclear incident. Zones should be established so that limited exposure occurs to rescuers. The principles of time, distance, and shielding should be used for personal protection. Patients may require decontamination. The same principles of decontamination used in a hazardous materials incident apply to patients exposed to chemical, biological, or radiological agents. (Refer to Chapter 44, “Hazardous Materials,” for a detailed discussion of personal protective equipment and decontamination.) Typically, those specially trained in decontamination will perform this critical task. If you are not properly trained in specialized rescue when dealing with hazardous materials or the proper methods of decontamination, you should perform other tasks related to patient treatment or transportation.

**SUMMARY**

Weapons of mass destruction (WMD) are intended to produce widespread death and destruction. The weapons may be chemical, biological, radiological, nuclear, or explosive agents. Conventional explosive agents have the greatest likelihood of being used in an attack.

Prehospital personnel must be prepared to respond to a WMD incident. Preplanning is crucial to effective management of the incident and the patients. In preplanning, consideration must be given to supplies and equipment, medical direction, provider education and preparation, response to the scene, and scene safety issues. Also, having a basic knowledge of the signs and symptoms and emergency care necessary for the various agents will better prepare the EMT to manage the patients who are victims of a WMD incident.

**Scene Size-up**

You have been dispatched to the local college football stadium for an explosion with injuries. As you arrive on the scene, you note a large number of people running from the stadium. Some of the patients appear to have suffered some type of trauma.

Your partner finds an open parking lot next to the dormitories that is upwind and uphill from the stadium. He immediately contacts dispatch and indicates that there are a large number of possible patients and to implement the disaster plan with specification of an explosive agent. This triggers the response of the emergency management agency and local public health officials. He then sets up the EMS command center and erects the identification flag. Soon after, the assistant fire chief and police major converge on the parking lot and establish their respective command centers.

Meanwhile, you have immediately sought out the fire officer in charge at the stadium. He indicates the explosion appears to have been a conventional-type bomb that exploded under the east sector of the stands. He has fire personnel in the stadium and is beginning rescue operations. You put on your helmet, turnout coat and pants, leather gloves, and eye protection and proceed to the east side of the stadium. You see that the midsection of the stadium has collapsed. There are wounded people walking about and others trapped within the concrete rubble.

**Primary Assessment and Triage**

Communicating with your partner, who is still the EMS incident commander, you approach the walking patients and instruct them all to move to the south side of the stadium. You instruct the next arriving EMT to go to the south side, gather all the walking injured patients, and take them to the practice field located just east of the stadium. You then pull out the colored ribbons from the multiple-casualty kit and begin to perform triage, using the START method.

As additional firefighters arrive, you instruct them to gather backboards and begin to move the red-tagged

*continued*
patients from the scene to the secondary triage and treatment area located on the soccer field west of the stadium.

As you continue to perform the primary triage, you note typical injuries to the patients from an explosive device. Many have penetrating injuries.

Establishing Sectors
While you are conducting the initial triage, your partner, the EMS incident commander, establishes the secondary triage and treatment sector, supply sector, extraction sector, staging sector, and transportation sector. As the EMS units arrive, he appoints the EMTs as sector officers.

Before long, patients are moving quickly from the incident area to the secondary triage and treatment sectors. Arriving EMS units are now being directed toward the treatment sector for manpower or to the staging and transportation sectors. The red-tagged patients are being moved from the treatment sector to the local medical facilities. The operation appears to be going smoothly with an estimated 150 people injured.

Additional Threats
The specially trained experts in weapons of mass destruction are now on the scene, evaluating the situation for the possibility of chemical weapons used in conjunction with the explosive device, but there is no confirmation at this point. Also, there is concern that a secondary explosion may be set to go off.

You continue with initial triage of the patients as the fire department personnel continue with rescue. There are no further explosions, and the WMD experts indicate that this was only a conventional-type explosive device. No evidence of chemical, biological, or nuclear material is apparent. You continue to work until the scene is completely cleared of all patients.

## IN REVIEW
1. Name the types of weapons of mass destruction.
2. Describe the safety issues to EMS providers when responding to a scene where weapons of mass destruction have been used.
3. Define a conventional weapon and incendiary device.
4. Describe the injuries expected from detonation of an explosive.
5. Explain the difference between a primary, secondary, and tertiary blast effect associated with an explosion.
6. List and describe the different types of chemical agents used as weapons of mass destruction.
7. Describe the emergency care for the different types of chemical agents.
8. List and describe the various biological agents that are used as weapons of mass destruction.
9. List the general principles of treatment of biological agent exposure.
10. List and describe the different types of radiation.
11. List the injuries that are most likely to occur with detonation of a nuclear device.
12. Describe the general emergency care of a radiation exposure patient.

## CRITICAL THINKING
You are responding to the local mall for a large number of ill patients. You are the second EMS unit to arrive on the scene. You find a crowd of approximately 60 people huddled in the parking lot. They claim they heard a loud bang and then, within minutes, many of them started to cough and choke. Most of them are now complaining of shortness of breath and irritation of the throat. You note that most patients have a runny nose, tears, cough, and secretions. You also note wheezing and crackles on auscultation of the lungs of many of the patients.

1. What is the first action you would take?
2. How would you initially manage the patients?
3. What do you suspect they are suffering from?
At times, Advanced EMTs or paramedics may ask that you assist in setting up equipment so that they can perform an advanced skill. Two of the most common advanced skills that EMTs assist with are intravenous (IV) therapy and ECG monitoring. Be sure to follow your local protocol when assisting with ALS skills.

**ASSISTING IN INTRAVENOUS THERAPY**

Intravenous therapy is a common advanced life support procedure that is initiated on many patients in the pre-hospital environment by Advanced EMTs and paramedics. An intravenous line is typically inserted to administer fluids or medication to the patient. A large number of the medications that the Advanced EMT and paramedic administer are given through an intravenous route.

In intravenous therapy, a catheter is inserted directly into a vein. The catheter is connected to intravenous tubing that allows the fluid to flow from the intravenous bag into the vein. The fluid in the bag is primarily composed of water and either electrolytes, such as sodium chloride or others (normal saline and lactated Ringer’s), or sugar (5% dextrose in water, or D$_5$W). These solutions have specific purposes for different patient conditions. Pay close attention to the solution the Advanced EMT or paramedic is requesting when preparing to set up for intravenous therapy.

**Intravenous Therapy Equipment Components**

There are three major equipment components involved in intravenous therapy:

- Catheter
- Tubing
- Bag of fluid

**Catheter**

When assisting, you will typically be asked to set up or prepare the bag of fluid and the tubing. The Advanced EMT or paramedic may ask you to retrieve the catheter, or you may do nothing more than open the packaging. The catheters come in different sizes according to diameter and length. The diameter is identified by the gauge, and the length is in inches. A higher gauge number indicates a smaller diameter. Most often you will find 14-, 16-, 18-, 20-, and 22-gauge catheters. The catheters typically used in the prehospital setting are 2- to 1 $\frac{3}{4}$-inches in length.

**Intravenous Tubing**

The intravenous tubing is also called the administration set. It connects the fluid bag to the catheter. The tubing is typically identified by the number of drops per minute it takes to deliver 1 mL of fluid. For example, it may be a 10-, 15-, 20-, or 60-drop/mL administration set. The lower-drop tubings deliver fluid at a faster rate. The higher-drop tubings deliver fluid at a more controlled and slower rate. The drops/mL may also be referred to as gtt/mL. A mini-drip tubing is a 60 gtt/mL solution set, whereas the macro-drip tubing delivers more fluid through the 10-, 15-, and 20-gtt/mL sets.

The tubing has five major components:

- **Spike.** The spike is the pointed and angled hard plastic barrel at the top of the tubing. It is sterile and covered with a plastic cap or covering to protect it from being contaminated. The spike is used to puncture through the seal of the intravenous bag to allow fluid to flow into the tubing.
- **Drip chamber.** The drip chamber is near the top of the tubing. The size refers to the plastic or metal barrel contained in the chamber. The smaller the barrel, the higher the number of drops it will take to deliver 1 mL of fluid. Drip chambers deliver 10, 15, and 20 gtt/mL.
- **Flow control or regulator valve.** This device controls or regulates the rate at which the fluid is delivered through the tubing and into the vein. It can also completely stop the flow of fluid.
- **Drug or needle or needleless injection port.** The drug or needle or needleless injection port is located below the flow control valve. It is where the Advanced EMT or paramedic administers medication to the patient.
- **Hub connector.** The hub connector is where the tubing inserts into the hub of the catheter. This area of the tubing is protected by a plastic cover or cap to keep it sterile. This should only be removed immediately prior to insertion into the hub of the catheter to protect against the introduction of infection into the vein. The caps are perforated to allow fluid to escape when flushing the tubing.
Bag of Fluid

The bag of fluid comes in a protective outer package. On the front of the bag, the type of solution and the amount of solution in mL is clearly marked. An expiration date is also found on the bag. The bag has two pigtail devices. One has a pull-type cover and the other has an injection port. The pull-type-cover pigtail is where the spike will be inserted.

Preparing the Intravenous Setup ("Spiking the Bag")

Often the Advanced EMT or paramedic will ask you to "spike a bag" of an intravenous solution, typically normal saline, lactated Ringer's, or D5W. He is referring to setting up the solution for use. To do so, perform the following steps (EMT Skills A1-1):

1. Remove the protective wrap (EMT Skills A1-1A).
2. Check the fluid for impurities, particulate matter, and discoloration. Check the expiration date (EMT Skills A1-1B).
3. Select the proper administration set based on the instructions from the Advanced EMT or paramedic. Tear open the packaging of the solution set and uncoil the tubing. Be careful not to let the ends of the tubing touch the ground. Close the flow regulator, if it is open, by rolling the stopcock valve away from the bag.
4. Remove the protective covering from the intravenous bag pigtail port. Be careful not to contaminate the inside of the port.
5. Remove the protective cap or covering from the spike (EMT Skills A1-1C). Be sure not to touch or drop the spike, since it is sterile. If you contaminate the spike, discard the tubing and use another administration set.
6. Insert the spike into the intravenous bag pigtail port (EMT Skills A1-1D).
7. Holding the bag higher than the drip chamber, squeeze the drip chamber once or twice to fill it to the marker line, which is about 1/3 full (EMT Skills A1-1E).
8. Open the flow regulator to "flush" the tubing of all of the air (EMT Skills A1-1F). Most devices will allow easy flushing without removing the hub connector cap; however, some tubing may require that you briefly remove the cap to allow the fluid to be released. Make sure the entire length of tubing has been flushed free of air. If the hub connector cap was removed, do not allow it to touch anything, since it is sterile. Be sure to replace it immediately without contaminating it. If it becomes contaminated by touching the ground, your gloves, or any other object, replace the tubing so that you don’t introduce any bacteria or other microorganisms into the patient.

At this point, the intravenous bag is “spiked” and prepared for insertion into the hub of the catheter.

Saline Lock or Heparin Lock

A saline lock or a heparin lock (Figure A1-1) is used when a patient requires occasional IV medication but does not need continuous fluid. Each of these lock devices is a peripheral IV cannula with a distal medication port. In a saline lock, saline is injected into the device to maintain its patency. In a heparin lock, flushes of heparin solution, which inhibits coagulation, maintain patency.

ECG Lead Placement

An electrocardiogram (ECG) is a device that provides information about the electrical activity of the heart. This electrical activity may indicate to the Advanced EMT or paramedic that the patient is experiencing an abnormal rhythm (dysrhythmia) or, with more advanced monitoring techniques and equipment, that the patient is potentially experiencing a myocardial infarction.

You may be asked to place the electrodes and leads on the patient to assist the Advanced EMT or paramedic. To do so effectively, become familiar with the specific equipment used in your system. Some systems may use a form of combined monitoring electrodes and defibrillation pads, which are much larger than the standard ECG electrode. You may be asked to apply a “3-lead,” “4-lead,” or “12-lead” monitor. This will depend on local protocol and the scope of practice defined by your state.
3- or 4-Lead Electrode Placement

If asked to apply a 3- or 4-lead monitor, you will apply the three or four “limb leads” by performing the following steps (EMT Skills A1-2):

1. Cleanse the skin with alcohol or an abrasive pad to remove dirt, body oil, and other substances that may interfere with the conductivity between the electrode and the skin (EMT Skills A1-2A). If there is a significant amount of chest hair, shave it quickly. Dry the skin if there is a large amount of diaphoresis (sweat). Some systems use antiperspirant or tincture of Benzoin to keep the skin dry to allow for effective adhesion of the electrode.

2. Apply the electrodes to the skin. Some prefer to attach the lead or cable to the electrode prior to placing it on the skin. Others will apply the electrodes and then attach the leads. If three leads are used, apply the electrodes and leads as follows (EMT Skills A1-2B):
   a. Place one electrode to the right side of the anterior chest just under the clavicle at the midclavicular line. This is where the negative lead attaches. The lead is usually white and it has RA on the head of the lead—indicating “right arm” placement, even though the lead is being placed to the right chest.
   b. Apply the second electrode to the left anterior chest just under the clavicle at the midclavicular line. This is where the ground lead attaches. The lead is usually black, brown, or green and it has LA on the head of the lead—indicating “left arm” placement, even though the lead is being placed to the left chest. Since this is the ground electrode, it can be placed in other areas on the chest in the 3-lead configuration.
   c. Apply the third electrode to the left lower chest at about the seventh intercostal space on the anterior axillary line. This is where the positive lead attaches. The lead is usually red and it has RL on the head of the electrode—indicating “right leg” placement, even though the lead is placed on the lower left lateral chest.
   d. If a fourth lead is to be used, apply the electrode to the right lower lateral chest wall. This lead is often green in color and will have LL for “left leg” on the head of the electrode.

12-Lead Electrode Placement

A 12-lead ECG monitor will provide a much more detailed picture of the electrical activity of the heart than will a 3- or 4-lead application. The 12-lead arrangement requires placing 10 electrodes and leads on the patient (the four “limb leads” plus six “precordial leads” as shown in Figure A1-2). To apply the 12-lead ECG monitor, perform the following steps (EMT Skills A1-3):

1. Cleanse the skin with alcohol or an abrasive pad to remove dirt, body oil, and other substances that may interfere with the conductivity between the electrode and the skin. If there is a significant amount of chest hair, shave it quickly. Dry the skin if there is a large amount of diaphoresis (sweat). Some systems use antiperspirant or tincture of Benzoin to keep the skin dry to allow for effective adhesion of the electrode.

2. Place the four limb leads according to the manufacturer’s recommendation. These are the right arm, right leg, left arm, and left leg electrodes and leads (EMT Skills A1-3A). The true limb lead placement is to the upper left and right arm between the shoulder and wrist. The leg leads should be placed on the right and left leg between the hip and ankle leads (EMT Skills A1-3B). When placing the limb leads, be sure to avoid the bony prominences. Bones are not good conductors of electricity. The right arm and left lead...
3. The precordial leads are V1, V2, V3, V4, V5, and V6. These are all placed on the anterior chest. The electrode heads are imprinted with the respective lead numbers.

4. Place lead V1 to the immediate right of the sternum at the fourth intercostal space (EMT Skills A1-3C).

5. Place lead V2 to the immediate left of the sternum at the fourth intercostal space (EMT Skills A1-3D).

6. Out of order, next place lead V4 to the left midclavicular line at the fifth intercostal space (EMT Skills A1-3E).

7. Place lead V3 midway between lead V2 and V4 on the left anterior chest (EMT Skills A1-3F).

8. Place lead V5 to the left anterior axillary line at the same level as V4 (EMT Skills A1-3G).

9. Place lead V6 to the left midaxillary line at the same level as V4 and V5 (EMT Skills A1-3H).

10. Check to ensure that all leads are properly placed, especially the precordial leads (EMT Skills A1-3I) and that all of the leads are properly adhering and are making good contact with the skin.

As an EMT, there may be other skills that you are asked to assist the Advanced EMT or paramedic with during the call. Be sure you are familiar with the equipment and that you have been properly trained in applying or setting up the equipment before doing so. The intent of your assistance is to save valuable time in providing an intervention, as with the intravenous line, or in gaining clinical information about the patient, as in the case of the ECG monitor. Follow your local protocols in determining what assistance you can provide.
Assisting with IV Administration

- **A1-1A** Remove the protective covering from the IV bag.
- **A1-1B** Inspect the IV fluid for impurities, particulate matter, and discoloration and check the expiration date.
- **A1-1C** Remove the protective covering from the spike.
- **A1-1D** Spike the IV bag.
- **A1-1E** Fill the drip chamber to the marker line.
- **A1-1F** Open the flow regulator to flush the IV tubing of all air.
**EMT SKILLS A1-2**

**ECG 3-Lead Placement**

- **A1-2A** Cleanse the skin.
- **A1-2B** Apply the limb-lead electrodes according to the manufacturer’s recommendations.

**EMT SKILLS A1-3**

**ECG 12-Lead Placement**

- **A1-3A** Cleanse the skin and apply the four limb leads according to the manufacturer’s recommendations.
- **A1-3B** Leads applied to the legs.
A1-3C  Place lead V₁.

A1-3D  Place lead V₂.

A1-3E  Place lead V₄.

A1-3F  Place lead V₃.

A1-3G  Place lead V₅.

A1-3H  Place lead V₆.

A1-3I  All leads in place.
There are some situations in which manual maneuvers and basic airway adjuncts are not adequate to maintain or possibly even to establish an airway. In those situations, the use of advanced airway adjuncts is necessary.

Advanced airway skills are not included in the National EMS Scope of Practice for the EMT and can only be performed if the EMT is specifically trained and at the discretion of the medical director and local jurisdiction. If allowed by your medical director and local jurisdiction, you will find learning and maintaining these skills to be challenging.

**AIRWAY AND RESPIRATORY ANATOMY AND PHYSIOLOGY**

The basic anatomy and physiology of the airway and respiratory system have already been discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation,” and Chapter 16, “Respiratory Emergencies.” However, advanced airway management requires a more detailed understanding of upper airway anatomy, because many anatomical landmarks there must be visualized and identified when performing certain maneuvers. Also, to use various pieces of equipment correctly, it is necessary to understand their relationship to the parts of the upper airway.

**Airway Anatomy**

The respiratory system is made up of the upper and lower airway. The upper airway extends from the opening of the nose and mouth down to the larynx. It includes the nasopharynx, oropharynx, and hypopharynx, which is also called the laryngopharynx. The lower airway continues from the inferior (lower) portion of the larynx and consists of the trachea and bronchi. The bronchi branch out, treelike, into the bronchioles and terminate at the alveoli of the lungs.

**Nose, Mouth, and Pharynx**

The nose is the superior (upper) part of the airway and has several functions: (1) It warms and humidifies the air, (2) it serves as a passageway for inhaled air, and (3) its nasal hairs serve as an initial filter of foreign bodies. The air entering the nose passes through the nasopharynx, the area of the throat just behind the nose.

The mouth also serves as a conduit for airflow. Air enters the mouth and passes into the oropharynx, the area of the throat just behind the mouth. The reflexes of the oropharynx protect the airway in the responsive patient; however, in the unresponsive patient, the mandibular and submandibular muscles relax and allow the tongue to drop into the posterior pharynx, causing a potentially life-threatening obstruction.

The openings of the esophagus and larynx begin at the level of the hypopharynx (or laryngopharynx). The esophagus is an oval, hollow, tubelike structure that lies posterior to (behind) the larynx and trachea. The openings to the esophagus (which leads to the stomach) and the larynx (which is part of the airway to the lungs) are very close together, and this—as you will learn during this chapter—is the reason for a number of the complications involved in establishing an airway and ventilating a patient.

**Larynx**

The larynx, which contains the vocal cords and is the major organ of speech, lies inferior to the pharynx and superior to the trachea. It connects and allows air to travel from the pharynx into the trachea. The larynx is composed of three cartilaginous structures: the thyroid cartilage, the cricoid cartilage, and the epiglottis.

The thyroid cartilage is the bulky, shieldlike structure—commonly known as the Adam’s apple—that is found at the anterior (front) portion of the neck. The cricoid cartilage is a firm circle of cartilage that is located below the thyroid cartilage. The cricoid is attached by ligaments to the first ring of the trachea. Immediately posterior to the cricoid is the esophagus. When performing advanced airway techniques, it is sometimes useful to occlude, or close off, the esophagus. This can be accomplished by applying pressure directly to the cricoid ring to push it back against the esophagus, a maneuver known as cricoid pressure or the Sellick maneuver. The Sellick maneuver is controversial and is no longer a standard technique that is commonly applied.

The epiglottis is a leaf-shaped cartilaginous structure (consisting of cartilage, a gristlelike tissue) that covers the opening of the larynx during swallowing. When a person swallows, the muscles of the larynx contract and move the epiglottis downward and the larynx upward, closing the opening and preventing food and liquid from entering the trachea. A depression that is located between the base of the tongue and the epiglottis is known as the vallecula. The glossoepiglottic ligament, which helps support and suspend the epiglottis, is found in the center of the vallecula (Figure A2-1). The vallecula and glossoepiglottic ligament are important anatomical structures that are sometimes manipulated to indirectly lift the epiglottis, making it possible to visualize the
vocal cords and glottic opening during advanced airway management.

The vocal cords are located in the larynx. The true vocal cords, which are normally pale and pearly white, regulate the flow of air into the trachea and produce sounds by vibrating. The space between the true vocal cords is the glottis or glottic opening (Figure A2-2). The glottic area is covered by the epiglottis during swallowing. The false vocal cords lie above the true vocal cords. The true and false vocal cords can close the glottic opening, preventing air or foreign bodies from entering the trachea. This serves a protective function but can also cause an obstruction by blocking airflow in some conditions.

The larynx also contains three sets of paired cartilages. The arytenoids are irregular, pyramid-shaped structures located on the superior aspect of the posterior cricoid ring. The corniculates are cone-shaped and are attached to the top of the arytenoids. The cuneiforms are more elongated and are attached to the posterior arytenoids. These structures are extremely important in advanced airway maneuvers where visualization of the glottic opening is required.

The pertinent glottic structures that the EMT should visualize and identify during intubation are (1) the epiglottis, which will comprise the anterior border of the glottic opening; (2) the true vocal cords, which form the lateral borders of the glottic opening; and (3) the arytenoid cartilages, which form the posterior border of the glottic opening. Additionally, the EMT should be able to see the cartilaginous rings, which comprise the trachea inferior to the glottic opening. Directly posterior to these structures, the EMT should also be able to visualize the esophagus.

As already noted, the openings of the larynx and of the esophagus are in close proximity, making incorrect placement of a tracheal tube a common error. It is also a serious error. Inadvertent placement of a tracheal tube in the esophagus instead of the trachea means that the stomach rather than the lungs will receive the air during ventilation.

Fortunately, the cartilaginous structures just described provide landmarks to differentiate the opening of the larynx from that of the esophagus. One key difference between the two openings is that the esophagus does not have cartilage surrounding its opening as does the larynx. Therefore, before inserting a tube into the larynx, it is imperative to identify the cartilaginous structures and vocal cords to ensure that you are directing the tube into the larynx and trachea, not the esophagus.

**Trachea, Bronchi, and Bronchioles**

The trachea extends from the lower portion of the larynx to the bronchi. The trachea has 16 to 20 incomplete C-shaped cartilage rings on its anterior surface that support the airway and prevent it from collapsing. The trachea is shaped like the letter D with the straight edge on the posterior side. The C-shaped cartilage rings are joined together by fibrous and elastic tissue. Posteriorly, the trachealis muscle, a muscular wall that closes the C-shaped rings, abuts the esophagus, which lies directly posterior.

At about the level of the fifth thoracic vertebra, the trachea splits into the right and left mainstem bronchi. This point, where the right and left mainstem bronchi split from the trachea and enter the right and left lungs, is known as the carina. The right mainstem bronchus branches from the trachea at a much lesser angle and appears to be almost in line with the trachea, whereas the left mainstem bronchus branches at a greater angle. Because of this difference, aspiration of food, liquids, or foreign bodies is far more common on the right side than on the left. More important, the lesser angle makes it easier to misdirect a tracheal tube into the right mainstem bronchus than in the left if it is advanced too far.
The bronchi continue to subdivide into smaller passages known as the bronchioles. The bronchioles terminate at the alveoli, the sacs where gas exchange occurs in the lungs.

**Lungs**

The right and left lungs are found in the thoracic (chest) cavity. They are separated by the space called the mediastinum, which contains the heart and other structures and tissues. The right lung has three lobes and the left lung has two lobes. The lungs contain the alveoli and supporting tissue. Both lungs are covered by the pleura. The pleura consists of two layers, the inner visceral pleura and the outer parietal pleura. Between the layers of the pleura is a small amount of pleural fluid, which acts as a lubricant that reduces friction when the lungs move during respiration. There is also a negative (or subatmospheric) pressure between these layers, which causes the lungs to expand and return to the thoracic cavity as intercostal and diaphragmatic muscle contraction. The diaphragm is located at the base of the thoracic cavity and separates the chest from the abdominal cavity. The diaphragm is the major muscle of respiration, providing roughly 60 percent of the effort needed for normal breathing. The mechanics and physiology of respiration were discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

**Airway Anatomy in Infants and Children**

There are considerable differences between the airways of adults and those of infants and children. These differences are extremely important to remember when performing advanced airway maneuvers on patients in these age groups.

**Head**

The head of an infant is much larger in proportion to its body than that of an adult. Because the head is larger, especially the occiput (back of the head), when an infant is placed in a supine position its head tilts forward, flexing the neck and constricting the airway structures. Any type of padding placed under the head in children less than 9 years of age may cause an airflow obstruction. For infants and young children, in fact, it is commonly necessary to place a small, folded towel under the shoulders to keep the airway aligned and ensure airflow.

**Mouth, Nose, and Pharynx**

The structures in these areas are smaller and more pliable in infants and children and thus more easily obstructed by secretions, foreign objects, and swelling. The infant is basically a nose breather during much of his first year because of the more superior location of the epiglottis and anterior location of the larynx, so obstruction of the nasal passages is especially critical.

The most common cause of airway obstruction in the infant or young child is the tongue falling back and blocking the pharynx. This is an even greater problem in infants and children than in adults because the child’s tongue is larger in proportion to the mouth and pharynx and the jaw is less prominent. When the muscles of the pharynx relax, the tongue is pulled back like a valve during inspiration, causing an obstruction. The larger tongue also interferes with visualization of anatomical structures during tracheal intubation.

**Larynx**

The airway of the infant and child is narrowest at the level of the cricoid cartilage. Also, that cartilage is less developed and less rigid than in adults. This is important to keep in mind during tracheal intubation. The tube may pass easily through the vocal cords but be too large to fit through the cricoid ring. Therefore, it is necessary to have tracheal tubes available that are at least one half-size larger and smaller than the one you estimate is correctly sized when performing this procedure. Pressure on the cricoid and overextension or overflexion of the neck can cause an obstruction.

**Trachea and Bronchi**

The major airways are narrower and shorter in infants and children. The trachea is also softer and more flexible. This means that the airway can be more easily occluded by swelling and other obstructions or kinked by flexion or extension of the neck. Small movements of the head or neck may also cause a tracheal tube to advance into the right mainstem bronchus or out of the glottis.

**Chest Wall and Diaphragm**

The chest wall in infants and children is softer and more flexible than in adults. Infants and children also have a tendency to rely more heavily on the diaphragm for breathing.

**Summary of Pediatric Airway Considerations**

As just discussed, there are important anatomical and physiological differences between the pediatric and adult airway that factor not only into how you assess the airway but also into how you manage the airway.

Remember that infants are obligate nose breathers, and therefore a nasal obstruction may be a critical airway occlusion. Recall also that the tongue is
proportionally larger in the oral cavity, and the mandibular muscles that support it may not be fully developed. This combination allows the tongue to become a formidable obstruction in an unresponsive pediatric patient. These conditions, in conjunction with the larger occipital region of the head, easily allow the tongue to block the airway when the neck flexes in the supine, unresponsive pediatric patient. Additionally, the glottic opening is positioned more cephalad (toward the head) and more anterior than in the adult, which makes direct visualization of glottic structures more challenging during advanced airway procedures.

The ribs and intercostal muscles are usually more pliable and less developed than in the adult, so when there are increased demands on the pediatric pulmonary system, these muscles may fail to adequately support the lungs, which will allow a more rapid onset of respiratory distress and progression to respiratory failure. The pediatric patient consumes oxygen at a rate roughly double that of the adult patient, so hypoxemia occurs rapidly during periods of hypoventilation.

Recent studies have shown that pediatric patients under 14 years of age have better outcomes when managed with bag-valve-mask ventilation than with intubation. Therefore, pediatric patients should be intubated only when BVM is unsuccessful.

**BASIC AIRWAY MANAGEMENT**

One of the situations in which advanced airway management techniques are of great use is when prolonged ventilation of a patient becomes necessary. Some advanced airways reduce problems of poor mask seal and of hand fatigue from holding a mask seal for a prolonged period or performing one- or two-handed bag-valve ventilation. Before using advanced airway management, however, you must first determine whether a patient is breathing adequately or inadequately. Methods of assessing for adequate or inadequate breathing were discussed in Chapter 10, "Airway Management, Artificial Ventilation, and Oxygenation," and Chapter 16, "Respiratory Emergencies."

The first step in airway management is to establish a patent airway by using a manual maneuver. The head-tilt, chin-lift maneuver is used in the patient with no suspected spinal injury. The jaw-thrust maneuver is used in a trauma patient or any patient with suspected spinal injury. If any blood, secretions, vomitus, or other substances are in the airway, you must suction them immediately to prevent aspiration. Two basic mechanical airway adjuncts, the oropharyngeal and the nasopharyngeal airways, can be inserted to help maintain the airway. You can review these basic methods of establishing and maintaining an airway in Chapter 10.

Basic airway techniques must be employed prior to advanced airway management. There are some conditions where immediate use of an advanced airway technique is necessary, as in upper airway burns and in anaphylaxis, where swelling of the larynx requires immediate insertion of a tracheal tube through the larynx and into the trachea. In most situations, however, if the basic steps of airway management and ventilation are omitted and advanced procedures are performed instead, the patient can become dangerously hypoxic and suffer irreversible consequences. The patient can utilize the oxygen that was made available during basic airway management and ventilation during insertion of the advanced airway.

For the most part, advanced airway management techniques are used for the following reasons: when it is necessary to protect the patient from aspiration of secretions, blood, or vomitus; when prolonged ventilation by the EMT is necessary; or when basic airway management techniques are not adequate. Remember, though, that in these situations, the airway is initially controlled with basic techniques while the patient is being ventilated and oxygenated and the necessary equipment is being prepared.

Although advanced airway management is often performed under highly stressful circumstances when the patient's life is threatened by the compromised or potentially compromised airway, bear in mind that airway management procedures can be extremely frightening and uncomfortable to the patient (even if minimally responsive) or to the patient's family. These procedures are rarely performed in an awake patient without sedation.

**Oropharyngeal Suctioning**

Before you use any advanced airway techniques, remove any secretions, blood, vomitus, or other substances from the oropharynx with suction. If you hear a gurgling sound during ventilation, it is an indication that some liquid is in the airway and should be suctioned immediately. Some suction units cannot adequately remove heavy vomitus or solid objects, such as teeth, from the airway. You may have to sweep the mouth with your finger, a tongue blade, or the end of the rigid suction catheter to remove the vomitus or object.

A variety of suction units exist. It is vital that a portable suction unit, either electrical or hand operated, be available during airway management, especially when advanced airway procedures are to be performed. Hard, or rigid, suction catheters are used when suctioning the mouth and oropharynx. Soft, or French, suction catheters are useful for suctioning the nose and nasopharynx. Soft suction catheters are also used in clearing secretions from the trachea once a tracheal tube is in place (a technique that is discussed later in this appendix). Also note that as the lower structures are visualized, further suctioning may be required. Review oropharyngeal suctioning in Chapter 10.
OROTRACHEAL INTUBATION

Orotracheal intubation (from oro, meaning “mouth,” and tracheal, referring to the trachea) is the insertion of a tube through the mouth and along the oropharynx and larynx directly into the trachea. Because the distal end of the tube is designed to be placed in the trachea, it is referred to as a tracheal tube or endotracheal tube (from endo, meaning “into,” and tracheal, referring to the trachea). The process of inserting the tube is known as intubation. The terms orotracheal intubation, endotracheal intubation, and tracheal intubation are often used almost interchangeably.

Orotracheal intubation requires the EMT to visualize anatomical landmarks with the use of a device called a laryngoscope. The laryngoscope, equipped with a light to aid in visualization, is inserted into the mouth and down into the pharynx. It is used to lift, either directly or indirectly, the epiglottis and to expose the vocal cords and glottic opening. The tracheal tube is then passed through the vocal cords and directly into the trachea.

Visualization of the tracheal tube as it enters and passes through the vocal cords is extremely important to reduce the risk of improper placement in the esophagus. The EMT must be completely familiar with techniques of properly placing the tracheal tube and must be able to differentiate immediately between a tracheal intubation and an esophageal intubation. If a tube is inadvertently placed in the esophagus, the patient’s lungs will receive no ventilation or oxygen and the patient will die.

Advantages

Tracheal intubation is the most effective means of controlling the patient’s airway. The following advantages make tracheal intubation the preferred method for controlling the airway in the apneic patient (patient who is not breathing):

• It provides complete control of the airway. The tracheal tube is placed into the trachea, establishing a direct route of ventilation and oxygenation. The tongue no longer threatens airway occlusion, so it is not necessary to maintain a head-tilt, chin-lift or jaw-thrust maneuver, allowing the EMT to focus on other critical tasks, such as ensuring that adequate tidal volumes are being delivered at an appropriate rate.

• The tracheal tube is designed to isolate the trachea, eliminating the risk of aspiration of material into the lower airways and lungs. Secretions, blood, vomitus, and other substances are blocked by the tracheal tube in the upper portion of the trachea and pharynx and kept from traveling farther down the airway. The substances can then be removed by suction.

• The tracheal tube permits better ventilation and oxygen delivery. The bag-valve device is connected directly to the tracheal tube, thus allowing more effective ventilation because air goes directly into the trachea and lungs. Because no mask seal is required, only one EMT is needed to perform two-handed bagging. Also, hazards associated with air entering the esophagus and subsequently the stomach are eliminated since the tube directs ventilation into the trachea and lungs.

• A suction catheter can be passed through the tracheal tube to allow for deeper suctioning of the trachea and bronchi. This removes secretions that the patient may not have been able to eliminate otherwise and effectively clears the airway.

• The tracheal tube with positive pressure ventilation can overcome both mechanical and physiological problems that compromise normal ventilation.

Indications

Not every patient requires tracheal intubation. It should be used only under certain conditions. Indications for its use include the following:

• The EMT is unable to ventilate the apneic patient effectively with standard methods such as mouth-to-mask or bag-valve mask. Establishing a good mask seal may be very difficult in some patients, especially those with trauma to the mouth or jaws. Sealing the mask may also be difficult in patients who have no teeth or dentures. A good seal is difficult to maintain during a long transport.

• The patient cannot protect his own airway. This includes patients who are unresponsive or in cardiac arrest. Whenever you determine that a patient is unable to protect his own airway, consider endotracheal intubation. Keep in mind that good basic airway maneuvers, basic airway devices, and suctioning are the preferred methods to manage the airway for the EMT. The patient who cannot protect his own airway is the patient who:

  • Is unresponsive to any type of stimulus. In a completely unresponsive patient, the muscles that control the tongue and epiglottis relax and easily occlude the airway. The patient cannot clear blood, vomitus, secretions, and other substances from his airway, and the risk of aspiration is high.

  • Has no gag reflex or loses the cough reflex. The gag and cough reflexes are very important in protecting the airway against foreign body occlusion and aspiration. The loss of these reflexes leaves the airway vulnerable to blockage or foreign body aspiration; however, the presence of the reflexes does not guarantee a protected airway.

As a general rule, if you are able to insert an oro-pharyngeal airway in the patient without incident, you can assume that he has lost his gag reflex and cannot protect his airway; he is, therefore, a good candidate for tracheal intubation. Since the patient is unable to protect his own airway, have a suction device ready in case of
The laryngoscope has two components: the handle and the blade. The laryngoscope handle is a cylindrical device that contains batteries as a source of power. During intubation, the EMT holds the laryngoscope handle in his left hand and uses it to control the laryngoscope blade. The laryngoscope blade is the component that directly or indirectly lifts the epiglottis for visualization during intubation. A locking bar on the laryngoscope handle interfaces with a c-channel fitting at the base of the blade, which allows the two components to securely lock into each other, and which also enables the electrical circuit to the lighted end of the blade. A bulb is located in the distal third of the blade and serves as a light source to permit visualization of the glottic opening and the vocal cords. Fiberoptic laryngoscope handles have the light source in the handle and a fiber-optic strand in the blade to provide a bright light.

Two types of laryngoscope blades are traditionally available: the straight blade (Miller, Wisconsin, or Flagg) or the curved blade (McIntosh) (Figure A2-3). The name of the blade describes its shape. Both types of blades can lift the epiglottis, but each type does this differently. The choice of blade type is basically a matter of personal preference.

**Straight Blade.** The straight blade is straight at the distal end and has a more rounded edge. The blade is narrower than the curved blade and has a hollow central channel. The straight blade comes in a variety of sizes ranging from 0, the smallest, to 4, the largest. A size 0 blade would be used on an infant, whereas a size 4 would be used to intubate a large adult.

The end (or distal edge) of the straight blade is fitted under (or posterior to) the epiglottis and directly lifts it to expose the vocal cords and glottic opening (Figure A2-4a). During insertion, the rounded part of the blade is used to push the tongue over to the left side as the blade is brought into the midline of the mouth and oropharynx. The top of the straight blade is then used to gently lift the tip of the epiglottis. The hollow channel is used as a sight as the tracheal tube is advanced from the corner of the mouth and placed between the vocal cords and into the glottic opening. The channel is not used to advance the tube. Attempts to force the tracheal tube through the straight blade channel will likely result in damage to the tube and obstruct visualization of the vocal cords. If the tube is damaged, it is necessary to remove it and repeat the intubation process. During this time, the patient’s airway is not protected.

The straight blade is preferred for performing intubation in infants and children. Because of the anatomical differences, the straight blade provides greater displacement of the tongue and better visualization of the vocal cords and glottic opening and causes less tissue damage in this age group. The straight blade is also preferred in larger patients with short, thick necks.

**Curved Blade.** The curved blade is curved at the distal end and has a beaded or blunt edge. The blade has a broad surface and tall flange that is used to move and hold the tongue out of the way during

**Standard Precautions**

When performing tracheal intubation, the EMT must get extremely close to the patient’s open mouth and visualize deep into the airway. Contact with the patient’s secretions, vomitus, and/or blood is likely during the intubation procedure. Put on gloves, eye protection, and a mask before attempting the procedure to avoid contact with body fluids.

**Equipment**

Several pieces of equipment are required for tracheal intubation. Check that the equipment is in proper working order before any attempt at intubation. The equipment needed for intubation includes the following:

- Laryngoscope (handle and blades)
- Tracheal tube
- Stylet
- Water-soluble lubricant
- 10 mL syringe
- Tracheal tube securing device
- Suction unit
- Towels or padding
- Stethoscope
- End-tidal CO₂ or esophageal detection device

**Laryngoscope**

The laryngoscope is inserted into the mouth along the right side and then directed into the hypopharynx by sweeping the tongue to the left. In the hypopharynx the laryngoscope is used to lift the epiglottis and provide visualization of the vocal cords and glottic opening. This procedure is known as laryngoscopy. Laryngoscopes may be reusable or disposable.

The name of the blade describes its shape. Both types of blades can lift the epiglottis, but each type does this differently. The choice of blade type is basically a matter of personal preference.

Two types of laryngoscope blades are traditionally available: the straight blade (Miller, Wisconsin, or Flagg) or the curved blade (McIntosh) (Figure A2-3). The name of the blade describes its shape. Both types of blades can lift the epiglottis, but each type does this differently. The choice of blade type is basically a matter of personal preference.
intubation (Figure A2-4b). The curved blade also comes in a variety of sizes ranging from 0 for the infant to 4 for the large adult.

The beaded end of the curved blade is inserted into the vallecula, the space located between the epiglottis and base of the tongue. When the edge of the blade is placed in the vallecula it presses on the glossoepiglottic ligament, causing the epiglottis to be indirectly lifted upward and exposing the vocal cords and glottic opening.

**Alternative Blades.** Newer, redesigned blades that share some of the features of the straight and curved blades have come to market in the past several years. These newer blades, as well as some adjunctive intubation equipment, are discussed later in this appendix.

**Assembly.** The indentation on the laryngoscope blade is designed to lock onto the bar of the laryngoscope handle. The blade is lifted upward so it is at a right angle to the handle. The electrical connection is then made and the bulb at the end of the blade is lit. Check to be sure that it is on. The light should be tight, bright, and white. If it is not, check that the blade is securely locked. The bulb must be tightly screwed into the socket of the blade. If the bulb is loose, tighten it. If the light is not bright and white, it may also be necessary to change the batteries in the handle. It is best to check the equipment daily and always to have an extra bulb and batteries available in case of failure.

In fiber-optic laryngoscope handles and blades, the fiber-optic light source is located in the handle. The blade contains a fiber-optic strand, rather than a bulb, to provide illumination at the end of the blade. This provides a brighter light source for visualizing the glottic structures.

**Tracheal Tubes**

The tracheal tube is a flexible, translucent tube made of polyvinyl chloride that is open at both ends. Tracheal tubes come in a variety of sizes (Figure A2-5). The size noted on the outside of the tube is the tube’s internal diameter (i.d.). The external diameter is estimated by adding 2–3 mm to the internal diameter size. In general, an adult male will require an 8.0–8.5 mm i.d. tube and the adult female will take a 7.0–8.0 mm i.d. tube. Tube sizes for infants and children range from 2.5–6.0 mm i.d.

If you are uncertain what size to use, it is prudent to select a smaller-sized tube. In an emergency, a 7.5 mm...
The tracheal tube has several components (Figure A2-6). At the proximal end, a 15 mm connector allows attachment of a bag-valve and other ventilation devices. The distal end has a cuff that serves to seal off the trachea. An inflation line extends up the main tube to a pilot balloon that verifies that the cuff is inflated. A one-way inflation valve allows use of a syringe to inflate the cuff. The cuff will hold approximately 10 mL of air. The cuff should be inflated to prevent any leakage of air from around the cuff and the tracheal tube and between the tube and the tracheal wall. Typically, tubes for infants and children under 8 years of age have no cuff at the distal end and are referred to as uncuffed. The i.d. sizes for these uncuffed tracheal tubes are usually less than 6.0 mm. Uncuffed tubes are usually used in this age bracket because the narrowest portion of the airway is the cricoid ring and not the vocal cords as in an adult. In the hospital setting, it has been found that cuffed tracheal tubes can also be used safely for infants beyond the newborn age. In this environment, the use of a cuffed tracheal tube may be preferable in situations of poor lung compliance or high airway resistance. However, greater attention needs to be given to the selected tracheal tube size, the position of the cuff, and the pressure in the cuff once inflated. Because of these particularities, the use of a cuffed tracheal tube by the EMT in the prehospital environment may not be common practice.

At the distal end of the tracheal tube is a Murphy eye. This is a small hole on the side opposite the beveled side. The eye lessens the chance of complete tube obstruction. If the distal end of the tube becomes obstructed by the tracheal wall, blood clots, or secretions, the Murphy eye will still allow air to escape and ventilation to take place.

The length of the tube from the distal end is indicated in centimeter (cm) markings along the tube. The length of the tube for the adult is 35 cm. Following placement of the tube in the adult, the 22 cm marker is typically at the level of the teeth. The level should be documented on the prehospital report. This is only a general rule and does not apply to all patients because of variations in their sizes. Other standard measurements are: 15 cm from the teeth to the vocal cords; 20 cm from the teeth to the sternal notch; and 25 cm from the teeth to the carina. The tube marking at the level of the lip line should be reassessed every time the patient is moved or transferred.

The measurements are helpful, but you must rely on good clinical assessment skills to determine that the tube is properly placed. When properly placed, the distal tip of the tracheal tube is in the trachea and midway between the carina and the vocal cords and good equal breath sounds are heard over both lungs with rise of the chest observed. The tip of the tube must not extend past the carina. If the tube is inserted beyond the carina, it will most likely enter the right mainstem bronchus (because it is straighter and at a lesser angle from the trachea than the left mainstem bronchus) and only ventilate the right lung. This is referred to as a right mainstem intubation, a common complication of tracheal intubation.

Once you verify that the tube is correctly placed, it is extremely important to note the centimeter level marking on the tube at the teeth and record it on the prehospital report. This should be reverified any time the patient is moved or transferred. If at any time the level marking has changed, it is an indication that the tube has been inserted deeper or has been pulled back. You must then immediately reassess tube placement. The tube can become dislodged and end up either in the right mainstem bronchus if pushed farther down or, worse, in the esophagus if pulled upward and then pushed down again. Continuous reassessment of tube placement is necessary.

**Stylet**

The malleable stylet is a piece of pliable metal wire, typically coated with plastic, that is inserted into the tracheal tube to alter its shape and provide stiffness (Figure A2-7). The stylet should be lubricated with a water-soluble jelly prior to insertion in the tube to facilitate easy removal. The stylet should not be inserted
You can employ an elaborate commercial device or the trachea; it does not secure the tube in place. There mainstem bronchus. The cuff on the tracheal tube seals to become dislodged and end up in the esophagus or removal of the ventilation device can cause the tube must secure it. Movement of the patient or attachment readjustment is needed.

Inflation is maintained. Keep the syringe near in case the tracheal tube to facilitate insertion and to the stylet to stiffness and shape the tube. It should not extend past the end of the tube.

Beyond the Murphy eye and should never extend or project out of the distal end of the tracheal tube. This could lead to severe trauma to the airway and trachea from accidental perforation. The end of the stylet must be recessed at least 1/2 inch from the distal end of the tube. To ensure proper stylet position, recess the stylet at least one-quarter inch from the cuff or proximal end of the Murphy eye. Once the stylet is in place, it can be used to form the tube into a “hockey stick” shape to aid in proper insertion. After the tube is passed through the vocal cords, carefully remove the stylet, holding the tube securely to avoid dislodging it.

Other Intubation Equipment

Water-soluble lubricant is applied to the end of the tracheal tube to facilitate insertion and to the stylet to allow for easy removal. Tube displacement may result from pulling out a syringe that is not lubricated. Do not use petroleum-based lubricants, because they may damage the tracheal tube and can irritate and inflame the tracheal lining.

A 10 mL syringe is used to inflate the cuff at the distal end of the tracheal tube. Prior to insertion, check the cuff to ensure it is working properly by injecting 10 mL of air into the inflation port. It is then necessary to deflate the cuff completely by pulling back on the plunger of the syringe while ensuring that the syringe is firmly engaged into the one-way inflation valve before inserting the tube. During intubation, leave the syringe attached to the inflation port. Once the tube is in place, use the syringe to inflate the cuff, and then immediately remove the syringe. The cuff can deflate if the syringe is left attached. Assess cuff inflation by checking the volume of air in the pilot balloon. Being able to seal the trachea through cuff inflation is a primary advantage of the tracheal tube. Monitor constantly to ensure that inflation is maintained. Keep the syringe near in case readjustment is needed.

Once the tracheal tube is properly positioned, you must secure it. Movement of the patient or attachment or removal of the ventilation device can cause the tube to become dislodged and end up in the esophagus or mainstem bronchus. The cuff on the tracheal tube seals the trachea; it does not secure the tube in place. There are, however, a variety of devices available to do this job. You can employ an elaborate commercial device or simply use tape. Follow your local protocol or medical direction’s advice for securing the tube.

The tracheal tube is flexible enough so that if the patient should bite down or clench his teeth, the tube will be crimped and occluded. An oral airway or bite block should be inserted after the tracheal tube has been successfully placed to avoid this problem, especially if the patient begins breathing on his own or becomes more responsive after being intubated. Some commercially available securing devices contain a bite block.

A suction unit must be available during tracheal intubation to clear any fluid, vomitus, blood, secretions, or debris from the oral cavity. A large-bore catheter is needed for suctioning the oropharynx. Once the patient is intubated, a flexible French catheter is used for tracheal suction (as is described later).

Towels may be placed under the patient’s shoulders or back of the head to help align the airway axis for easier visualization during intubation. In patients with suspected spinal injury, you must maintain stabilization of the head in a neutral, in-line position during intubation.

Ensuring proper tube placement is of utmost importance when performing this skill. The EMT should utilize both clinical assessment findings and confirmation devices to ensure that the tracheal tube is placed properly. Initially, tube placement should be confirmed during the intubation procedure. Since the EMT is only allowed to perform visual orotracheal intubation, the tip of the tracheal tube should have been seen passing between the vocal cords. Following placement, the tube is further assessed by auscultation of the epigastrium and the chest. An end-tidal CO2 and esophageal detector device are additional tracheal tube confirmatory devices used after auscultation to ensure proper tube placement. Confirmation of tracheal tube placement occurs when the EMT does not hear sounds of air entering the stomach when listening over the epigastrium, and does hear sounds of air entering the lungs bilaterally. In addition, the end-tidal carbon dioxide detector should register the presence of exhaled carbon dioxide. If the esophageal detector is used, it should rapidly reinflate.

Cricoid Pressure

Cricoid pressure, also known as the Sellick maneuver (Figure A2-8 ■), was once thought to effectively reduce complications associated with positive pressure ventilation with a pocket mask, bag-valve mask, or other device when the airway of an unresponsive patient is not protected by an advanced airway device. The technique was intended to reduce the incidence of gastric inflation, regurgitation, and aspiration of gastric contents.

According to the 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, cricoid pressure is not recommended for routine use, but it can be applied to facilitate insertion of an endotracheal tube in the adult patient. In the pediatric patient, cricoid pressure can be
finger slowly toward the feet until you feel the obvious cartilage prominence.

2. Continue to slide your fingers downward until you feel the base of the thyroid cartilage and, below it, a small, soft midline indentation, the cricothyroid membrane. Immediately below the cricothyroid membrane is the bulky cricoid cartilage.

3. Place your index finger on one side of the cricoid cartilage, your thumb on the other side, and apply firm backward pressure.

The cricoid cartilage is the only complete cartilaginous ring (review Figure A2-8). When forced backward, it may collapse the esophagus behind it against the cervical vertebrae. A collapsed esophagus may prevent air from traveling down to inflate the stomach and may also prevent stomach contents from moving up. In this way, cricoid pressure protects the airway from regurgitation and consequent aspiration of stomach contents and also protects against gastric inflation. If the patient starts to regurgitate, release the cricoid pressure to prevent an esophageal tear. Immediately turn the patient onto his side, if possible, and suction the airway until clear.

Slow, sustained ventilation over a 1-second period with a controlled tidal volume is the best method to reduce the incidence of gastric inflation. Additionally, proper and adequate positioning of the airway with the head-tilt, chin-lift maneuver will reduce the amount of resistance in the airway and allow more of the ventilation to flow down the trachea and into the lungs instead of down the esophagus and into the stomach.

Tracheal Tube Insertion in an Adult

When properly placed, the tracheal tube is the only adjunct that will ensure an airway. However, if it is misplaced, the tube can contribute to rapid deterioration and death. You must become completely competent in orotracheal intubation during your education program. As a certified EMT, you must continuously review and practice the technique. This is one of the most critical and complicated skills that you will ever perform.

The steps for orotracheal intubation are as follows (EMT Skills A2-1A to A2-1H):

1. The person performing the intubation should take the necessary Standard Precautions, including wearing gloves, eye protection, and a mask.
2. Prior to any intubation attempt, the patient must be adequately ventilated with a bag-valve-mask device and a high concentration of supplemental oxygen to achieve hyperoxegenation of the patient.
3. Ventilate the patient for 2 minutes before the intubation attempt.
4. Gather the necessary equipment for inserting and securing the tube, assemble it, and test it.
a. Test the cuff on the tracheal tube by injecting 10 mL of air into the inflation port with a syringe and feeling the cuff to ensure that it is inflated fully and does not automatically deflate. Then deflate the cuff by withdrawing all of the air with the syringe. Leave the syringe attached to the inflation port. The tracheal tube should be kept in its packaging, if possible, while checking the cuff to avoid any unnecessary contamination.

b. Assemble the laryngoscope blade and handle. Lift the blade to illuminate the bulb and check the brightness. Also check the bulb to ensure that it is tight and will not become dislodged during the intubation.

c. If a stylet is to be used, lubricate it with a water-soluble lubricant and insert it into the tube. Check the distal end of the stylet to ensure that it is not projecting out of the tracheal tube and is recessed adequately. Form the tube into a hockey-stick configuration.

d. Lubricate the distal end of the tracheal tube with a water-soluble lubricant.

e. Have a suction unit equipped with a large-bore catheter available. Check to make sure that the suction unit works adequately.

f. Prepare the device that will be used to secure the tube in place.

5. Position yourself at the patient’s head. The tracheal tube and suction unit should be on your right and the laryngoscope on your left.

6. The patient’s head must be positioned properly to permit maximum visualization of the vocal cords and glottic opening. The position of the head will depend on whether a spinal injury is suspected.

   • **No spinal injury suspected.** Tilt the head backward and lift the chin forward into a “sniffing position.” The sniffing position is created by extension of the neck at cervical vertebrae 1 and 2 combined with flexion of cervical vertebrae 6 and 7. Do not hang the head over the end of a table or bed. If visualization is unsuccessful, it may be necessary to reposition the head. You can place folded towels of approximately 1-inch thickness under the shoulders or under the back of the head to adjust flexion or extension as necessary. The desired position aligns the mouth, pharynx, and trachea and permits better visualization during intubation.

   • **Suspected spinal injury.** If a spinal injury is suspected, maintain in-line spinal stabilization throughout the intubation procedure. One EMT should hold the head and neck stable from below while the EMT who is to intubate secures the head and neck with his thighs (EMT Skills A2-1D). The limited ability to align the head and neck will make visualization more difficult.

7. Stop ventilation and remove the oropharyngeal airway if one has been used. Ventilation must not be interrupted for more than 30 seconds while intubating. The 30-second period begins when positive pressure ventilation is stopped and ends when ventilation is resumed following placement of the tube. If you cannot intubate within 30 seconds, stop the procedure and immediately resume oxygenating the patient. Research has found that a healthy person who has breathed 100% oxygen for 3 to 5 minutes prior to the intubation attempt will not desaturate for 4 to 6 minutes without ventilation; therefore, the 30-second rule is very aggressive. Follow your local protocol. After 2 minutes of ventilation and hyperoxygenation, try again to intubate. It is also desirable to monitor the pulse oximeter reading during the procedure for evidence of deoxygenation.

8. If enough personnel are available, one EMT should apply cricoid pressure to reduce the possibility of regurgitation during the intubation procedure. The intubator may use backward pressure on the thyroid cartilage to move the glottic opening slightly posterior and may make visualization of the vocal cords easier. The mnemonic BURP (backward, upward, rightward pressure) is often used to describe the thyroid pressure used to bring the glottic opening into the best position for visualization by the intubator. Cricoid pressure must be maintained until after the cuff of the tracheal tube is inflated. Cricoid pressure and BURP are two separate maneuvers.

9. Hold the laryngoscope in your left hand and insert the blade into the right corner of the mouth. You may need to use a crossed-finger (scissors-type) technique to separate the teeth, using the thumb and index finger of the right hand. Move the blade to the midline, gently sweeping the tongue to the left to allow for more room and better visualization. Advance the blade to the base of the tongue and place it in the proper position, depending on the type used:

   • **Curved blade.** The tip of the curved blade is inserted into the vallecula (the indentation between the base of the tongue and the epiglottis).

   • **Straight blade.** The tip of the straight blade is placed under the epiglottis.

The handle and blade are lifted up and forward, away from the patient’s teeth and gums and in the direction of the laryngoscope handle. Do not angle the handle backward in a prying motion or use the teeth as a fulcrum; such actions could cause trauma to the airway and teeth. Do not use a digging motion with the blade and handle in trying to expose the glottic opening. The movement should be smooth and controlled. Exposure should be achieved in three easy movements of the blade: (1) insert the blade in the right corner of the mouth, sweeping the tongue to the left; (2) advance the blade to the base of the tongue; (3) gently lift up and forward to expose the glottic opening.
When using the straight blade, you may see the epiglottis tip when lifting up and forward. Remember, the straight blade is used to get under the epiglottis and lift it up. Drop the blade down slightly and gently advance the blade farther into the hypopharynx to slip the tip of the blade under the epiglottis. Lift up and forward to expose the glottic opening. The straight blade can easily be advanced past the glottic structures and into the esophagus. This is why you should not just blindly insert the blade into the mouth and begin the lifting movement without properly identifying the structures. If, however, the blade is accidentally inserted too deep, pull back on the blade and again attempt to visualize the structures. This is the method preferred by some experienced intubators.

10. Identify the glottic opening by (1) cartilaginous structures surrounding it, (2) the fact that it is round—not oval like the esophageal opening, and (3) the fact that it contains the vocal cords. Once you identify the vocal cords and glottic opening, do not lose sight of them.

11. Insert the tracheal tube through the right side of the mouth. It may help to have an assistant lift upward and out on the patient’s right cheek. Guide the tracheal tube through the vocal cords. You must actually visualize the tube passing through the vocal cords. Continue to insert the tube until the proximal end of the cuff is advanced about 1/2 to 1 inch beyond the vocal cords. This should place the tip of the tracheal tube about halfway between the carina and the vocal cords. This position will allow for some movement of the patient’s head and neck without displacement of the tube out of the trachea or into a mainstem bronchus. Typically, the tube marker will be at about 19–23 cm at the level of the teeth.

Do not attempt to advance the tube through the hollowed-out area of the blade. This space is for visualization only and will likely tear the cuff as well as obscure your view of the glottic opening.

12. Remove the laryngoscope blade and fold the blade down so that it is parallel with the handle. This will shut off the light. Hold the tube firmly at all times until it is properly secured in place.

13. If a stylet was used, remove it gently by pulling it out in the direction it was inserted. Hold the tube securely against the patient’s cheek with one hand while removing the stylet with the other. Pulling the stylet out without holding the tube securely in place may cause accidental extubation, or removal of the tube. Reconfirm the marking at the corner of the mouth.

14. With the syringe attached to the inflation port, inflate the cuff by injecting 10 mL of air. Remove the syringe when you have completed inflation so that the cuff does not deflate.

15. Hold the tracheal tube in position at all times until it is properly secured. Once the tube is in place, do not let go until the securing device is applied.

16. Have your partner attach the bag-valve device to the tracheal tube and begin to deliver positive pressure ventilation.

17. Confirm correct tube placement. This is one of the most important parts of the intubation process. You must verify that the tube has been properly placed in the trachea. As the first ventilation is delivered, you must simultaneously confirm tube placement through these confirmatory techniques:

- **Auscultate over the epigastrium.** Gurgling or rushing sounds heard while auscultating over the stomach during ventilation are an indication that the tube is improperly placed in the esophagus. Do not deliver any more ventilations. Deflate the cuff, and immediately remove the tube. Resume ventilating the patient with the bag-valve-mask device. It is common for the patient to vomit after esophageal placement of a tracheal tube, so have a suction unit ready. Ventilate for approximately 1–2 minutes and reattempt the intubation. If you are unsuccessful on the second attempt, resume ventilation and contact medical direction or follow your local protocol to determine if additional intubation attempts should be made.

- **Watch for chest rise and fall during ventilation.**

- **Auscultate breath sounds.** If there are no sounds over the epigastrium and the chest rises with ventilation, auscultate the breath sounds in both lungs. Listen to each apex (top) at about the second intercostal space, midclavicular. Compare the breath sounds heard over the left apex to the sounds over the right apex. Then auscultate at the fourth intercostal space midaxillary and over the bases at about the fourth intercostal space on the anterior side, again comparing the right and left sounds. Breath sounds should be equal on both sides. Patients with unilateral chest injury (e.g., pneumothorax) may have unequal breath sounds unrelated to tube placement.

    If breath sounds are heard on the right, but the breath sounds are diminished or absent on the left, the tube has likely been advanced into the right mainstem bronchus. The problem with a bronchial intubation is that only one lung is being ventilated, which could lead to hypoxia. If a right mainstem intubation is indicated, you should:

    a. Deflate the cuff and gently withdraw the tube slightly (1–2 cm) while continuing to ventilate the patient and to auscultate for breath sounds on the left side.

    b. Be careful not to pull the tube completely out of the trachea. Pull back on the tube only enough to restore breath sounds on the left.

    c. Once breath sounds become evident on the left, begin to compare the left and right breath sounds. When both sides are equal, reinflate the cuff, secure the tube, and resume positive pressure ventilation. If there is any doubt, use
the laryngoscope to visualize whether the tube is passing through the vocal cords. At least one other confirmatory method must be used to assess for proper tracheal tube placement. These are:

a. Use of an end-tidal carbon dioxide detector to measure the concentration of exhaled carbon dioxide. A lack of carbon dioxide indicates that the tube is improperly placed in the esophagus. There are several different types and models of detectors available, from simple colorimetric devices to more elaborate electronic devices with digital readout (Figure A2-9). The end-tidal carbon dioxide detector is used as an adjunct in assessment of tracheal tube placement, in addition to the methods that have been described. In some cardiac arrest patients, the extremely low blood flow to the lungs does not produce amounts of carbon dioxide adequate enough to be detected. An alternative device should be available to confirm tube placement when no CO2 is found in the cardiac arrest patient. Capnometry will be discussed further later in this section.

b. Use a syringe- or bulb-type esophageal detection device (EDD) (Figure A2-10). The function of these devices depends on a key difference between the structure of the trachea and the structure of the esophagus. The trachea is surrounded by rigid cartilage and does not collapse when negative pressure is applied, whereas the esophagus is fibroelastic tissue and collapses easily when negative pressure is applied. The syringe and bulb devices connect to the end of the 15 mm adapter of the tracheal tube once the patient has been intubated and the cuff inflated. With the syringe device, the plunger is pulled back. If air enters the syringe, you can assume that the tracheal tube has been properly placed in the trachea. If resistance is met, you should suspect that the esophagus has been intubated and is collapsing.
as negative pressure is applied by the syringe. Remove the tube immediately. Similarly, with the bulb device, the bulb is squeezed, placed on the 15 mm adapter, and allowed to refill. If the refill is swift, you assume that the tube is properly placed in the trachea. If the bulb refills slowly or doesn’t refill at all, you presume that the tube is in the esophagus. Immediately remove the tube and ventilate the patient with a bag-valve-mask device. Unlike the colorimetric device, the esophageal detector will generally provide reliable results in both the perfusing and the nonperfusing patient. The device may, however, provide inaccurate results in patients who are extremely obese, in late pregnancy, in status asthmaticus, or in patients with large amounts of secretions. In an obese patient or one in late pregnancy, the trachea will have a tendency to collapse when negative pressure is applied by the bulb syringe device. In the patient suffering from status asthmaticus or one who has copious amounts of secretions, the smaller airways may be blocked and prevent air from being aspirated from the lower airways, providing a false reading.

c. Exhaled condensation should be evident in the tracheal tube, although this is not completely reliable. Another clinical sign indicative of good placement is the presence of equal chest rise and fall and relative ease in ventilating the patient manually.

Indications that the tube is improperly placed are:

a. Inability to visualize the tracheal tube passing into the glottic opening.
b. Presence of air passing into the stomach with ventilation, as heard upon auscultation.
c. Lack of carbon dioxide when an end-tidal carbon dioxide detector is used.
d. Inability to rapidly aspirate air when using an esophageal detector device.
e. Absence of bilateral breath sounds upon auscultation, or unilateral breath sounds.

The following are indications that the tracheal tube may have become displaced:

a. A sudden drop in pulse oximeter reading may indicate a misplaced tracheal tube. (A pulse oximeter is a device attached to a patient’s finger or earlobe that “reads” the oxygen saturation of the blood.) Immediately use conventional methods to assess for proper tube placement.
b. A patient who begins to deteriorate rapidly, becomes combative, or begins to exhibit cyanosis or cardiac arrest could be suffering from tracheal tube misplacement. Again, you should immediately use conventional methods including direct visualization to check tube placement.

18. If no sounds are heard over the epigastrium, the chest rises and falls with each ventilation, the breath sounds are equal bilaterally, and the tracheal confirmation device reads correctly, the tube should be secured in place with a tape or commercial securing device that has been approved by medical direction. Once the tube has been secured, you should do the following:

a. Ventilate the patient at the appropriate rate based on his age.
b. Note the centimeter marking on the tracheal tube at the level of the teeth. This should be included in your written documentation.
c. Insert an oral airway or other appropriate device to serve as a bite block. Neck immobilization may be needed to prevent tube dislodgement, especially in pediatrics.

19. Reassess breath sounds as often as possible. It is necessary to reassess breath sounds following any movement of the patient, including movement onto a stretcher or out to the ambulance. If breath sounds are heard only on the right after a move, assume a right mainstem intubation and reposition the tube as described earlier to correct the placement. If no breath sounds are heard but sounds are heard over the epigastrium, suspect an esophageal intubation and immediately stop ventilation, remove the tube, and resume ventilation with the bag-valve-mask device. If you are uncertain that the tube is properly placed after reassessment, remove it. Remember, an esophageal intubation is lethal. There is no room for error in judgment. Err to benefit the patient.

Note: If you were the EMT who performed the intubation, it is necessary for you to confirm tube placement. Others, such as Emergency Medical Responders or other EMTs, can help you to check tube placement, but do not rely on them to confirm your placement; they may lack the necessary training. Likewise, if an inexperienced EMT has intubated the patient, you must confirm that the tracheal tube is properly placed. This is a critical skill that requires repetition and experience to produce true competence. Measuring and monitoring end-tidal carbon dioxide is recommended for ensuring correct placement.

**Capnometry**

Partial pressure of end-tidal carbon dioxide (PETCO₂) monitoring is a noninvasive method of measuring the levels of carbon dioxide (CO₂) in the exhaled breath, which is an excellent gauge of how well the lungs are being ventilated. Over time, numerous terms and labels have been associated with capnography, and a quick review of the following terms may help you understand the material in this section:

- **Partial pressure of end-tidal CO₂ (PETCO₂)** represents the measurement of the CO₂ concentration at the end of expiration, which correlates with the maximum CO₂ content in the exhaled gas.
- \( \text{PaCO}_2 \) represents the partial pressure of \( \text{CO}_2 \) in the arterial blood, which is directly impacted by quality of alveolar ventilation.
- **Capnometry** is the measurement of expired \( \text{CO}_2 \). It typically provides a numeric display of the partial pressure of \( \text{CO}_2 \) in torr or mmHg.
- **Capnogram** refers to the visual representation of the expired \( \text{CO}_2 \) waveform throughout the phases of breathing.

\( \text{CO}_2 \), a normal by-product of cellular metabolism, is transported by the venous system to the right side of the heart. From there it is delivered to the capillary beds of the lungs so that the \( \text{CO}_2 \) can be off-loaded to the alveoli and exhaled. With normal cardiovascular and pulmonary function, there is a relatively reliable correlation between the PETCO\(_2\) and the \( \text{PaCO}_2 \) (the concentration of \( \text{CO}_2 \) in the arterial blood). Capnometry is the process of monitoring the exhaled carbon dioxide in the body. This information is helpful in making clinical inferences as to the patient’s status. Initially, a device that changed color according to the presence or absence of exhaled carbon dioxide (colorimetric) was used to help determine if the trachea was properly intubated by the EMS personnel. However, as the cost of electronic end-tidal \( \text{CO}_2 \) technology lowered and the use and familiarity of capnography expanded, so did the instances of clinical use.

In the prehospital setting, the use of continuous electronic capnometry (instead of single “snapshot” readings) has increased over the past several years. In fact, the EMT may be working in an ALS system that uses cardiac monitors or mechanical ventilators already equipped with this technology for both the breathing and nonbreathing patient. The advantage of monitoring the exhaled carbon dioxide levels is that it provides clinical information as to the degree of alveolar ventilation that is occurring. Since carbon dioxide is created by the peripheral tissues at a fairly constant rate and the venous blood is constantly being perfused to the lungs, elevations or depressions in the ETCO\(_2\) levels will occur as changes in alveolar ventilation or tissue perfusion occur.

If perfusion to the lungs decreases, this may alter PETCO\(_2\) as well, because venous blood rich in carbon dioxide is not being delivered to the lungs. Likewise, if for some reason the metabolic activity of the body increases, for example during a seizure or if the patient has a high temperature, the amount of carbon dioxide in the venous blood will increase or decrease in shock and will change the amount monitored by the electronic end-tidal \( \text{CO}_2 \) device. The normal physiological range for PETCO\(_2\) is about 38–42 mmHg, although the acceptable range may be slightly wider.

Following are some possible reasons for changes in the PETCO\(_2\) level:
- The PETCO\(_2\) level may decrease if there is a rise in alveolar ventilation (increased ventilation lowers the PETCO\(_2\)), if there is diminished cardiac output, or if there is a decline in metabolic activity.
- The PETCO\(_2\) level may increase if there is a drop in alveolar ventilation (because each exhaled breath will then contain more carbon dioxide) or if metabolic activity suddenly increases.

Capnometry provides a noninvasive measure of PETCO\(_2\) levels, thus providing the EMT information not only about the degree of alveolar ventilation, but also about the status of systemic metabolism and the patient’s circulatory status. The use of capnography is commonplace in the operating room, critical care departments, and emergency departments of the hospital and is increasingly common in the prehospital setting.

### Complications of Orotracheal Intubation

Many complications, some severe, can occur from tracheal intubation. The complications are typically associated with either the laryngoscopy (the lifting of the epiglottis to expose the vocal cords and glottic opening with the laryngoscope) or actual tube placement. Some complications can be lethal if they are not recognized immediately and corrected; other complications are minor. Some of the more common complications of tracheal intubation include the following:

- **Hypertension** (elevated blood pressure), **tachycardia** (increased heart rate), and **dysrhythmias** (irregular heart rhythms) may result from stimulation of the airway during intubation. These conditions can occur during intubation of an adult patient who is not in cardiac arrest.
- **Bradycardia** (decreased heart rate) and **hypotension** (decreased blood pressure) may be seen in infants and children and some adults, particularly those who are hypoxic, because of stimulation of the airway during intubation, an opposite response from that in adults. Also, heart rates in infants and children may drop as they become hypoxic. Closely monitor the heart rate during intubation.
- **Frequent complications include trauma to the lips, tongue, gums, teeth, and airway. The blade, the end of the tracheal tube, and an improperly positioned stylet projecting from the end of the tube can all perforate soft tissue.**
- **Inadequate oxygenation and severe hypoxia can result from prolonged attempts at intubation.** The apneic patient has no other source of ventilation and oxygenation except what you are providing. Cessation of positive pressure ventilation during intubation can lead to hypoxia. Therefore, it is important (a) to ventilate the patient before the intubation attempt and (b) to oxygenate after either proper tube placement or a failed attempt. A properly oxygenated patient has a functional residual capacity in the lungs.
of 2,500 mL of oxygen, which can sustain the apneic patient for several minutes in some cases.

- **A right mainstem intubation may result in hypoxia, because only one lung is being ventilated.** Closely assess breath sounds and pull back on the tube until bilateral breath sounds are heard equally.

- **Absence of ventilation or oxygenation will result from misplacement of a tracheal tube in the esophagus. This is a lethal complication if it is not immediately recognized and corrected.** If you suspect an esophageal intubation, immediately deflate the tracheal tube cuff, remove the tube, and ventilate the patient with the bag-valve-mask device and high-concentration oxygen.

- **Vomiting may result from stimulation of the gag reflex during intubation.** Be sure to have a suction device readily available when intubating. If the patient begins to vomit and no spinal injury is suspected, turn him on his side to facilitate removal of the vomitus and suction to clear the airway. Prevention of aspiration should be a high priority.

- **The cuff may leak, requiring reinflation.** If the cuff does not stay inflated, extubation and insertion of a new tracheal tube will be required.

- **Stimulation of the epiglottis or vocal cords during intubation may cause laryngospasm.** The vocal cords will close completely and not allow air to pass through. The vocal cords will eventually relax and allow air to pass through again. Ventilation with a bag-valve-mask device may be necessary if the cords do not relax immediately.

- **The patient may be accidentally extubated during movement or ventilation.** To avoid accidental extubation, secure the tube adequately and limit any unnecessary pulling or pushing on it. If a bag-valve device is connected to the tube and is being used to ventilate the patient, do not drop it while it is still connected to the tube, as for example when clearing during defibrillation. Dropping the bag-valve device while it is connected to the tube puts the weight of the device directly on the tube, greatly increasing the risk of tube displacement. If you have to clear the patient or interrupt ventilations, remove the bag-valve device from the 15 mm adapter. Reconnect it when you are ready to resume ventilation. After every interruption, check tube placement by assessing chest rise, breath sounds, and gastric sounds during ventilation and the marking on the tube.

- **The patient may become responsive enough to extubate himself following resuscitation or intervention.** If the patient makes attempts to remove the tube, reassure the patient and restrain his hands.

---

**OROTRACHEAL SUCTIONING**

Orotracheal suctioning is the process in which a long, soft suction catheter is inserted through the tracheal tube to clear secretions. The suction catheter is advanced down the tracheal tube and beyond its tip to the level of the carina. As the catheter is being withdrawn, suction is applied to remove any heavy secretions that could block the airway. In contrast to suctioning of the oropharynx or nasopharynx, where the catheter is never advanced beyond the posterior pharynx; this procedure allows for deep suctioning at the level of the trachea.

### Indications

There are two major indications for performing orotracheal suctioning:

- **Obvious secretions in the tracheal tube.** While performing positive pressure ventilation, you may notice secretions in the tracheal tube. These secretions could reduce the effectiveness of ventilation or obstruct the tracheal tube.

- **Poor compliance or an increase in resistance when ventilating with the bag-valve device.** These may be signs of obstruction of the tracheal tube or trachea by heavy, thick secretions that should be cleared by orotracheal suctioning.

Many conditions or illnesses can produce secretions that require suctioning. Patients with respiratory conditions may have problems not only with bronchospasm or inflammation of the lower airways but also with overproduction of mucus. The secretions are usually very thick and heavy and can occlude the trachea and bronchi. The best method for removal, if the patient is unable to remove them himself by coughing, is through orotracheal suctioning. Also, trauma may cause bleeding in the trachea, bronchi, or lungs that may require suctioning.

### Suctioning Technique

The procedure for performing orotracheal suctioning is as follows (EMT Skills A2-2A to A2-2F):

1. Take the necessary Standard Precautions, including gloves and eye protection.
2. Ventilate the patient using a high concentration of supplemental oxygen. The patient should be ventilated for 2 minutes before suctioning. This will build up his oxygen reserve and reduce the chances of severe hypoxia.
3. Assemble and check all equipment to be sure it is in working order. Orotracheal suctioning is a sterile procedure; do not contaminate the catheter while assembling or checking it. A sterile glove must be used to handle the catheter. The catheter should remain inside the sterile package until ready for use.
4. Measure the catheter length from the lips to the ear and down to the level of the nipple. This length of catheter should allow placement at about the level of the carina.
5. Set the suction between 80 and 120 mmHg (negative pressure).
6. Insert the catheter down the tracheal tube with no suction applied.
7. Advance the catheter to the carina or its approximate depth as previously measured.
8. Apply suction. While doing so, withdraw the catheter in a twisting motion. Do not apply suction for longer than 15 seconds in the adult patient.
9. Ventilate the patient for 2 minutes. The procedure can be repeated, if necessary, following the same steps.

Complications of Orotracheal Suctioning

As with any advanced invasive maneuver, complications can occur with orotracheal suctioning. Many of those complications result from the interruption of ventilation to perform the procedure. The following are common complications associated with orotracheal suctioning:

- Hypoxia can result from a decrease in lung volume during the application of suction, because you are removing residual air and also interrupting ventilation. (In other words, you are removing whatever air was left in the lungs, and you have stopped providing replacement air.) If hypoxia is severe, it could lead to cardiac arrest. Proper ventilation and the use of a high concentration of oxygen for 2 minutes before and after suctioning will reduce the possibility of severe hypoxia. Even more important, do not apply suction for a period greater than 15 seconds in the adult.

- Cardiac dysrhythmias can result from suctioning. Tachycardia may occur from stimulation of the airway (or bradycardia in infants and children). Other, more lethal cardiac dysrhythmias may result from a decrease in the supply of oxygen to the heart secondary to hypoxia. Or such dysrhythmias may result from an increase in the oxygen demand from hypertension and tachycardia. Stimulation of the vagus nerve during suctioning as a result of inserting the suction catheter too deeply into the trachea can cause bradycardia and hypotension.

- Coughing may be triggered by the catheter stimulating the mucosal lining. Coughing can increase pressure within the skull and decrease the blood flow to the brain. This is especially dangerous in a patient with a head injury, stroke, or other condition that had already caused an increase in pressure within the brain.

- The catheter may damage the mucosa, causing swelling, bleeding, and ulcerations that can lead to tracheal infections.

- Bronchospasm can occur if the catheter is inserted beyond the carina and into the bronchi.

### ALTERNATIVE INTUBATION METHODS

#### Alternative Intubation Equipment

**Grandview Intubation Blade**

The Grandview blade (Figure A2-11) is a redesigned blade that shares characteristics of both the curved and straight blades. It shows less curvature than a traditional curved blade and is designed with an 80 percent wider blade surface than standard blades. With the redesigned curve, which closely mirrors the normal human anatomy, and the wider width with a short flange, the blade is said to improve direct visualization. It also removes the need to choose between a straight or a curved blade, since the Grandview blade is designed with the best features of both. The adult blade is 165 mm in length to fit the majority of adult patients, creating a universal blade for most cases. A pediatric version is also available and measures 120 mm in length. The Grandview fits all standard laryngoscope handles with no special connections required.

**C-MAC Pocket Monitor**

The C-MAC Pocket Monitor (Figure A2-12) provides the advantages of video laryngoscopy. It is a pocket-sized device, which makes it exceptionally portable. A small LCD monitor attached to the laryngoscope handle allows...
video visualization of the larynx without blocking direct view of the patient. The adjustable screen pivots along two planes for optimum viewing and folds to the side of the laryngoscope for transport and storage. The device uses standard straight and curved blades in neonate through adult sizes. Other devices such as Airtraq and GlideScope® Ranger (Figure A2-13) use similar technology to aid in visualization and passage of the endotracheal tube.

### Eschmann Tracheal Tube Introductor

The Eschmann tracheal tube introducer (Figure A2-14) is used to facilitate tracheal intubations when intubation is (or is anticipated to be) difficult because of incomplete visualization of the glottic opening. It is a 60–70 cm long, semi-rigid, styletlike device with the tip bent at about a 35° angle, 2.5 cm from the distal end. The device is suitable for use with tracheal tubes that have an internal diameter of 6.0 mm or greater. The longer (70 cm) version is easier to thread the tracheal tube over.

During laryngoscopy, prior to tube insertion, the introducer is carefully advanced so that the bent tip is in contact with the posterior surface of the epiglottis. It is then advanced into the larynx and through the cords until the tip enters the trachea. When the introducer enters the trachea, the EMT should be able to feel “bumps” as the curved tip of the introducer slides over the tracheal rings bordering the anterior trachea. The introducer should be advanced to about the 25 cm mark at the corner of the mouth. When the tip arrives at the carina, usually at about 27 cm, the EMT will note that the introducer is “held up,” and any further advancement will not be possible. By interpreting the combination of “bumps” and “hold-up,” the EMT confirms that the introducer is in the trachea. If the EMT identifies that the introducer can be advanced farther than about 27 cm, or there is an absence of the “bumping” and “holding-up,” the introducer is probably in the esophagus.

If the device is in its correct position, the first EMT will maintain the laryngoscope in position and hold the inserted introducer. A second EMT can then pass the tracheal tube over the end of the introducer and into the larynx. Once the tracheal tube is in place, the introducer
is removed. Normal confirmation procedures for the tracheal tube should then proceed.

**Alternative Intubation Techniques**

You may encounter situations in which you are unable to intubate a patient using the standard techniques already described. There are, however, several ways of inserting a tracheal tube orally that employ different techniques and equipment. To use these techniques, some of which are described in the following sections, you must be completely familiar with them and the equipment they require. You must also have approval from medical direction before attempting any of the alternative intubation techniques. Remember that any method for inserting the tracheal tube into the trachea that does not employ direct visualization of the glottic opening is associated with a higher rate of tube misplacement and other complications. If the EMT does not utilize direct visual orotracheal intubation, it is a step backward in accuracy of placement. Remember that the laryngoscope can also be used after insertion of the endotracheal tube to confirm placement. Otorhacheal intubation is still the preferred method for intubating adults or pediatrics.

**Digital Intubation**

In digital intubation, the EMT inserts his fingers into the patient's hypopharynx and uses them to lift the epiglottis. The tracheal tube is then passed through the glottic opening with the help of the fingers. Digital intubation may be used in a patient who is in cardiac arrest or is completely unresponsive, has no gag reflex, and is in a position where direct visual orotracheal intubation is impossible. It may also be considered for patients with distortions to the necessary visual landmarks.

Digital intubation is referred to as a “blind” technique, because you do not actually visualize the tracheal tube passing through the vocal cords. As already stated, standard intubation using a laryngoscope is preferred because it permits such visualization. However, you may encounter situations where the patient’s position or condition precludes tracheal intubation with a laryngoscope—for example, when you cannot manipulate the head and neck of an immobilized patient with suspected spinal injury. It is very difficult in such a case to achieve an axis that allows for proper visualization without moving the patient’s head and neck. Because digital intubation can be performed without visualizing the vocal cords, it eliminates the need to manipulate the head or neck.

Another situation in which digital intubation might be used is with a patient trapped in a wrecked vehicle. The patient's immediate airway problem may be severe, but the time required for extricating him from the wreck may be long and the position in which he is trapped makes standard intubation with a laryngoscope virtually impossible. Digital intubation may be helpful in such a case.

Digital intubation would allow you to insert a tracheal tube even if the laryngoscope was not working properly or if its batteries or bulb failed and no spares were available. This should not be performed if the patient has an intact gag reflex or has the ability to bite.

**Equipment.** The equipment needed to perform digital intubation includes the following:

- Appropriately sized tracheal tube
- Malleable stylet
- Water-soluble lubricant
- 10 mL syringe
- Bite block
- Device to secure the tracheal tube

**Procedure.** Follow these steps to perform a digital intubation (EMT Skills A2-3A and A2-3B):

1. Take the necessary Standard Precautions. Gloves, eye protection, and a mask are recommended.
2. Ventilate the patient for approximately 2 minutes while delivering a high concentration of supplemental oxygen.
3. Check the tracheal tube as you normally would. Lubricate the tube with a water-soluble lubricant. Lubricate the stylet and insert it to form the tube into an open J shape.
4. If the patient is suspected of having a spinal injury, have an EMT or other properly trained rescuer manually stabilize the patient’s head and neck. Face the patient and kneel at his left shoulder.
5. Instruct the person ventilating the patient to stop. Quickly place a bite block between the patient’s molars to prevent him from biting down on your fingers during the procedure. Ideally, the technique should be reserved for the unresponsive patient only.
6. Insert the middle and index fingers of your nondominant hand into the patient’s mouth. Advance your fingers down the midline while simultaneously lifting the tongue up and out of the way. Palpate the epiglottis with your middle finger (EMT Skills A2-3A).
7. Press upward and move the epiglottis forward. Insert the tracheal tube into the mouth with your dominant hand and advance the tube using your index finger to maintain the tip of the tube against the middle finger. The tip will be directed upward toward the epiglottis. Guide the tip of the tube into the glottic opening with the index finger by sliding it alongside your middle finger that is retracting the epiglottis (EMT Skills A2-3B).
8. Remove your fingers while holding the tube in place with your other hand. Inflate the cuff with 5–10 mL.
of air. Attach a bag-valve device to the tube. Artificial ventilation must not be interrupted for more than 30 seconds during the insertion.

9. As with any tracheal intubation, ensure that the tube is not misplaced in the esophagus or mainstem bronchus. Auscultate over the epigastrium (gurgling should not be heard) and at the apices laterally and at the bases of the lungs (breath sounds should be present and equal). Watch for equal rise and fall of both sides of the chest with each ventilation. Take the steps described earlier in this appendix to correct any misplacement of the tube. Ventilate the patient between attempts to intubate.

10. When correct placement is confirmed, secure the tube as described earlier. Reassess tube position whenever the patient or the ventilating device is moved.

**Transillumination (Lighted Stylet) Intubation**

Another method of inserting a tracheal tube is transillumination, or the “lighted stylet” technique. In this procedure, a special lighted stylet is inserted into the tracheal tube, which is then inserted through the mouth, into the hypopharynx, and on into the larynx and trachea.

The trachea is anterior to the esophagus, so the bright light seen through the soft tissues at the front of the neck will indicate that the tube is correctly placed in the trachea. This means that the EMT can pass the tracheal tube through the glottic opening without visualizing the structures directly to ensure correct placement. There is no need to manipulate the head or neck during this procedure. Thus, the transillumination technique can be an effective means of intubating a trauma patient.

The stylet used in this technique is a special device with a high-intensity bulb at the distal end. A small battery housed at the proximal end supplies power for the light and is controlled by an on-off switch. Because tube placement with this method requires seeing the light through the tissues of the neck, the technique is best performed in a darkened room or, if in the sunlight, with the neck shielded or in a shadow. A major problem with this technique is the inability to see the stylet light well in bright ambient light.

**Equipment.** The equipment needed to perform transillumination tracheal intubation includes the following:

- Appropriately sized tracheal tube
- Lighted stylet
- Water-soluble lubricant
- 10 mL syringe
- Scissors (to trim the tube if necessary)
- Securing device for the tracheal tube

**Procedure.** To perform a transillumination intubation:

1. Take the necessary Standard Precautions including gloves, eye protection, and a mask.

2. Ventilate the patient for approximately 2 minutes while delivering a high concentration of supplemental oxygen.

3. Assemble and check the equipment. The tracheal tube should be between 7.5 and 8.5 mm i.d. Some older tubes will need to be cut to 25 to 27 cm to accommodate the stylet. (Most newer devices do not require cutting the tube.) Place the stylet into the tube and bend it just proximal to the cuff.

4. Kneel on one side of the patient, facing his head.

5. Turn on the stylet light.

6. With your index and middle fingers inserted deeply into the patient’s mouth and your thumb on the chin, lift the patient’s tongue and jaw forward. Insert the tube/stylet combination and advance it through the oropharynx and into the hypopharynx along the midline. Using a “hooking” motion, lift the epiglottis out of the way (Figure A2-15).

7. When you see a circle of light at the level of the larynx on the anterior neck, hold the stylet stationary (Figure A2-16). Advance the tube off the stylet into the larynx approximately 1/2 to 1 inch. Indications of misplacement of the stylet and tube are as follows:

   - If the light at the front of the neck is diffuse, dim, or hard to see—or not visible at all—this indicates that the tube/stylet combination is incorrectly placed in the esophagus. The tube should be withdrawn immediately and hyperventilation resumed.
   - A bright light appearing lateral to the upper aspect of the thyroid cartilage (Adam’s apple) indicates that the tube/stylet is placed in the right or left pyriform fossa (furrow). Immediately withdraw the tube and resume ventilation. Make another attempt after a few minutes.
Several other devices are available to help control the airway. Extraglottic airway (EGA) devices are inserted into the upper airway but do not enter the glottic opening. (Extraglottic means “outside the glottis.”) These devices require no visualization during insertion.

EGA devices are further categorized depending on where, anatomically, the airway is eventually placed. Retroglottic airways are designed to be placed in the esophagus, behind the glottis and trachea. (Retroglottic: “behind the glottis.”) These devices are further classified as dual lumen or single lumen retroglottic airways. Supraglottic airways, when placed, sit above the glottic opening. (Supraglottic: “above the glottis.”)

Even though insertion techniques for these extraglottic devices are relatively simple, just as with any intubation, the ability to assess and differentiate tube placement is the key to using them effectively. Medical direction is required prior to use of any of these devices.

### Dual Lumen Retroglottic Airway Devices

A dual lumen device, as the name indicates, has two internal tubes. The Pharyngeo-Tracheal Lumen (PtL) airway and the Esophageal Tracheal Combitube (ETC) are dual lumen EGA devices.

#### Pharyngeo-Tracheal Lumen (PtL) Airway

The Pharyngeo-tracheal Lumen (PtL) airway is a dual-lumen, or two-tube, device designed to be inserted into the airway without direct visualization (Figure A2-17).
Actually, the PtL is a tube within a tube. A long, clear tracheal-type tube with a cuff at the distal end is situated inside a shorter, wider tube that is designed to fit just proximal to the glottic opening. The shorter tube has a large balloon cuff on the distal third of the device. The balloon is inflated to seal the entire pharynx. The proximal end of the shorter tube is green in color. The longer tube has a cuff at the distal end that can be inserted into either the trachea or the esophagus. That distal cuff is then inflated to seal the trachea or the esophagus. The proximal end of this tube is longer, is clear in color, and contains a semi-rigid plastic stylet.

When the long, clear tube has been inserted into the trachea, the plastic stylet is removed and ventilation is performed through that tube with a bag-valve or other ventilation device attached to its proximal end. However, if the long tube is placed in the esophagus, as occurs in most instances, the plastic stylet is left in place and ventilation is delivered through the short green tube. Since the long tube and its inflated cuff seal off the esophagus, and the balloon cuff on the short tube seals off the pharynx, the ventilations delivered through the short tube into the space between the cuffs have nowhere to go but into the trachea.

Inflation lines are provided to inflate the two cuffs—the one on the long tube and the one on the short tube—simultaneously or separately. The oropharyngeal cuff on the short tube can be deflated to allow for oro-tracheal intubation if the long tube has been placed in the esophagus. The short tube also serves as a bite block that keeps the patient from biting down and occluding the tube with his teeth.

This device is only used in an adult patient. Only one size is available.

**Advantages.** Advantages of the PtL airway over standard tracheal intubation include the following:

- The PtL cannot be improperly placed. It can function when placed in either the trachea or esophagus.
- A mask seal is not required because the large pharyngeal cuff seals the upper airway and does not allow air to escape.
- Insertion is a blind technique that does not require visualization at the level of the glottic opening. Thus, less skill is required for the insertion technique.
- It can be used in a trauma patient with suspected spinal injury because the head or neck does not need to be moved during insertion.
- The pharyngeal cuff helps protect the lower airway from secretions and from blood coming from the nasopharynx or mouth.
- It can be inserted following failed attempts at tracheal intubation when visualization is hampered by difficult anatomy or position.

**Disadvantages.** Disadvantages of the PtL airway include the following:

- The tube requires accurate assessment of tracheal versus esophageal placement for appropriate ventilation.
- The patient must be completely unresponsive and cannot have a gag reflex.
- It cannot be used in a patient younger than 16 years of age or less than 5 feet tall.
- It must be removed when the patient starts becoming responsive or regains a gag reflex.
- If the pharyngeal cuff deflates and the longer tube is in the esophagus, the tube loses its effectiveness.

**Indications.** Standard tracheal intubation is the preferred method of airway control. However, you can consider using the PtL in the following circumstances:

- Tracheal intubation is not successful after two attempts.
- Tracheal intubation is indicated but is not allowed or cannot be performed immediately.
- Tracheal intubation cannot be performed or is unsuccessful because the patient’s head is immobilized in a neutral position because of possible spinal injury.
- The patient’s anatomy or profuse bleeding or vomiting are obstructing direct visualization.

**Contraindications.** The PtL airway should not be inserted in any of the following situations:

- The patient is younger than 16 years of age.
- The patient is less than 5 feet tall.
- The patient is responsive or has a gag reflex.
- The patient has swallowed a caustic substance.
- Esophageal disease is present.

**Equipment.** The following equipment is necessary for PtL insertion:

- Pharyngeo-tracheal Lumen (PtL) airway
- Water-soluble lubricant
- Suction unit

**Insertion.** Before inserting the PtL airway, you must ensure that the patient is being adequately ventilated with a bag-valve mask or other acceptable ventilation device.

Gather and prepare the equipment that will be used in insertion. Make sure that both the pharyngeal and distal tube cuffs are completely deflated. The tubes and inflation ports are marked as follows: The inflation port is designated as #1, the green shorter tube is #2, and the long clear tube is #3. Be sure that the white inflation port cap is closed. If the cuffs require further deflation, remove this white cap and compress the cuffs until they are completely flat. A clamp is located on the inflation port allowing deflation of the pharyngeal cuff while the cuff on the distal end of the longer tube remains inflated. Lubricate the long clear #3 tube with a water-soluble lubricant. An adjustable cloth strap is used to secure the PtL airway in place.

Follow these steps to insert the PtL airway:

1. Ventilate the patient for 2 minutes while delivering a high concentration of supplemental oxygen.
2. Place the patient’s head into a hyperextended position if no spinal injury is suspected. If a spinal injury is suspected, maintain the head in a neutral, in-line position.

3. Insert your thumb deep into the mouth, grasping the tongue and lower jaw between the thumb and index finger, and lift the tongue and lower jaw forward.

4. Insert the PtL airway into the mouth with your free hand while maintaining the tongue-jaw lift with the other hand. Insert the airway so that it follows the natural curvature of the oropharynx. Insert the tip into the patient’s mouth and advance it carefully beyond the tongue until the teeth strap touches the patient’s teeth. You will feel modest resistance when passing the tube at the correct angle in the oropharynx. Do not use force during insertion. If the tube is not advancing, either redirect the tip or withdraw it and attempt insertion a second time, following 2 minutes of ventilation. Do not interrupt artificial ventilation for more than 30 seconds when inserting the device.

5. When the flange that holds the strap meets the teeth, the tube is in the proper position. Slide the neck strap over the patient’s head and tighten it with the hook-and-tape closures on both sides.

6. Inflate both cuffs simultaneously by blowing into the main inflation valve #1 with a sustained breath. If the cuffs are not inflated properly, the pilot balloon will not be inflated or air will rush from the mouth during ventilation. These may be indications that one of the cuffs is defective and the device needs to be replaced. If the pilot balloon is inflated, puffs of air delivered through inflation port #1 can improve the seal if some air leakage is noticed.

7. Attach the bag-valve device to the shorter green #2 tube and deliver a ventilation. If the chest rises with the ventilation and breath sounds are heard over the chest in the apex and base of each lung, you know that the longer #3 tube has been placed in the esophagus and ventilations through the shorter tube are being directed into the trachea. Continue to ventilate through the shorter green #2 tube with a bag-valve or other ventilation device (Figure A2-18).

8. If the chest fails to rise or no breath sounds are heard upon ventilation through the short green #2 tube, you will assume that the longer #3 tube has been placed in the trachea and is blocking ventilations delivered through the short tube. Detach the bag-valve from the #2 tube, remove the plastic stylet from the #3 tube, attach the bag-valve device to the #3 tube, and deliver ventilations through the #3 tube.

   Auscultate the chest for breath sounds, auscultate the epigastrium for gurgling sounds in the stomach, and watch the chest for rise and fall with each breath. Breath sounds should be equal bilaterally, no gurgling sounds should be heard over the stomach, and the chest should rise and fall with each ventilation. If these conditions apply, you have confirmed that the longer #3 tube has been placed in the trachea and is functioning much like a tracheal tube.

9. After insertion, resume ventilation. Continuously reassess the breath sounds and chest rise and fall to ensure correct tube placement. Check the pilot cuff periodically to ensure that the cuffs are adequately inflated.

**Removal.** If either the patient regains responsiveness or his gag reflex returns, the PtL airway must be removed. Tracheal intubation is very difficult to perform around the PtL airway; therefore, in some cases it may be necessary to remove it to achieve proper visualization and oral placement of a tracheal tube. Follow these steps when removing the PtL airway:

1. Take the necessary Standard Precautions including gloves, eye protection, and a mask. Splatters of secretions and vomitus should be expected.

2. If the patient is not suspected of having any spinal injury, turn him on his side into the lateral recumbent position. If the patient has a suspected spinal injury and is properly secured to a long backboard, turn the entire board on its side.

3. A gastric tube can be inserted through the tube not being used for ventilation and passed on into the stomach. In this way, you can decompress and evacuate the stomach contents prior to PtL removal. This should only be done if you are properly trained in the procedure and have received approval from medical direction. You may be asked to remove the PtL airway in the medical facility, where you can suggest that personnel decompress the stomach by insertion of a Levine (gastric) tube down the nonventilation tube.

![Figure A2-18](image-url) The PtL airway in place. The longer tube is shown placed in the esophagus while ventilations delivered through the shorter tube are directed into the trachea.
Advantages. The advantages of the ETC airway over standard tracheal intubation are similar to those of the PtL airway. They include the following:

- No visualization is required during insertion, allowing for rapid insertion.
- The device is properly placed whether it is in the esophagus or trachea.
- The inflated pharyngeal cuff prevents ventilations delivered through the tube from escaping through the nose and mouth. This eliminates the need to maintain a mask seal.
- The pharyngeal balloon (cuff) is self-adjusting and self-positioning, an advantage over the PtL.
- The esophageal intubation is easier to achieve when the ETC airway is in the esophagus.
- There is no stylet in the distal lumen, allowing for immediate suctioning of the gastric contents. This is another advantage over the PtL airway.

Disadvantages. The complication rate reported with use of the ETC in one limited study group was low. However, complications do exist. Disadvantages to ETC use include the following:

- The ETC requires accurate assessment of tracheal versus esophageal placement.
- Tracheal intubation is difficult to achieve when the ETC airway is in the esophagus.
- The ETC cannot be used in responsive patients or those with a gag reflex.
- Tracheal suctioning cannot be done with the device in the esophagus.
- The device cannot be used in patients younger than 16 years old or less than 5 feet tall.
**Indications.** Standard tracheal intubation is the preferred method of controlling the airway. However, as with the PtL, you can consider using the ETC when tracheal intubation is not successful after two attempts, when tracheal intubation is not allowed or cannot immediately be performed although indicated, when in-line immobilization of the patient with possible spine injury prevents successful tracheal intubation, or when the patient’s anatomy, bleeding, or vomiting obstruct the direct visualization required for tracheal intubation.

**Contraindications.** As with the other airway adjuncts, there are times when the ETC should not be used. Do not use an ETC if the patient is younger than age 16 or less than 5 feet tall, if the patient is responsive or has a gag reflex, if the patient has swallowed a caustic substance, or if esophageal disease is present.

**Insertion.** ETC insertion should be attempted only after the patient has been well ventilated and hyper-oxygenated with an appropriate device. Take Standard Precautions. Because this is an invasive procedure, you should use gloves, eye protection, and a mask. The procedure for insertion of the ETC is as follows:

1. Ventilate the patient for at least 2 minutes while delivering a high concentration of oxygen.
2. Assemble and check the equipment. Ensure that the cuffs on the ETC are not leaking. Lubricate the distal end of the tube with a water-soluble lubricant.
3. Place the patient’s head and neck in a neutral position. If a spinal injury is suspected, maintain the head in a neutral, in-line position.
4. Perform a tongue-jaw-lift maneuver and insert the device to the level of the black rings. The teeth should be between the two black rings. If the patient has no teeth, use the gum line where the bony structure once held the teeth.
5. Use the large syringe to inflate the pharyngeal cuff with 100 mL of air. The pharyngeal balloon will self-position behind the hard palate in the posterior pharynx. The pharynx will be sealed once the cuff is inflated. For proper placement of the device, the pharyngeal cuff must be inflated prior to the distal cuff.
6. Inflate the distal cuff with 10–15 mL of air with the smaller syringe.
7. Attach the ventilation device to tube #1, the longer of the two tubes. This is the esophageal tube. It is ventilated first because the tube has most likely been placed in the esophagus (directing ventilations through the holes above the sealed-off esophagus and into the trachea—Figure A2-20 ■). During the ventilation, auscultate over the epigastrium and listen for gurgling sounds. If no sounds are heard, watch for chest rise and auscultate for breath sounds. If equal chest rise and breath sounds are present bilaterally and no gastric sounds are heard over the stomach, continue to ventilate through tube #1.
8. If you hear gurgling sounds in the stomach over the epigastrium, assume that the device has been placed in the trachea and the ventilations exiting through the holes are going into the esophagus. Cease ventilation immediately and reposition the ventilation device on the shorter #2 tube, which will direct the ventilations into the trachea (Figure A2-21 ■). Auscultate over the epigastrium and listen for gurgling. If gurgling is present, remove the tube. If no gurgling is heard, assess the breath sounds. If the breath sounds are equal bilaterally, continue to ventilate through tube #2.
9. Resume ventilation. Reassess tube placement after each move involving the patient. Periodically check the pilot balloon located on each tube to ensure the cuffs are adequately inflated.

**Removal.** If the patient regains responsiveness or his gag reflex returns, the ETC airway must be removed. As with the PtL, removal of the ETC is likely to be followed by vomiting. Remove the tube gently and discard it. Be alert for vomiting. If the patient is not suspected of having any spinal injury, place him in a lateral recumbent position. If the patient has a suspected spinal injury and is properly secured to a long backboard, turn the entire board on its side. Have suctioning equipment ready for use. Reassess the patient’s breathing status and resume positive pressure ventilation, if necessary.
Supraglottic Airway Devices

There are many supraglottic airway devices, which are designed to be placed above the glottic opening. A commonly used supraglottic airway device is the laryngeal mask airway (LMA). An alternative supraglottic device is the Cobra Perilaryngeal Airway (PLA). Other supraglottic devices are available. Become completely familiar with the device you are permitted to insert and do frequent training on the insertion and assessment of proper placement.

Laryngeal Mask Airway (LMA)

The laryngeal mask airway (LMA) (Figure A2-22) was developed by a British anesthesiologist in 1981 and has been widely used by anesthesiologists and prehospital providers in the United Kingdom for several years. For the past few years, the LMA has been used more widely in the United States. The LMA is an emergency adjunct airway device that may be considered for prehospital airway management when difficult tracheal intubation or bag-valve-mask ventilation is encountered or as a primary adjunct to control the airway.

An intubating LMA (ILMA or LMA FasTrach) (Figure A2-23) is available in which a tracheal tube is inserted through the LMA once it is properly positioned. This intubating LMA device is also equipped with a handle, which allows one-handed insertion, removal, or manipulation to ensure proper alignment with the glottic opening. This does not require visualization of the vocal cords and is performed as a blind tracheal-tube insertion technique.

The LMA consists of a tube similar to a tracheal tube connected to a cufflike mask at the distal end of the tube. An inflation line is used to inflate the mask, and a pilot balloon monitors the mask inflation. The tube is connected to the mask at a 30° angle. Two vertical bars inside the inflatable mask support the epiglottis and prevent it from falling into the opening of the tube. The tube is inserted in the hypopharynx, and the cufflike mask forms a seal around the laryngeal opening. The LMA comes in a variety of sizes from 1 for neonates to 5 for adults.
**Insertion.** Insert the LMA, following these steps (Figure A2-24 ■):  
1. Ventilate the patient for 2 minutes while delivering a high concentration of oxygen.  
2. Check the LMA mask for leaks. Be sure to completely deflate the mask prior to insertion.  
3. Lubricate the posterior portion of the mask with a water-soluble lubricant.  
4. If no cervical injury is suspected, place the patient’s head in a sniffing position with the head hyperextended and the neck flexed. Hold the occiput of the head with your free hand to ensure the correct position. Another EMT may assist in opening the patient’s mouth by lifting the chin forward.  
5. Hold the LMA device like a dart as you insert it into the patient’s mouth. Make sure the opening of the mask is anterior with the black line on the tube aligned with the middle of the patient’s nose.  
6. Advance the LMA into the hypopharynx until resistance is met. Do not rotate the tube. Keep the black line aligned with the middle of the nose. The tube should now be properly placed.  
7. Inflate the cuff with the proper volume of air. The tube may rise about 1.5 cm once the mask is inflated. The black line should be midline against the upper lip.  
8. Confirm tube placement by assessing for the presence of breath sounds bilaterally and no epigastric sounds.  
9. Insert an oropharyngeal airway or a bite block to keep the patient from biting down on the tube.  
10. Once you have confirmed proper tube placement, secure the device in place.

**Complications.** The LMA has only a few complications associated with its use. They are:  
- Vomiting during the insertion when used in a patient who still has a gag reflex  
- Possible airway obstruction if the mask is improperly aligned in the hypopharynx  
- Ineffective ventilation caused by escape of air around the mouth resulting from mask deflation or improper mask seal  
- Aspiration (Remember that the LMA does not protect the patient from aspiration like an appropriately placed tracheal tube.)

**Cobra Perilaryngeal Airway (PLA)**  
The Cobra perilaryngeal airway (PLA) (Figure A2-25 ■) is similar to the LMA in its basic design. It is inserted into a supraglottic location where the “cobra head” of the device holds the epiglottis and surrounding soft tissue out of the way to allow airway patency. Ventilations are then...
provided through the hollow tube of the airway from the proximal 15/22 mm adapter, and exit the airway through the fenestrated openings at the distal end. Like the LMA, it comes in a variety of sizes from pediatric to adult. After ensuring medical direction will allow use of the device, the EMT should be completely familiar with the indications, contraindications, insertion, and removal techniques prior to use.

**Single Lumen Retroglottic Airway Device**

A single lumen device, as the name indicates, has just one internal tube. The King LT, often referred to as a supraglottic airway device, is more accurately termed a single lumen retroglottic device because the distal end is designed to fit into the esophagus behind the glottic opening and because it has only one ventilation port and one internal tube.

**King LT Airway**

The King LT Airway (Figure A2-26), as just explained, is a single lumen retroglottic airway device that is gaining popularity in emergency prehospital care. It is a tubular device with a large pharyngeal cuff that disperses pressure over a large surface area at the pharyngeal level to stabilize the airway at the base of the tongue and minimize the risk to the vocal cords and trachea. The distal end of the tube is equipped with a smaller cuff that occludes the esophagus. Between the cuffs there is a large opening, or port, from the tube. When a ventilation is delivered through the proximal end of the device, the ventilation exits through the port between the cuffs. Since the cuffs have blocked off the esophagus below and the pharynx above, the ventilation that exits the port is directed through the only available pathway, the glottic opening, and from there via the trachea into the lungs.

The King LT airway is supplied in three sizes, and both disposable (King LT-D) and reusable (King LT) models are available. After ensuring that medical direction will allow use of the device, the EMT should be completely familiar with the indications, contraindications, insertion, and removal techniques prior to use.

---

**OROTRACHEAL INTUBATION IN INFANTS AND CHILDREN**

The procedure for pediatric intubation is much the same as in adults. However, there are special considerations with infants and children about when and how to intubate.

**Indications in Infants and Children**

The airway in an infant or child should be managed with the proper manual position and an airway adjunct. Most often, a bag-valve-mask device is all that is needed to ventilate the patient adequately. Research has shown that prehospital pediatric intubation is an infrequently performed skill, which may lead to poor outcomes. However, there are some situations where ventilation cannot be properly achieved without tracheal intubation. Tracheal intubation for the infant and child should be considered in the following circumstance:

- *Artificial ventilation cannot be delivered adequately when using other airway maneuvers and adjuncts.*

Tracheal intubation may be considered in the following circumstances; however, a person with experience intubating pediatric patients should perform the intubation.

- *Prolonged positive pressure ventilation is required.*
- **The patient is completely apneic.** The patient in respiratory arrest or cardiac arrest should be intubated.
- **The patient is unresponsive, with no gag or cough reflex.** If the unresponsive patient accepts an oropharyngeal airway without gagging, consider tracheal intubation. The infant or child has the same risk of
aspiration as the adult in this circumstance. Tracheal intubation minimizes the risk of aspiration by sealing off the trachea at the level of the cricoid cartilage. Cricoid pressure can be used to reduce the chances of aspiration during the intubation procedure.

**Anatomical Considerations**

Additional skill is needed when performing intubation in infants and children because of their anatomical differences from adults. Special considerations related to anatomical differences include the following:

- In general, infants’ and children’s noses, mouths, and jaws are smaller and their tongues are disproportionately larger. This makes visualization of the glottic opening and the vocal cords more difficult.
- Sizing of tracheal tubes for infants and children is based on the internal diameter of the cricoid cartilage and not the glottic opening. Most often, tracheal tubes used in infants and in children less than 8 years of age do not have cuffs; the tubes are sealed by the narrow cricoid cartilage. Therefore, ensuring a proper fit of a tracheal tube is vital.
- The vocal cords and glottic opening are typically more anterior and cephalad (toward the head), making visualization more difficult. It is difficult to create a single, clear visual plane from the mouth through the pharynx to the glottic opening during intubation.
- Bradycardia may result from stimulation of the airway during intubation. The onset of bradycardia may limit your intubation attempt to even less than 30 seconds. Infants and children are extremely sensitive to hypoxia, which normally results in bradycardia.

**Equipment for Infants and Children**

The same basic equipment is used for intubating adults, infants, and children. However, because of the anatomical differences, the equipment has some variations and must be carefully sized prior to the intubation procedure. One aid to determining the proper equipment necessary to perform tracheal intubation in the infant and child is a resuscitation tape. Refer to Figure A2-27 to see an example of a resuscitation tape (the Broselow tape), which is commercially available. The tape is stretched from the head to the feet of the patient and provides information regarding appropriate tube sizes and drug dosages as well as other information necessary in the emergency management of the pediatric patient.

**Suction Devices**

A suction device should be readily available during the pediatric intubation procedure. As in the adult, there may be fluid, blood, or heavy secretions obstructing your view of the landmarks and increasing the patient’s risk of aspiration. Any substance must be removed immediately. A suction unit with an adjustable regulator that can tailor the negative pressure used to between 80 and 120 mmHg is warranted. Ensure that the appropriate suction catheter and noncollapsible suction tubing are available.

**Laryngoscope Handles and Blades**

The same laryngoscope handle used in adult intubation is also used interchangeably with the infant and child laryngoscope blades. A smaller-diameter laryngoscope handle is available, if necessary, for infant intubation. The locking mechanism and assembly are the same as in adult equipment.

A straight laryngoscope blade is preferred in infants because it provides greater displacement of the tongue and better visualization of the glottic opening, which is more anterior and cephalad. It also causes less damage to the soft tissues. The straight blade is fitted under the epiglottis and directly lifts it up and forward to expose the vocal cords and glottic opening. The straight blade comes in sizes from 0 to 4. A size 0 blade is usually used in premature infants, whereas a full-term infant would require a 0 or 1. A size 2 blade is usually used to intubate children from 2 to 8 years old. A size 3 straight blade is typically used in adolescent patients.

The curved blade is preferred in older children because its broader base and flange provide better displacement of the tongue in this age group. Curved blades also come in a size range of 0 to 4. A size 2 curved blade is typically used in 8- to 12-year-olds. A size 3 curved blade is used for 12-year-olds and adolescents. The curved blade is inserted into the vallecula and indirectly lifts the epiglottis with an upward and forward movement of the handle.

**Tracheal Tubes**

When intubating an infant or child, tubes at least one-half size above and below the selected size must be
immediately available. The tube should be of uniform diameter and not tapered. It should have centimeter distance markings along its length for use as reference points. Some tubes have a vocal cord marker at the distal end to ensure that the tip of the tube is midway between the carina and the level of the vocal cords.

Tracheal tubes used in infants and children under age 8 are typically uncuffed, with no inflation cuff at the distal end of the tube (Figure A2-28). The cricoid ring is the narrowest portion of the upper airway in infants and children and serves as a functional cuff to seal off the trachea. Therefore, sizing the tube is extremely critical. Cuffed tubes should be used for children older than 8 years. When a cuffed tube is inserted into the trachea, the proximal end of the cuff is inserted approximately 1/2 inch beyond the level of the vocal cords, since no vocal cord marker may be available on the tube. The use of cuffed tracheal tubes in pediatrics, as discussed earlier, is becoming more common in the hospital. Your medical director may allow the use of uncuffed tracheal tubes in this age range. Always use the equipment recommended by your medical director when you perform this skill.

The best, most accurate method of selecting the appropriate-sized tracheal tube for infants and children is to refer to a sizing chart. You should carry a copy of the chart or keep one in the airway kit containing the infant and child intubation equipment. A commercially available resuscitation tape can be used to determine the appropriate-sized tracheal tube. The tape, which is stretched out alongside the infant or child, has reference areas corresponding to the height of the infant or child.

Several formulas can be used to estimate the correct size of tracheal tube for children. For a child 1–10 years of age, the formula for an uncuffed tracheal tube is: tube size = 4 + (age in years/4). For example, the formula for a 4-year-old child would be: 4 + (4/4) = 5.0 mm i.d. tracheal tube. A half size above and below this range (4.5 and 5.5) should also be available. If the EMT is using a cuffed tracheal tube, per medical direction, tube size of age, the formula for an uncuffed tracheal tube is: tube size = 3 + (age in years/4). This formula will result in a tube size that is slightly smaller than the uncuffed version. This is to allow the cuff at the distal end adequate space to inflate to secure the airway. When inflating the cuff of a small tracheal tube such as this, you should inflate with no more air than is needed to make the inflation port mildly tense after inflation, yet enough to prevent air or fluid from passing by the inflated cuff.

Other methods for estimating the size of the uncuffed tracheal tube can be used. One method calls for choosing a tracheal tube with the same outside diameter as the child’s little finger. Another method is to select a tube with an outside diameter that is the same as the internal diameter of the child’s nares, or nostrils. These methods at best are estimations; therefore, it is vital to have tubes one-half size larger and one-half size smaller than the one you select available during intubation.

Newborn infants typically require a 3.0–3.5 mm tracheal tube. A 1-year-old usually requires a 4.0–4.5 mm tube size. An 8-year-old child usually requires a 6.0 mm cuffed or uncuffed tracheal tube. Refer to Table A2-1 for other tracheal tube sizes.

Both infant- and child-sized tracheal tubes have centimeter markers as reference points to monitor the depth of tube insertion. The depth also corresponds with age (Table A2-2). A formula that can be used to estimate the proper depth of insertion in centimeters for a child older than 2 years of age is: (age in years/2) + 12. For example, depth of insertion for a 4-year-old, according to the formula, is (4 years/2) + 12 = 14 cm. The 14 cm marker should be at the level of the lip, putting the tip of the tracheal tube midway between the larynx and the carina. An alternative method to determine the distance from the distal end of the tube to the lip can be estimated by multiplying the internal diameter of the tube by 3. For example, the 4-year-old patient who requires a 5.0 mm i.d. tube would have an estimated tube length of 15 cm (5.0 mm i.d. × 3 = 15 cm). Thus,

the tube marking at the level of the lips should be approximately 15 cm. However, this level must always be confirmed clinically for proper placement.

### Tracheal Tube Insertion in an Infant or Child

Orotracheal intubation in infants and children is basically the same as in adults except for some variations caused by anatomical differences in the upper airway and by the size of the laryngoscope blades and tracheal tubes. Some research suggests that bag-valve-mask ventilation is as effective as ventilation with a tracheal tube. However, this level must always be confirmed clinically for proper placement.

The patient must be ventilated and hyperoxygenated. Because of their high metabolic rate, children will desaturate more quickly than adults.

The heart rate should be continuously monitored during the intubation attempt. Bradycardia is an early sign of hypoxia. ( Interruption of ventilation to intubate can drastically reduce the oxygen level and cause severe hypoxia, especially if the intubation attempt lasts longer than 30 seconds.) Stimulation of the airway in infants and young children can also cause bradycardia. If the heart rate drops below 80 beats per minute in an infant or below 60 beats per minute in a child, the intubation procedure should be stopped and the patient ventilated with a bag-valve-mask device with supplemental oxygen. Continuously monitor the pulse oximeter reading.

- Align the axes of the mouth, pharynx, and trachea to achieve better visualization of the glottic opening. This can be done by tilting the patient’s head back, flexing the neck forward, and lifting the chin to place him in a “sniffing position.” This should only be done if there is no suspicion of spinal injury. If spinal injury is suspected, the head and neck must be stabilized manually in an in-line position during the intubation attempt. If you are unable to visualize the cords, raise the patient’s shoulders 1 inch by placing a folded towel or sheet under them. The height required will vary with the age of the patient and will need to be adjusted accordingly. (Remember that the larger occipital region of the pediatric head may result in flexion of the neck when the patient is supine, making the intubation procedure more difficult.)

- The laryngoscopy should be very gentle. Never use force. Do not use the handle in a prying or levering motion as if digging in the airway. Doing so could cause extensive damage to the upper airway. Do not use the teeth or upper gums as a fulcrum. Pull in the direction of the handle to get better visualization.

- The epiglottis is more flexible and less developed in infants and young children. As a result, it is more likely to cause obstruction of your view and may require extra effort to control when using the straight blade.

- Application of cricoid pressure during intubation will reduce the risk of vomiting and aspiration. Pressure on the cricoid and thyroid cartilage will move the glottic opening slightly posterior, making visualization easier.

- Insert the tube until the vocal cord or glottic marker on the uncuffed tube, if available, is at the level of the vocal cords. If a cuffed tube is being used, insert the tube until the proximal end of the cuff is approximately 1/2 inch beyond the vocal cords.

- The tracheal tube must be held in place until it is properly secured. Any movement could easily dislodge it.

- Confirm tracheal tube placement using the methods described earlier for adults, including use of end-tidal CO₂ detection devices. An esophageal detection device may be less reliable in infants and children. If corrective action is necessary, follow the procedures that were described. Be aware, however, that observing symmetrical rise and fall of the chest is the best indicator of proper placement in infants and children. Breath sounds could be misleading because sounds are easily referred and transmitted to the other side of the chest and epigastrium because of the small size of the chest cavity.

- Improvement in heart rate and skin color should occur after intubation. If the tube is not placed properly, the patient’s heart rate may continue to deteriorate and the cyanosis may worsen.

</table>
• If the tube is properly placed, secure it with tape or a commercial device approved by medical direction. Insert an oropharyngeal airway as a bite block.
• Note the centimeter marker at the level of the patient’s teeth or gums when the tube is properly positioned. If at any time you note a change in insertion depth, immediately reassess tube placement. Remember that small movements of the head or neck of the child can dislodge the tube.
• Once tube placement is confirmed and the tube secured, the patient’s head should be immobilized to limit movement that might dislodge the tube. Remember that flexion or extension of the neck in an infant or child can displace the tube. Consider immobilizing the neck, even if no trauma is suspected.
• If the tube is properly placed but inadequate lung expansion or tidal volume is noted, assess for one of the following causes:
  • The tube is too small and there is an air leak around the cricoid cartilage. Such a leak can be heard when auscultating over the neck. If a leak is detected, the tube should be replaced with a larger one. If using a cuffed tube, inflate the cuff until the air leak is eliminated. Check the pilot balloon to determine if the cuff is still working properly. A defective cuff may leak and deflate.
  • The pop-off valve on the bag-valve device is not deactivated (as it should be) and air is escaping with ventilation. This is a problem particularly in children with poor lung compliance or high airway resistance.
  • The bag-valve device has a leak or is not functioning properly. Check all its parts, especially the valves, to be sure they are working properly. Remove the bag-valve device from the tube and occlude the tube connection while squeezing the bag to check for any leaks or malfunctions.
  • The EMT performing ventilation is not delivering an adequate volume with each squeeze of the bag. Have the ventilator increase the volume delivered by squeezing more air out of the bag. Be careful, however, because a pneumothorax can result from overly aggressive ventilation.
  • The tube has become blocked with secretions or has kinked. Perform tracheal suctioning to remove any secretions. Visualize the tube with the laryngoscope to detect any kinks. If the tube remains occluded, remove it and begin positive pressure ventilation by bag-valve mask. After ventilation for 2–5 minutes, attempt intubation again.
• Excessive force and/or volume in ventilating an infant or child can easily cause rupture of a lung (barotrauma) and a subsequent pneumothorax (leakage of air into the chest cavity—an extremely dangerous condition). Carefully inspect the chest with each ventilation and watch for rise. As soon as the chest rises adequately, cease your ventilation.

Once the patient is intubated, it is necessary to continuously monitor the patient for deterioration that may result from a problem associated with the tracheal tube or ventilation device. A common mnemonic that can be used to determine possible causes for deterioration in the patient’s oxygenation or ventilation status is DOPE (displacement, obstruction, pneumothorax, and equipment failure).

The tube may be displaced from the trachea or may have been pushed farther into the trachea, creating a right or left mainstem bronchus intubation. Auscultate the lungs carefully to check for tube placement and, if necessary, perform a laryngoscopy to be sure the tube has not been displaced into the esophagus. A right or left mainstem bronchus intubation can be corrected by pulling back on the tube. If the tube is in the esophagus, it must be immediately removed and ventilation with a bag-valve-mask device or other ventilation device immediately initiated with a manual airway maneuver.

The tracheal tube may become obstructed with secretions, pus, blood, or a foreign body, or it may kink. Pass a suction catheter through the tube to ensure that it is free of any obstructions. If the tube is obstructed and cannot be unobstructed with suction applied via a catheter, remove the tube immediately and provide positive pressure ventilation with a bag-valve-mask device or other ventilation device with a manual airway maneuver.

The patient may have suffered a pneumothorax, which can lead to rapid deterioration of the patient. If you suspect a tension pneumothorax, expedite transport and contact an ALS unit for thoracic decompression.

Equipment failure must be considered in acute deterioration of the intubated patient. Check to be sure the oxygen has not become disconnected from the ventilation device, the oxygen source has not run out, and the ventilation device is still working properly.

NASOGASTRIC INSERTION IN INFANTS AND CHILDREN

Gastric distention (air in the stomach) tends to be a greater problem in infants and children than in adults. Because of their small airway structures, it is easy to ventilate them too quickly or too hard, causing air to enter the esophagus and be forced into the stomach. The child’s less-developed diaphragm is easily pushed upward by the air in the stomach, compressing the small chest cavity to the point where effective ventilation is impossible, leading to hypoxia. The risk of regurgitation and aspiration of gastric contents is also increased.

In this instance, the gastric air pressure must be relieved by inserting a nasogastric (NG) tube, a specialized catheter that is inserted through the nose and down
Contraindications

An NG tube should not be inserted in a patient who has suffered major facial, head, or spinal trauma. Consult medical direction about using oral insertion with such trauma patients. Do not insert the NG tube if you suspect an airway disease such as epiglottitis or croup unless the patient is intubated. This can cause spasms or exacerbate swelling to the point of occluding the airway. The NG tube is also contraindicated if the patient has ingested certain caustic substances (alkalis) and some hydrocarbons.

Equipment

The equipment for nasogastric intubation includes the following:

- A nasogastric tube (NG tubes come in a variety of sizes and are measured in units called French. Newborns and infants typically take an 8.0 French; toddlers or preschool children, a 10 French; school-age children, a 12 French; and adolescents, a 14–16 French.)
- 20 mL syringe to check tube placement
- Water-soluble lubricant to facilitate insertion of the tube
- An emesis basin, in case the patient vomits
- Tape to secure the tube
- Stethoscope to check for proper placement
- Suction unit and suction catheters in case of vomiting and to evacuate the stomach contents following tube placement
Insertion

Before beginning insertion, take Standard Precautions. Gloves, eye protection, and a mask should be worn because of the potential for splatters of secretions, blood, and vomitus. Then insert the NG tube using the following procedure (EMT Skills A2-4A to A2-4F):

1. Prepare and assemble the equipment.
2. Determine which nostril appears more patent. If obstruction or other deformity is present in one nostril, select the other.
3. Measure the tube by placing it at the tip of the nose, around the ear, and extending it until the most proximal of the holes at the distal end is just below the xiphoid process. Mark the tube with a piece of tape at the level of the tip of the nose; the tape will serve as a guide, indicating when an adequate length of tube has been inserted to enter the stomach.
4. Lubricate 6–8 inches of the distal end of the tube with water-soluble lubricant.
5. If trauma is not suspected, place the patient supine with the head turned to the side.
6. Insert the tube gently in one of the nostrils. Advance the tube straight back toward the ear along the floor of the nostril. Continue to advance the tube until the tape marker is at the level of the tip of the nose. If resistance is met when advancing the tube, rotate the tube slightly and continue to advance it. If significant resistance is met, stop, pull back on the tube, and reevaluate its position. Do not force the tube if resistance is found.
7. Check the placement of the nasogastric tube by:
   a. Attaching the 20 mL syringe to the tube, pulling back on the plunger, and aspirating the gastric contents.
   b. Placing your stethoscope over the epigastric region and auscultating while injecting 10–20 mL of air into the tube. A gurgling sound should be heard over the stomach.
8. Secure the tube in place with tape.
9. Attach the tube to low suction and aspirate the gastric contents.

Complications

There are several possible complications associated with placement of the nasogastric tube:

- Tracheal intubation is possible, with the NG tube entering the larynx and trachea instead of the esophagus. The patient will typically begin severe coughing and choking. Pull back on the tube until it is at the posterior pharynx and reattempt insertion.
- Nasal trauma can occur from insertion of the tube. Be sure the tube is adequately lubricated. Do not insert the tip of the tube in an upward direction in the nose. This commonly causes pain and bleeding.
- Insertion of the NG tube may stimulate the gag reflex and cause the patient to vomit. Be prepared to clear the airway and suction.
- A rare complication is passage of the tube into the cranium if a basilar skull fracture exists, particularly with midfacial fractures. Do not attempt this procedure on patients with significant facial trauma.
- The tube may become curled in the nose, mouth, or trachea. If insertion becomes difficult, inspect inside the mouth and withdraw the tube to determine its position.
- Perforation of the esophagus may occur with an overly aggressive insertion technique.

Medical direction or your local protocol may allow insertion of the NG tube only after tracheal intubation. Once the airway is secured with a tracheal tube, the risks of misplacing the NG tube in the trachea or of vomiting and aspiration are greatly reduced.
**EMT SKILLS**

**A2-1**

**Orotracheal Intubation**

- **A2-1A** Ensure adequate ventilation and oxygenation. Prior to any intubation attempt, ventilate and hyperoxygenate the patient.

- **A2-1B** Assemble and test the equipment.

- **A2-1C** In the nontrauma patient, tilt the head and lift the chin into a “sniffing position.” Insert the blade on the right and sweep the tongue to the left until the blade is midline.

- **A2-1D** The trauma patient with suspected spinal injury must be intubated with in-line spinal stabilization maintained. The EMT intubating secures the patient’s head with his thighs while the second EMT holds the head from a position below the patient’s neck.

- **A2-1E** Visualize the vocal cords and glottic opening and insert the tracheal tube through the vocal cords. Lift in the direction of the blade handle.
A2-1F To visualize the glottic opening (shown here), lift the laryngoscope in the direction of the handle. (© Gastrolab/Photo Researchers, Inc.)

A2-1G Confirm tube placement.

A2-1H Secure the tube and reassess for tube placement.

EMT SKILLS A2-2

Orotracheal Suctioning

A2-2A Preoxygenate the patient for 2 minutes prior to orotracheal suctioning.

A2-2B Check the suction equipment. Orotracheal suctioning is a sterile procedure; therefore, do not contaminate the suction catheter.

continued
**EMT SKILLS A2-3**

**Digital Intubation**

- **A2-2C** Insert and advance the catheter without suction being applied.

- **A2-2D** Continue to advance the catheter to the level of the carina.

- **A2-2E** Apply suction by covering the open part on the catheter. Using a twisting motion, withdraw the catheter with suction.

- **A2-2F** Resume ventilation of the patient for 2 minutes following suctioning.

- **A2-3A** Insert your index and middle fingers into the patient’s mouth. Elevate the epiglottis with your middle finger.

- **A2-3B** Guide the tube forward and into the glottic opening with your index and middle fingers.
Nasogastric Intubation

- **A2-4A** Oxygenate the patient.

- **A2-4B** Determine the proper length by measuring from the tip of the nose, over the ear, to just below the xiphoid process.

- **A2-4C** Slightly flex the neck by supporting the head with your hand. Advance the tube straight back, not toward the head.

- **A2-4D** Confirm placement by injecting 15–20 mL of air into the tube while auscultating over the stomach. If air is heard entering the stomach, proper placement is confirmed.

- **A2-4E** Apply negative pressure to the syringe to aspirate gastric material and air.

- **A2-4F** Tape the NG tube in place.
There is some form of agricultural activity in every state in the United States. Agriculture-related accidents usually involve heavy machinery and specialized equipment, which can present unique challenges to EMTs and other emergency care personnel.

Injuries that occur on a farm also occur in urban areas, since farm-type machinery is used for many applications. The equipment in many industries is similar: The pizza dough roller works on the same principles as the printing press or the agricultural combine, for example. Workers who do snow removal, construction work, and factory work also use similar machinery—and are prone to similar accidents.

**RESPONSE TO AGRICULTURAL AND INDUSTRIAL EMERGENCIES**

Farm accidents and industrial accidents often involve unique mechanisms of injury. The outcome of an accident involving agricultural or industrial machinery is likely to be severe trauma. This may involve a combination of open and closed musculoskeletal and soft tissue injuries—both penetrating and blunt force trauma—with crush injuries, avulsions, and amputations being common (Figures A3-1a to A3-1f).

The assessment guidelines that follow apply to trauma; however, farm accidents can also involve other problems such as drownings or poisonings, which are discussed later.

**Assessment-Based Approach: Agricultural and Industrial Emergencies**

**Scene Size-up**

Before you begin any rescue at an agricultural or industrial accident, perform a scene size-up. Make sure you will not be exposed to gases, fumes, chemicals, unstable equipment, or livestock. Toxic fumes are found especially in or near silos. If necessary, wait for fire personnel or specialized hazardous materials teams to control the scene. If there has been a tractor accident, call for the fire department to handle fire that may ignite from spilled fuel and hot hydraulic fluid. The EMS team will extricate and treat the patient.

A scene is not safe until machinery is stabilized and shut down and other hazards such as leaking fuel have been controlled. If rescue must be conducted in an agricultural storage area, do not attempt rescue alone. All rescuers must wear the appropriate personal protective equipment, including a self-contained breathing apparatus (SCBA) and lifeline.

**Primary Assessment**

When the scene is safe, perform a primary assessment. The tremendous kinetic energy involved in agricultural machinery can cause extensive injuries. Always assume spinal injury, and establish manual in-line stabilization on first contact with the patient. Assess the patient’s mental status. Manage any life-threatening problems with the airway, breathing, and circulation. Make a priority decision for further care and transport.

**Secondary Assessment**

After you have identified and cared for life-threatening injuries, perform a secondary assessment. If the mechanism of injury is significant, the patient has an altered mental status, or multiple injuries are suspected, perform a rapid secondary assessment, checking for evidence of trauma. Chest injuries—including pneumothorax and sucking chest wounds—and abdominal injuries are common with accidents involving farm and industrial machinery, as are bone and joint injuries to the extremities. Record baseline vital signs and gather the history from the patient or bystanders. Obtain as much information as possible about events leading to the injury. If there were no witnesses to the accident, this information may have to be surmised from the mechanism of injury as determined from your scene size-up.

**Emergency Medical Care**

In general, provide emergency care to a patient injured in a farm accident in the same way you would treat any patient with similar injuries:

1. **Establish a patent airway.** While maintaining manual in-line stabilization, use a jaw-thrust maneuver to open the airway. Suction the airway and insert an airway adjunct, if appropriate. Consider calling for ALS backup, especially if there has been trauma to the face or neck that will require advanced airway procedures.
Injuries Sustained from Farm Machinery

2. **Assess ventilation and oxygenation.** If breathing is inadequate, initiate positive pressure ventilation with supplemental oxygen connected to the ventilation device. If breathing is adequate, administer oxygen based on the SpO₂ reading and patient signs and symptoms. If the SpO₂ reading is greater than 94% and no signs or symptoms of hypoxia, respiratory distress, or heart failure are present; and there is no complaint of dyspnea, oxygen is not necessary. If signs of hypoxia or respiratory distress are present, if the SpO₂ reading is less than 94%, signs or symptoms of hypoxia, respiratory distress, or heart failure are present; or the patient complains of dyspnea, apply a nasal cannula at 2 lpm. Titrate the liter flow to
achieve and maintain an SpO₂ of 94% or greater. If inhalation of a toxic substance is suspected, place the patient on a nonrebreather mask at 15 lpm.

3. **Control severe bleeding.** Apply direct pressure to the bleeding wound. If direct pressure is not effective and the wound is to an extremity, apply a tourniquet. If pressure from the farm or industrial equipment is tamponading bleeding by the pressure it places on the injury, consider leaving the equipment in place and transporting it with the patient unless you are specially trained in extrication from farm equipment. Be prepared to initiate CPR and apply the AED if the patient becomes pulseless.

4. **If the patient was exposed to chemicals or manure,** remove all exposed clothing and flush the patient with copious amounts of water before transport. Check for burns from spilled engine coolants, transmission fluid, hydraulic fluid, and battery acid.

5. **Preserve all avulsed body parts,** however mangled their appearance, and transport them with the patient.

6. **Stabilize all injuries.** Splint and immobilize bone or joint injuries. (If the patient is a high priority for transport, splinting may need to be done en route.)

7. **Immobilize the patient to a long backboard if vertebral or spinal cord injury is suspected.**

8. **Treat for shock and transport.**

### Reassessment

Perform a reassessment, repeating the primary assessment and rapid secondary assessment, monitoring vital signs, and checking interventions. Be prepared to adjust care if the patient’s condition begins to deteriorate.

### Characteristics of Agricultural Accidents

Farmers work long hours, often seven days a week. During that time they are exposed to heat, cold, and unstable weather conditions, as well as excessive noise and vibration. They often use old equipment because of the tremendous expense of replacement, and many accidents occur during maintenance and repair of these complicated machines (Figures A3-2a to A3-2d).

These factors and a number of others contribute to making agricultural accidents most often the cause of serious injury:

- Many farmers do not use personal protective equipment.
- When a worker becomes entangled in equipment, lengthy extrication is often required, which aggravates and increases the severity of injuries.

### Farm Equipment

- **Figure A3-2a** Front-end loader moving hay bales. (© Kevin Link)
- **Figure A3-2b** Moving grain in a silo. (© Kevin Link)
- **Figure A3-2c** Haybine repair. (© Kevin Link)
- **Figure A3-2d** Combine harvesting wheat. (© Kevin Link)
• Since many farmers work alone in remote areas, they may not be missed for hours. Many die from injuries that would not have been fatal if they had been discovered in time.
• Long transport times contribute to the severity of injuries. Farms in rural areas can be long distances from hospitals.

Mechanisms of Injury
The mechanisms of injury commonly involved in agricultural equipment accidents include:
• **Pinch points.** Two objects meet to cause a pinching or pulling action.
• **Wrap points.** An aggressive component of machinery moves in a circular motion.
• **Shear points.** Two objects move close enough together to cause a cutting action.
• **Crush points.** Two large objects come together to cause a crushing action.
• **Stored energy.** Hazards remain after the machinery is shut down.

Agricultural accidents most often occur when the patient was in the process of maintaining or repairing a piece of equipment. Most trauma involves the hands and arms. Common types of injuries are abrasions, lacerations, contusions, punctures, sprains, strains, fractures, eye injuries, concussions, avulsions, amputations, burns, and bites from farm animals.

Stabilizing and Shutting Down Agricultural Equipment

**General Guidelines**
Before a patient can be extricated from agricultural equipment, the machine needs to be stabilized and shut down. To stabilize agricultural equipment, block or chock the wheels, set the parking brake, or tie it to another vehicle. Once stabilized, shut it down using the following procedure:

1. Enter the cab or climb onto the operator's platform. Locate the ignition switch or the key and throttle. **If you have any concern that you have not located the correct controls, do not touch them.** Wait for help.
2. Slow the engine down with the throttle, and then switch off the key. If the engine runs on diesel fuel, you may need to use a fuel or air shut-off lever instead of a key.
3. If you cannot shut down the engine from the cab or operator's platform, try the shut-off valve at the bottom of the fuel tank.
4. If that does not work, try using vise-grip pliers to clamp the fuel line shut. (The fuel line is a single metal or rubber pipe about one-half inch in diameter.)
5. If the patient is in a life-threatening situation and all other attempts to shut down the engine have failed, then discharge a 20-pound CO₂ fire extinguisher into the air intake. (Warning: This technique can cause extensive damage to the engine.)

Do not attempt to stop or move machinery that you are not familiar with. Instruct a person who knows how to operate the machinery in what needs to be done, such as shutting down the engine or motor.

**Tractors**

Before you attempt to rescue a patient from a tractor accident, stabilize the tractor and shut down the engine. Tractor engines can be fueled by gasoline, diesel, or propane. Fuel leaks, fires, and explosions are common. Many fatal farm injuries result from a tractor turning over backward or rolling to the side.

To stabilize a tractor, even when it is upright, lock up the rear wheels with two 1-ton cable hoists (come-alongs) and three chains:

1. Wrap one chain around the rear tire and through the high slot in the rim.
2. Wrap the second chain around the same tire and through the low slot in the rim.
3. Attach the third chain to the front of the tractor and stretch it to the hoist.
4. Attach the other hoist to the two rear chains. If the tractor does not have slots in the rims, stretch the hoist and chains across the rear tire to a strong point on the rear of the tractor. Make sure you do not lift the secure tire off the ground during hoisting.

To extricate the patient, try the simplest method first. For example, you might be able to remove soil from beneath the patient with a shovel to create enough space to free the patient. If the steering wheel is trapping the patient's arm to the ground, cut the steering wheel. In some cases, you might have to lift the tractor from the patient.

To lift a tractor:

1. Build a cross-crib capable of supporting the tractor. The crib should be as wide as possible, and the crib box should not be taller than it is wide. The crib should come to within about 2 inches of the axle or platform where you plan to lift.
2. Place the cribbing and lifting devices on a firm, solid surface. If the tractor is on soft ground or blacktop, use quarter-inch tread plates or similar equipment.
3. Place a steel plate on the cribbing to provide structural strength to the lifting system.
4. Place one or two high-pressure air bags on the steel plate, and then inflate them to lift the tractor. You may also place air bags on either side of the rear wheel, inflate them simultaneously to place pressure against the tire, and then rest the tractor on the cribbing until another air bag is placed under the tire.
5. If you do not have air bags, use power spreaders or hydraulic rams, hand-powered hydraulic jacks, or manual jacks, anchoring them against the steel plate.

6. Use cranes, wreckers, or boom trucks to lift extremely large tractors.

Any time you lift or remove an overturned tractor from an operator, continuously monitor the center of gravity. Watch for unstable conditions, such as changes of the angle between the lifting surface of the tool and the tractor or sinking of the tractor on the opposite side. Always lock the wheels in position before lifting the tractor.

To perform the lift as safely as possible, one rescuer should give lifting instructions while the others carry out the lift. If you use more than one lifting device, use extra care in coordinating the lift to keep the load from shifting. Constantly monitor the patient to make sure that the portion being lifted is moving properly and that another part is not putting more pressure on the patient.

**Power Takeoff Shafts**

The power takeoff (PTO) shaft is a specially designed shaft that connects the tractor's engine to other agricultural implements, such as mowers, corn pickers, forage harvesters, and augers (Figure A3-3). PTO-related accidents occur when clothing gets caught in the spinning shaft and pulls the worker in. Arms and legs may be amputated. The worker's body may be wrapped around the shaft. Because of the energy involved, injuries to the patient can be very traumatic and may require rapid treatment and transport. Aggressively control bleeding with universal or multi-trauma dressings at the site of an avulsion or amputation. If advanced care is available (air transport, ground paramedics), call for it as soon as possible.

To free the patient, in some cases, find the end of the wrap where the clothing is only a layer thick. Use rescue knives to cut at that point. If you cannot free the patient by cutting the clothing, you will need to remove the PTO shaft.

1. Place a fire pry bar at least 42 inches long into the implement side of the PTO shaft. (Some PTOs will free-wheel in either direction when the power is shut off.)

2. Uncouple the shaft. Slide it apart. If necessary, transport it with the patient to the hospital.

3. If you cannot uncouple the shaft, cut it with a power saw, portable band saw, gas circular saw, or hack saw. Lock the PTO shaft in place with a fire pry bar through the universal joint on both ends before you begin to cut.

**Combines**

The combine is a complex machine made of many parts joined by welding, screws, nuts, bolts, and rivets. It is assembled with multiple augers, shafts, belts, pulleys, roller chains, and sprockets. Instead of becoming overwhelmed by the complexity of it, look at the single part in which the patient is entrapped.

A common source of injury is the auger, which is used to move the threshed, separated, and cleaned grain from the cleaning shoe to the wagon for transport. The auger is the rotating part of a screw conveyor. It can pull in victims with extreme force, often causing complete amputations of extremities. Other sources of injury are the heads, which have oscillating cutting bars; reels, with hardened steel tines that can impale the patient; and snapping rollers, which cause severe crushing injuries.

To extricate a patient, identify the mechanism of injury and then follow these guidelines:

1. Never use the self-reversing feature on a combine to remove a trapped patient.

2. Always remember that stored energy can cause significant injury as you release parts of agricultural equipment. Use pry bars or other tools to prevent motion.

3. Spread snapping rollers on older equipment with power rescue tools, hand rescue tools, wooden wedges, and air bags. The rollers on newer equipment cannot be spread with conventional rescue tools.

4. Always lock the hydraulic system. A pipe or bar near the hydraulic cylinder will lock the header.

5. Just behind the combine header is a coupling device that attaches the head to the drive mechanism. It may be a shaft with a pin in it or a set of flat gears wrapped with a roller chain. Remove this device.

6. If you have to use an oxyacetylene torch to cut parts of the combine, reduce the risk of fire. Before cutting, wash down the combine and the surrounding soil with water. Then flush the inside of the combine header, feeder house, and main combine.

7. If the patient is trapped in the auger, disconnect the auger drive. Use a large pipe wrench on the shaft to prevent stored energy from reversing the auger.
8. Entanglement in an auger is usually too severe to handle in the field. If an auger has caused an avulsion, do not try to disentangle the patient. Instead, cut the auger free and transport it with the patient. Avoid excessive vibration or movement during cutting, and try to cut at a spot weld.

**Corn Pickers**

A corn picker removes the kernels from the cob as it is picked. It may be mounted on a tractor, pulled behind a tractor, or self-propelled. Corn pickers use a system of rollers, chains, belts, and blades to remove the ears from stalks and to remove the leafy cover of the corn.

Most injuries from corn pickers involve entrapment of the hands and arms and range from limited trauma to complete amputation. Some injuries can be fatal. When dealing with corn pickers, follow these steps:

1. Spread the snapping rolls with a portable power kit (two wooden wedges combined with two small hydraulic wedges). Insert one wedge at the top of the rolls, and the other below. Equip the bottom wedge with a rope so you can pull it through from above. You can also use high-pressure air bags or power hydraulic tools with the wooden wedges.
2. Once the rolls have been released, take great care to avoid an uncontrolled release of the springs. Release the tension by adjusting the nuts and bolts. Then remove the bolts that fasten the bearing housing to the side of the husking bed housing.
3. To remove the husking bed, take the machine apart with wrenches or cut the bolt heads with an air chisel.

**Hay Balers**

Balers are designed to bale hay, straw, corn stalks, and other forage into uniform shapes. Either oscillating forks or a short auger move forage into the bale chamber. On round balers, a series of flat belts rotate around the perimeter of the bale chamber to form the bale one thin layer at a time. The pickup assembly is a series of hardened metal tines that rotate on a shaft and rake the cut forage into a header.

A worker can be picked up and pulled into the header assembly. He can be entrapped up to the shoulders, and tines can cause penetrating wounds in the abdomen and chest. Avulsions of varying degrees can be caused by the cross auger.

To rescue a patient entrapped in a hay baler, follow the guidelines presented next. If the tailgate is open when you arrive, lock the tailgate from falling before you attempt the rescue. Some balers have a mechanical locking device or a hydraulic valve used as a safety lock. Then:

1. Disassemble the tines, which are held by one or two small bolts.
2. If the patient is entrapped in the cross auger, first try to loosen the drive belts driving the auger. Use a pipe wrench to hold onto the input shaft as you cut the chain or belt to prevent motion. Release stored energy slowly by hand.
3. If you cannot loosen the drive belts, raise the auger with power rescue tools, an air bag, power hydraulic tools, or a bottle jack and cribbing.
4. Never use oxyacetylene torches on a hay baler. Balers are filled with fine dust that can ignite with a single spark.
5. If the patient is entrapped in a set of smooth rollers, remove the mounting bolts on both ends of the housing to remove the bearings.

**Agricultural Storage Devices**

Suffocation and inhalation of toxic gases can occur in accidents involving grain tanks, silos, and manure storage areas and structures.

**Grain Tanks**

Usually loaded by augers, grain bins come in a variety of sizes. Workers who enter one to get grain flowing can be buried with grain in seconds. Because most bins unload from the center, most patients are found in the middle of the bin.

The temperature of stored grains is low, even in summer. A patient’s resulting hypothermia may prolong survival. For that reason, begin resuscitation, even if the patient has been trapped for a long period of time.

**Note:** Never enter the structure without the help of other rescuers, without being tied to a safety lifeline, and without wearing a disposable mechanical filter respirator rated for dust particles. Call for extrication teams and fire personnel immediately.

To rescue a patient from a grain tank:

1. Turn off electric power to the structure as soon as possible. Keep fans working until the actual extrication begins, since they may deliver more air to the patient but could hamper rescue operations.
2. Make sure the fire department has a charged fire line available as the side of the bin is breached.
3. Cut an 18-inch triangle in the side wall. Make it as high as you can but still below the surface of the grain. Do not open the triangle until you have cut another hole on the opposite wall. Then open the holes at the same time to allow grain to flow out of the bin evenly. This will help prevent structural failure. Cut additional holes as needed. Holes must be cut in the middle of the bin sheets, avoiding bolts, seams, and stiffeners. Do not use augers, openings in doors, or doors to unload the grain bin.
4. As soon as the patient is exposed, secure him with a lifeline. If you do not, the patient will flow with the grain.
5. Use whatever is available to shore the grain away from the trapped patient, such as plywood, metal sheets, spine boards, or a 55-gallon drum.
6. Your top priority for patient care is airway management. The airway may be filled with grain, so aggressive suctioning and clearing may be necessary. Suction and clear the patient’s airway in the bin while the extrication team prepares the patient for removal.
7. Immobilize the spine before you try to remove the patient from the grain bin.
8. Remove as much grain from around the patient as possible before extrication. Pulling against the force of the grain can cause further injury.

**Silos**

Silos are used to store chopped grain or hay as feed for livestock. They may be constructed of clay blocks, concrete blocks, steel sheets, poured concrete, or steel glass-lined sheets.

When crops are stored in silos, gases are formed by natural chemical fermentation. Fermenting crops can release high levels of carbon monoxide, methane, and oxides of nitrogen ("silo gas"). Red-brown to yellow-green in color, silo gas smells like household bleach and will kill within minutes in high concentrations.

Because it is heavier than air, silo gas flows down the side chute and out the open silo door. People working around the base of the silo or in the feed room or adjacent barn can be exposed to dangerous levels of silo gas (Figure A3-4).

The severity of injury to the patient depends on the length of exposure. Low concentrations of silo gas can irritate the nose, throat, airways, and lungs. Common reactions to mild exposure include eye irritation, cough, labored breathing, fatigue, nausea, vomiting, cyanosis, and dizziness or sleepiness.

The presence of silo gas may be recognized by the following signs:

- Bleach-like odor
- Yellowish or reddish vapor hovering over the product
- Stains of red, yellow, or brown on the product or other surfaces touched by the gas
- Dead birds or insects near the silo
- Nearby livestock with signs of illness

When rescuing a patient exposed to silo gas, follow these guidelines:

1. Put on a self-contained breathing apparatus (SCBA) before you enter the silo. All rescuers working around or in the silo should be wearing one, even if there are no immediate signs of the gas.
2. If the patient is breathing, immediately administer oxygen by way of an SCBA and a connecting tube. (If the patient is no longer near the silo, oxygen can be administered in the usual way by nonrebreather mask.)
3. If rescue will be delayed, run the silo blower to purge the air in the silo.
4. All patients exposed to silo gas must be transported to a hospital for further care. Complications such as severe pulmonary edema can develop up to 12 hours after the incident.

**Manure Storage**

Large livestock facilities handle manure by flushing down the confinement buildings with water. The liquid is then sent to an open pond for storage. In some cases, liquid manure is stored in a structure similar to a silo. There are two potential injuries from liquid manure: drowning and inhaling toxic fumes. (The liquid manure releases ammonia, carbon monoxide, carbon dioxide, methane, and hydrogen sulfide.)

Agitation of a manure pit can cause the sudden release of hydrogen sulfide. Signs and symptoms of hydrogen sulfide intoxication may include cough, irritation of mucous membranes, nausea, and pulmonary edema. High concentrations can cause respiratory paralysis and sudden collapse.

In rescuing a patient exposed to manure:

1. Put on an SCBA and a lifeline before you begin rescue. All rescue personnel who enter a livestock confinement house should be wearing SCBAs and lifelines.
2. Treat the patient who has suffered immersion in liquid manure as you would a drowning in water. If the patient is breathing at all, immediately administer an SCBA. Use a connecting tube to deliver supplemental oxygen.
3. Remove the patient’s clothing and flush the patient’s body with water. Green soap should be used to clean everyone who had contact with the manure.
4. Transport the patient to the hospital. Be sure that materials contaminated with manure are not put in the ambulance or helicopter, since fumes can overcome the crew.

### Agricultural Chemicals

Thousands of pesticides are currently used in agriculture to control insects, plant growth, fungi, rodents, birds, and bacteria. Pesticide poisoning may be overlooked because signs and symptoms are similar to those of heat exhaustion, food poisoning, asthma, congestive heart failure, smoke inhalation, influenza, or other illnesses. Common symptoms include excessive tearing, drooling, abdominal cramps, bowel movement, cough, flushed skin, wheezing, bizarre behavior, and seizures.

When farm workers do not wear personal protective equipment such as eyewear or fail to wash properly, pesticides can enter the body through the eyes and skin, as well as through inhalation and swallowing. If you suspect exposure or poisoning, follow these guidelines:

1. Put on protective clothing before entering the scene. If appropriate, call a specialized hazardous materials team for decontamination.
2. If you know that a patient has been exposed to a particular pesticide, check the label for instructions and precautions. If possible, take the label to the hospital with you.
3. Remove all the patient's clothing and flush the patient with water. Follow appropriate decontamination procedures.

### Injuries from Livestock

Many agricultural injuries are caused by livestock or by tasks involving livestock production. Common types of trauma include soft tissue injuries, concussions, sprains and fractures, and spinal, chest, and abdominal injuries. Common mechanisms of injury include falling on slippery floors and getting bitten, thrown, knocked down, stepped on, kicked, or punctured by an animal.

Treat a patient with a livestock injury as you would any patient with a similar injury. However, never enter a livestock building or open lot until all animals are secure. If animal feces are on the wound, flush the injury site before dressing and bandaging.

### INDUSTRIAL RESCUE

While some industrial injuries may seem complex, you can prepare for emergency care by observing what goes on around you. As mentioned earlier, the equipment in many industries is similar. Some industrial operations, such as quarries, are located in rural areas that may require special extrication techniques (Figure A3-5).

For the greatest effectiveness, learn the basic components of machinery and the working principles of each component, including pulleys, belts, rotating shafts, bearings, and augers. Apply that understanding to specific pieces of machinery in emergency situations.

In any industrial rescue, follow these guidelines:

- If you are not familiar with the company's operations, check with staff to determine potential hazards at the scene. Make sure all hazards are controlled before you approach the patient.
- Never assume any machine is locked and secured. Verify with company officials that all valves, switches, and levers that allow a machine to operate have been padlocked to the off position.
- If the patient is in a confined space, or if he has been injured by an airborne or spilled agent, wait for specialized personnel or hazardous materials teams to arrive and decontaminate the scene and the patient.

![FIGURE A3-5](image-url) Rescuers perform a basket rescue from a quarry.
CHAPTER 1 • Emergency Medical Care Systems, Research, and Public Health

IN REVIEW

1. The purpose of the modern EMS system is to allow those who need it easy access, a prompt response, and high-quality prehospital emergency care from trained professionals.

2. The public can access the EMS system by way of the universal telephone number 911 or by using a non-911 number such as a seven-digit number. The advantages of a universal number are that central dispatch is generally staffed by trained technicians—often certified Emergency Medical Dispatchers (EMDs)—and the number is easy to remember. In addition, all three services—police, fire, and EMS—are accessible by calling one number. Non-911 or seven-digit numbers are used much less often in communities to access the EMS system because of the inherent delay in reaching the appropriate services.

3. The four levels of emergency medical technician training are Emergency Medical Responder (EMR) (similar to First Responder), Emergency Medical Technician (EMT) (formerly EMT-Basic), Advanced Emergency Medical Technician (AEMT) (formerly EMT-Intermediate), and Paramedic (formerly EMT-Paramedic).

4. Six types of special facilities to which patients may be transported include trauma centers; burn centers; obstetric centers; pediatric centers; poison centers; and stroke centers.

5. The general responsibilities of the EMT include personal safety and the safety of others, patient assessment and emergency medical care, safe lifting and moving, transport and transfer, record keeping and data collection, and patient advocacy.

6. Among the ways you can protect your own safety as an EMT are to wear personal protective equipment such as gloves, eye protection, and mask and gown when indicated for scene hazards; drive safely; use seat belts; do not enter potentially hazardous sites; never enter a volatile crowd situation until it has been deemed safe by law enforcement; take extra precautions with patients, relatives, and bystanders who are under the influence of drugs or alcohol, have a behavioral disorder, or are emotionally charged; follow directions from police, fire, utility, and other expert personnel; create a safe area in which patients can be treated; redirect traffic for the safety of all; wear reflective emblems or clothing at night; and provide adequate lighting at an accident scene.

7. Among the ways you can act as a patient’s advocate are to protect the patient’s privacy and confidentiality, shield the patient as much as possible from curious bystanders, conceal from curious onlookers the body of a patient who has died, answer the patient’s questions truthfully, make sure the patient is aware of family and friends at the scene know how to get to the hospital, make certain you provide necessary information to hospital personnel, honor any patient requests that you reasonably can, and collect and safeguard a patient’s valuables and transport them with the patient as well as document what items were left with emergency department personnel.

8. The EMS system physician medical director’s primary responsibility is to oversee the clinical and patient care aspects of the system. The medical director is responsible for providing medical direction by developing and establishing the guidelines under which the emergency medical service personnel function.

9. To ensure that the public receives the highest quality of prehospital care, the goals of quality improvement are to identify those aspects of the system that can be improved and to implement plans and programs that will remedy any shortcomings of the system.

10. The EMT’s role in quality improvement includes careful documentation on every call; becoming involved in the QI process by performing reviews and audits as requested; gathering feedback from patients, other EMS personnel, and hospital staff; conducting preventive maintenance on vehicles and equipment; participating in refresher courses and continuing education; and maintaining skills in all aspects of patient care and equipment operation.

11. Evidence-based medicine focuses on research to provide substantiation that certain procedures, medications, and equipment improve the patient’s outcome. EMS has often had to rely on research conducted for the emergency department for changes in practice because there is currently very little research in prehospital care.

12. EMS professionals play an integral role in the mission of public health through activities such as health education, disease and health screening, disease surveillance, and injury prevention through the promotion of safety equipment such as seat belts and helmets.

CHAPTER 2 • Workforce Safety and Wellness of the EMT

IN REVIEW

1. The five stages through which a dying patient may pass are denial (“Not me”), anger (“Why me?”), bargaining (“Okay, but first let me”), depression (“Okay, but I haven’t”), and acceptance (“Okay, I am not afraid”).

2. Things you can do to help the dying patient may include the following: do everything possible to maintain the patient’s dignity, show respect for the patient, communicate who you are and what you are doing, allow family members to express themselves, listen empathetically, avoid giving false assurances, be honest but allow for some hope, use a gentle tone of voice, let the patient know that everything that can be done to help will be done, take appropriate steps if the family wants to touch or hold the body after death, and do what you can to comfort the family.

3. Signs and symptoms of chronic stress and burnout may include irritability with coworkers, family, and friends; inability to concentrate; difficulty sleeping and nightmares; anxiety; indecisiveness; guilt; loss of appetite; loss of sexual desire or interest; isolation; loss of interest in work; problems in thinking (confusion, inability to make judgments or decisions, loss of motivation, chronic forgetfulness, and loss of objectivity); psychological problems (depression, excessive anger, negativism, hostility, defensiveness, mood swings, and feelings of worthlessness); physical problems
(persistent exhaustion, headaches, gastrointestinal distress, dizziness, and pounding heart); behavioral problems (overeating, increased alcohol or drug use, grinding teeth, hyperactivity, and lack of energy); social problems (increased interpersonal conflicts); and decreased ability to relate to patients as individuals.

4. Ways to help deal with stress may include making lifestyle changes, such as improving diet, taking advantage of the benefits of exercise, practicing relaxation techniques, and avoiding self-medication of any kind. Other ways to deal with stress may include making changes to the work environment, such as developing a “buddy” system with a coworker, encouraging and supporting coworkers, taking periodic breaks for exercise, requesting work shifts that allow more time with family and friends, and requesting a rotation of duty assignment.

5. Negative feelings that families of EMTs may have include a lack of understanding about your job, a fear of separation or fear of being ignored, worry about on-call situations, inability to plan, and a frustrated desire to help and support you. Ways to help include explaining the nature of your work and what you do for patients and how you feel about what you do, answering their questions and easing their anxieties, and encouraging them to join you in staying fit. Always include time with them on your list of priorities.

6. Safety precautions to prevent the spread of infectious disease include Standard Precautions taken at all times, including hand washing; use of personal protective equipment such as protective eyewear, protective gloves, gowns, and masks; cleaning, disinfecting, and sterilizing clothing and equipment; immunizations; and reporting exposures as required by state law.

7. Under OSHA guidelines, employers have the responsibility for developing a written exposure control plan and providing training, certain immunizations, and the proper equipment for protection against disease transmission. The employer is also responsible for developing and enforcing a written policy to be used in the case of an exposure of an employee to an infectious substance.

8. Employees share—along with employers—the responsibility of ensuring that the necessary equipment and procedures are in place for protection against exposure to infectious disease. In addition, employees must complete proper training and follow the procedures outlined in their exposure control plan.

9. Personal protective equipment for special situations includes the following: in a hazardous materials situation, a self-contained breathing apparatus and specialized “hazmat” suit; in a rescue operation, turnout gear, puncture-proof gloves, impact-resistant protective helmet, protective eyewear, and additional equipment dictated by local protocol, such as reflective clothing, rubber boots and slip-resistant gloves, or dust respirator. If the rescue is being performed on a roadway, federal law requires rescuers to wear ANSI/ISEA approved high-visibility apparel. For violent scenes or crime scenes, some rescuers may also elect to wear body armor.

10. Prevention strategies include the use of vehicle restraint systems, safe lifting and moving techniques, getting an adequate amount of sleep, physical fitness and proper nutrition, and practicing proper disease transmission Standard Precautions. You must also protect yourself during rescue operations involving hazardous materials, potentially life-threatening rescues, violence, and biological and chemical weapons of mass destruction. It is imperative that you not fall victim to the same hazards that affect your patients.

11. The more common infectious diseases encountered in the prehospital setting are hepatitis, tuberculosis, and influenza.

12. Remaining well is fundamental to performing your role as an EMT. That can be achieved through physical fitness, such as cardiovascular endurance, muscular strength and flexibility, and maintaining an appropriate body fat composition. In addition, getting an adequate amount of sleep; avoiding smoking, alcohol, and drugs; and dealing with stress effectively can all improve your physical and mental well-being and contribute to your effectiveness in your profession.

**CHAPTER 3 • Medical, Legal, and Ethical Issues**

**IN REVIEW**

1. A DNR is a legal document, usually signed in advance by the patient and his physician, that indicates to medical personnel which, if any, life-sustaining measures should be taken when the patient’s heart and respiratory functions have ceased. When presented with a DNR, try to determine whether it is valid and interpret the manner in which the directive should be followed. Be familiar with your local protocols regarding DNRs and consult medical direction early for instructions on how to proceed. It is always better to initiate treatment until the directive can be interpreted and clarified. In doubt, provide resuscitation.

2. “Expressed consent” must be obtained from every conscious, mentally competent adult before treatment is started and after necessary procedures and related risks have been explained in terms the patient can understand. “Implied consent” occurs when you assume that a patient who is unresponsive, or who is not competent or who is unable to make rational decisions, would consent to emergency care if he could. “Consent to treat a minor” must be obtained from a parent, legal guardian, or other person who has been granted limited rights of decision making by the parent or guardian such as a teacher, stepparent, or other authorized caregiver.

3. In order to refuse care, the patient must be competent. The patient must be informed of and fully understand all potential risks and consequences involved in refusing treatment or transport, up to and including the possibility of death when appropriate. The patient must be able to explain back these consequences to you. The patient must sign an official “release from liability” form—or a patient’s witnessed refusal to sign the form must be obtained—and must be included with a full documentation of the case.

4. An EMT can be charged with abandonment if he discontinues treatment of a patient (unless so ordered by law enforcement personnel) or if treatment is discontinued without ensuring that another health care professional with at least as much expertise has taken over treatment. An EMT can be charged with negligence by deviating from an accepted standard of care through carelessness, inattention, disregard, inadvertence, or oversight, which results in further injury to the patient.

5. The duty to act is an obligation of the EMT to respond to the scene and to provide emergency care to the patient. Once a patient relationship has been established, which is simply done by the EMT making contact with the patient with the intent to provide emergency care, it cannot be terminated without the consent of the patient.

6. Federal law strictly protects the privacy of patient health care information. Releasing confidential patient information requires a written release form signed by the patient or a legal guardian except under the following specific exceptions: (1) when another health care provider needs to know the information in order to continue medical care; (2) if an official public health or governmental agency requires mandatory reporting of information related to your contact with
the patient such as incidents of rape, child abuse, communicable diseases, or domestic violence; (3) when requested to report the information to law enforcement as part of a potential criminal investigation; (4) if a third-party billing agency requires the information; and (5) when required by legal subpoena to provide the information.

7. As an EMT, you can preserve evidence at a crime scene by taking the same way into and out of the scene; touching only what you need to touch and remembering to tell a police officer if you move or touch anything; using the telephone only if the police have given permission; moving the patient only if the patient is in danger or must be moved in order to provide care; observing and documenting anything unusual at the scene; not cutting through holes in the patient’s clothing that may have been caused by bullets or stabbing weapons, if possible; and asking the rape patient not to change clothing, use the bathroom, or take anything by mouth.

8. It's essential that you familiarize yourself with the requirements in your state, but EMTs are commonly required to report the following situations: suspected abuse of children or the elderly; injuries that may have resulted from a crime, including sexual assault; drug-related injuries (which is different from drug addiction); suspected infectious disease exposure; use of patient restraints to treat or transport patients against their will; cases in which a patient appears mentally incompetent or intoxicated; attempted suicides; and dog bites.

CHAPTER 4 • Documentation

IN REVIEW

1. The documentation you collect has a variety of important uses. Documentation ensures continuity of care for the patient throughout his need for medical attention. In addition, the prehospital care report becomes part of the patient’s permanent hospital record. It is typically used to aid in administrative functions such as insurance and billing and may be used to provide statistics regarding the EMS service itself, such as response times and number and types of patients served. Finally, the prehospital care report may be used later as a legal document in litigation, and for data gathering as part of educational and research projects.

2. The most traditional format for the PCR is the written report. This format usually combines check boxes, write-on lines, and an area for writing a fuller narrative account of the patient contact. An alternative format widely accepted and used is the computerized report, which varies widely in style and may be entered via sheets scanned into a computer, handheld device, or laptop computer.

3. The U.S. Department of Transportation has made an effort to standardize the information collected on PCRs by creating the minimum data set. It is hoped that such standardization will allow more meaningful comparison and analysis of data from system to system and lead to a high general level of patient care across the nation.

4. “Accurate and synchronous clocks” means that all elements of an EMS system should use clocks or timekeeping devices that are accurately set and agree with each other. This is important because accurate timekeeping helps gather accurate medical information and can be critical if administrative issues or legal questions ever arise.

5. Pertinent negatives are signs and symptoms that might be expected, based on the chief complaint, but that the patient denies having. By noting the absence of pertinent signs and symptoms, you’ll provide a fuller picture of the patient’s condition.

6. When you encounter a patient who refuses treatment, first attempt to perform as much of an assessment as possible. In order to refuse care, the patient must be deemed competent. The patient must be informed of and fully understand all potential risks and consequences involved in refusing treatment or transport, up to and including the possibility of death when appropriate. The patient must be able to explain back these consequences to you. Consider consulting medical direction. The patient must sign an official “release from liability” form—or a patient’s witnessed refusal to sign the form must be obtained—and must be included with a full documentation of the case. Have a witness, preferably a family member or neutral person, sign the report. Before leaving the scene, encourage the patient to seek help if certain symptoms develop and explain that you or another EMT crew would be happy to return should the patient change his mind. Document all assessment findings, all care given, and the explanation given to the patient regarding the consequences of refusing care. Document if the patient refused to allow you to complete any or all of your assessment.

7. If it wasn’t written down, it wasn’t done’ means that no one, including emergency department staff, will know what was done if it wasn’t recorded, and you won’t be able to prove it was done, especially in a court of law. “If it wasn’t done, don’t write it down” means don’t falsify information on a report form.

8. Correct errors on a paper PCR by drawing a single horizontal line through the error, initialing it, and writing the correct information beside it. Do not erase or write over the error. Most electronic PCR formats provide a method to amend the report if an error is discovered.

9. Because of the volume of patients encountered by EMS during a multiple-casually incident, there may not be enough time to complete a standard PCR before turning to the next patient. EMTs may instead use temporary abbreviated forms, such as triage tags, that contain basic medical information. In MCI situations, PCRs will usually be less detailed than those of more typical, single-patient runs.

10. EMTs might be expected to file a special report with an agency or local authority outside the usual health care network in specific circumstances such as suspected abuse of a child or an elderly person, possible exposure to an infectious disease, cases of injury to an EMT team member, or any circumstances that the EMT deems unusual.

CHAPTER 5 • Communication

IN REVIEW

1. EMS communications are typically composed of a base station, mobile radios (transmitter/receivers), portable radios (transmitter/receivers), repeaters, digital equipment (encoders, decoders, and mobile data terminals), and cell phones.

2. Repeaters receive transmissions from a relatively low-powered source such as a mobile or portable radio and rebroadcast them at another frequency and a higher power. Repeaters make communications possible in EMS systems that cover a wide area or where the terrain makes transmission and reception of signals difficult.

3. The Federal Communications Commission (FCC) has jurisdiction over all radio operations nationally, including those in EMS systems. They license base stations, assign radio call signs, approve equipment for use, limit transmitter output, assign radio frequencies, and monitor field operations. The FCC also sets regulations to limit interference with emergency radio broadcasts and bars obscenity and profanity in radio communications.

4. Communicate with dispatch at the following points: (1) to acknowledge the call information was received; (2) to advise dispatch when the unit is en route to the call; (3) to estimate your time of arrival at the scene while
en route and/or to report any special road conditions or unusual delays; (4) to announce your arrival on the scene (some systems must additionally report when they reach the actual patient); (5) to announce the unit’s departure from the scene and announce the destination, number of patients transported (if more than one), and estimated time of arrival to the destination/hospital; (6) to announce your arrival at the receiving hospital or other facility or if you were meeting at a rendezvous point, announce your arrival there; (7) to announce that you are clear and available for another assignment after the patient has been transferred; (8) to announce that you are leaving the hospital and are on your way back to the station; and (9) to announce your arrival back at the station.

5. After receiving an order from medical direction to administer a medication or follow a procedure with a patient, repeat the order back word for word. This applies to things you’re told not to do as well. If you do not understand an order, ask that it be repeated and then repeat it back to medical direction word for word. Orders that appear inappropriate should be questioned in case a misunderstanding may have occurred.

6. Report the following information to the receiving facility while en route with the patient: your unit’s identification number and level of service (BLS or ALS), patient’s age and sex, chief complaint, pertinent history including scene assessment and mechanism of injury, major past illnesses, patient’s mental status, baseline vital signs, pertinent findings of the physical exam, description of the care you’ve provided, the patient’s response to care, the patient’s current condition, and ETA.

7. Once at the facility and turning the patient over to staff in the receiving facility, report the following information during your oral report: the patient’s chief complaint, vital signs taken en route, treatment given and response to it, and pertinent history not included in the earlier radio report.

8. Making eye contact with the patient when you are speaking communicates your interest and concern. But be aware that some cultures consider direct eye contact as impolite or aggressive. You may have to modify your behavior if you note that the patient is reluctant to make eye contact with you.

9. The way you position yourself in relation to your patient will impact how you are perceived. Use your arms and body position effectively by approaching with open arms, open hands, and relaxed shoulders to convey a message of concern, confidence, safety, and care. Position yourself at the same level as your patient unless the patient seems hostile or aggressive; you may find it preferable to keep your eye level above his to assert your authority. Be sensitive to the power of touch and the comforting, reassuring message it can send. Remember that you have to be comfortable, though, so as to not come across using it as a gimmick.

10. If the patient is deaf but indicates he can communicate with you through American Sign Language (ASL), check to see if relatives or bystanders can interpret for you. Also consider writing notes on a pad to communicate.

11. Communication begins when an individual, the sender, uses words and symbols to originate a message. Converting information into a message is called encoding. Once a message is encoded, it is sent to another individual, the receiver, to be decoded—a process of translation and interpretation. The closer that the decoded message matches the meaning of the encoded message, the more effective the communication can be. We refine the message through a process of feedback, and this exchange of messages and feedback is then repeated throughout the communication process.

12. Some categories of patients will require you to make adjustments to your communication methods in order to be most effective. When addressing a patient from a different culture, begin by introducing yourself as you want to be called and remember to pay careful attention to the space between yourself and the patient. When communicating with elderly patients, be prepared to take extra time; never appear brusque or impatient with helping an elderly patient. Make sure you always treat them with respect and compassion. Communicating with children also requires extra time, patience, and effort. Have the parents present to aid in communication and position yourself at eye level with the patient to avoid towering overhead. Give clear explanations and use simple language.

13. Culture is the thoughts, communications, actions, and values of racial, ethnic, religious, or social groups. It impacts how information is received, how illness is viewed, and what treatments are preferred by each individual patient.

14. One hazard of interviewing patients is that they may be hostile toward you. They may not want your help or may be under the influence of street drugs or alcohol. Attempting to establish a good rapport and maintaining a professional and nonthreatening demeanor may help in gaining their cooperation. But ultimately, your safety is paramount and you should use law enforcement help if necessary in case the patient becomes violent.

15. Using questions to obtain specific information from a patient is an important part of the interview because different types of questions promote different responses. First, be sure to ask only one question at a time and give the patient enough time to respond. Listen to the answer before asking another question; sometimes we’re so busy thinking about our next question that we forget to listen to the last answer. Asking “open-ended” questions will provide you with the most information, compared to a closed or direct question. For example, asking “What seems to be the problem?” (open-ended question) versus “When did the pain begin?” (closed question) will generate very different answers from the patient.

16. Common responses in communication are clarification, asking more questions to clarify the meaning of a message; summary, summarizing a patient’s messages in order to better understand what they mean; explanation, presenting information in a way the patient can understand; silence (sometimes what we don’t say is more powerful than what we do say); reflection, letting the patient know that you understand what he said or feels; and empathy, the ability to understand and recognize someone else’s state of mind or feelings.

17. Building a good rapport with your patient starts with first impressions, your physical appearance, and professional dress. Upon approaching the patient, do so respectfully and err on the side of formality with older people. Introduce your team and emphasize that you are there to help while gaining consent. Be prepared if the patient initially denies that there is anything wrong and approach confidently, competently, and compassionately. Make and maintain eye contact, respect the patient’s privacy, be aware of your body position, and work to control the physical environment and the presence of family members where appropriate. Be honest, be courteous, and actively listen.

**CHAPTER 6 • Lifting and Moving Patients**

**IN REVIEW**

1. Four principles for safe lifting include (1) keeping the weight of the object as close to your body as possible; (2) using your leg, hip, and gluteal (buttocks) muscles plus
contracted abdominal muscles to move an object; (3) "stacking" your shoulders, hips, and feet and moving them as a unit; and (4) reducing the height or distance through which the object must be moved.

2. To perform a power grip, your palm and fingers should come in complete contact with the object and your fingers should be bent at the same angle. A power grip should always be used for getting the maximum force from your hands when lifting or moving an object.

3. To perform the power lift, place your feet shoulder width apart and turn them out slightly; bend your knees and tighten the muscles of the abdomen; keep your back straight with your head facing forward in a neutral position; straddle the object, keeping feet flat with weight evenly distributed and just forward of the heels; place your hands about 10 inches apart; and use a power grip to lift. Your back should remain locked in as the force is driven through the heels and arches of your feet. Your upper body should come up before the hips. A power-lift technique helps prevent injury while lifting and protects the patient with a safe and stable move. Use it whenever possible. It is also the lift of choice for rescuers with weak knees or thighs.

4. Patients are generally moved in three ways. First, the "emergency move" is used when there is immediate danger to the patient or rescuer. Second, the "urgent move" is used when the patient is suffering from an immediate threat to life and must be moved quickly and transported for care. Finally, a "nonurgent move" is used when no immediate threat to life exists and the patient can be moved in a normal manner when ready for transport.

5. Guidelines and safety precautions for carrying patients and equipment include: keep the weight as close to your body as possible; keep your back in a locked-in position; do not hyperextend your back; keep shoulders, hips, and feet (base) in alignment; refrain from twisting; strenuous effort should be sustained for no longer than 1 minute; and whenever possible, carry patients and equipment on devices that can be rolled.

6. (a) Direct ground lift: two or three rescuers should line up, kneeling on one knee, on the same side of the patient. The first rescuer should cradle the patient's head by placing one arm under the patient's neck and shoulder and then place his other arm under the patient's lower back. The second rescuer should place the patient's arms on his chest and then place one arm under the patient's knees and one arm above the buttocks. A third rescuer, if available, places both arms under the waist. The other two rescuers then slide their arms either up to the midback or down to the buttocks. On signal from the first rescuer, they should lift the patient to their knees and roll the patient in toward their chests. On signal from the first rescuer, they should stand and move the patient to the stretcher or other patient-carrying device. (b) Extremity lift: the first rescuer kneels behind the patient at the patient's head and places one hand under each of the patient's shoulders until he can slip his hands through under the patient's arms to reach around and grasp the patient's wrists. The second rescuer slips his hands under the patient's knees. Both rescuers move up to a crouching position, keeping their backs straight and heads in neutral alignment. On signal from the first rescuer, they stand up simultaneously and move the patient. (c) Direct carry: position the stretcher perpendicular to the patient's bed. The first rescuer slides an arm under the patient's neck and cups the patient's shoulder. The second rescuer slides a hand under the patient's hips and lifts slightly so that the first rescuer can slide an arm under the patient's back. The second rescuer then places an arm under the hips and calves. The crew then slides the patient to the edge of the bed, lifts and curls the patient to their chests, and rotates the patient gently onto the stretcher. (d) Draw sheet method: first loosen the bottom sheet of the bed and position the stretcher next to the bed. Reach across the stretcher and grasp the sheet firmly at the patient's head, chest, hips, and knees. Slide the patient gently onto the stretcher.

7. The stair chair is recommended for carrying a patient up or down stairs. The spotter directs the move; for example, warning the rescuers of the number of stairs ahead. A newer model, the tracked stair chair, allows the chair to glide down stairs with less effort and eliminates the need to lift the chair while moving it down steps.

8. In a narrow or confined space, a portable stretcher, a stair chair, a backboard, a scoop stretcher, or a flexible stretcher may be used.

9. When reaching during a log roll, it is important to lean from the hips and not from the waist. Keep your back straight and use your stronger shoulder muscles to assist you whenever possible.

10. Whenever possible, it is safer to push rather than pull. However, if an object must be pulled, keep the load between your shoulders and hips close to your body. As always, try to keep your back straight and bend your knees slightly. When pushing, do so from the areas between your waist and shoulders. Always avoid pushing or pulling any object that is overhead.

CHAPTER 7 • Anatomy, Physiology, and Medical Terminology

IN REVIEW

1. Normal anatomical position: the patient is facing forward, with arms down at the sides and palms forward. Supine: the patient is lying face up on his back. Prone: the patient is lying face down on his stomach. Lateral recumbent: the patient is lying on his left or right side. Fowler's: the patient is lying on his back with the upper body elevated at a 45° to 60° angle. Trendelenburg: the patient is lying on his back with the legs elevated higher than the head and body on an inclined plane (head down, legs up).

2. Midline: drawn vertically through the middle of the patient's body, beginning at the top of the head and continuing down through the nose and the navel and to the ground between the legs. Midclavicular line: refers to the center of each of the collarbones (clavicles) and extends from the center of either collarbone down the anterior thorax. Midaxillary line: refers to the center of the armpit (axilla) and extends from the middle of the armpit to the ankle. Plantar: refers to the sole of the foot. Palmar: refers to the palm of the hand. Anterior: toward the front; the opposite is posterior, which means toward the back. Superior: toward the head or above the point of reference; the opposite is inferior, which means toward the feet or below the point of reference. Dorsal: toward the back or backbone (spine); the opposite is ventral, which means toward the front or belly (abdomen). Lateral: refers to the left or right of the midline, or away from the midline; the opposite is medial, which means toward the midline or center of the body. Distal: is distant or far from the point of reference; the opposite is proximal, which means near the point of reference.

3. The musculoskeletal system consists of a bony framework held together by ligaments that connect bone to bone, layers of muscles, tendons that connect muscles to bones, and various other connective tissues. The skeletal system generally consists of the skull, spinal column, thorax, pelvis, and the upper and lower extremities. It functions to give the
body its shape, to protect vital internal organs, to allow for movement, and to store minerals and produce blood cells. Body movements occur as a result of muscles contracting in coordination with nerve impulse stimulation.

4. Airway structures such as the nose, mouth, pharynx, epiglottis, larynx, trachea, bronchi, lungs, and diaphragm facilitate movement of air into and out of the lungs. Oxygen from the air comes into close association with small blood capillaries in lung tissue. Under normal conditions, this process facilitates blood oxygenation and the removal of carbon dioxide from blood and also serves as a buffer to maintain normal acid-base balance.

5. The circulatory system is composed of the heart, blood vessels, and blood. It is a closed system that transports blood to all parts of the body. Blood brings oxygen, nutrients, and other essential chemical elements to tissue cells, and removes carbon dioxide and other waste products resulting from cell metabolism. In addition, the circulatory system functions to buffer acids and bases in the body, provides a mechanism to deliver immune cells and other substances to fight off infection, and contains substances important in blood clotting.

6. The central pulse points are the carotid artery at either side of the neck and the femoral artery in the crease between the abdomen and the thigh. The peripheral pulse points include the radial artery at the point proximal to the thumb on the wrist; the brachial artery on the medial aspect of the arm, midway between the shoulder and the elbow; the posterior tibial artery on the posterior surface of the medial malleolus or ankle bone; and the dorsalis pedis artery on the anterior surface of the foot on the big toe side.

7. Shock, or hypoperfusion, is the insufficient supply of oxygen and other nutrients to some of the body’s cells and the inadequate elimination of carbon dioxide and other wastes that result from inadequate circulation of blood. It is a state of profound depression of the vital processes of the body.

8. The nervous system is divided into two main systems: the central nervous system, which includes the brain and spinal cord, and the peripheral nervous system, which includes the sensory and motor nerves. It is further subdivided into functional divisions called the voluntary and autonomic nervous systems which enable the individual to be aware of and to react to the environment and coordinate responses to stimuli to keep body systems working together. The nervous system generally functions to control and maintain a conscious and aware state, transmit sensory stimuli to the brain for interpretation, control motor function and transmit motor impulses to muscle for voluntary and involuntary movement, and control body functions through the autonomic nervous system.

9. The endocrine glands include the thyroid, parathyroids, adrenals, ovaries, testes, islets of Langerhans, and pituitary. The endocrine system is made up of ductless glands that secrete hormones, which are chemical substances that have effects on the activity of certain organs. Hormones are carried by the bloodstream to all parts of the body and influence critical body functions like reproduction, metabolism, and behavior.

10. The skin has three basic layers: the epidermis, the dermis, and the subcutaneous layer. All the various tissues, organs, and systems that make up the human body are separated from the outside environment by the skin, which is the largest organ in the body. The integumentary system functions to protect the underlying organ system from the environment, bacteria, and other foreign organisms. It also regulates temperature of the body; serves as a receptor for heat, cold, touch, pain, and pressure; and aids in the regulation of water and electrolytes.

11. The digestive system is composed of the alimentary tract (the passage through which food travels) and the accessory organs (organs that help prepare food for absorption and use by tissues of the body). The primary organs of the digestive system are the stomach, pancreas, liver, spleen, gallbladder, small intestine, and large intestine. The main functions of the digestive system are to ingest and carry food so that absorption can occur and waste can be eliminated.

12. The urinary or renal system consists of two kidneys, which filter waste from the bloodstream and help control fluid balance; two ureters, which carry the wastes from the kidneys to the bladder; one urinary bladder, which stores the urine prior to excretion; and one urethra, which carries the urine from the bladder out of the body. The primary function of the renal system is to filter and excrete wastes from the blood. The kidneys also play an important role in blood pressure regulation and serve as a buffer to maintain normal acid-base balance in the body.

13. The reproductive system of women and men consists of complementary organs that can function to accomplish reproduction. The reproductive system of the male includes two testes, a duct system, accessory glands (including the prostate gland), and the peris. The testes are responsible for the production of testosterone, the primary male hormone. The female reproductive system consists of two ovaries, two fallopian tubes, the uterus, the vagina, and the external genitals. The ovaries produce and secrete estrogen and progesterone, the primary female hormones. The male's sperm and the female's ovum contribute the genes that determine the hereditary characteristics of an offspring. Combination of a single sperm with a single ovum forms a fertilized ovum, which can grow into an embryo, then into a fetus, and finally into a newborn baby.

CHAPTER 8 • Pathophysiology

IN REVIEW

1. Aerobic metabolism occurs within the cell in the presence of oxygen and results in the breakdown of molecules, such as glucose, to give off energy. The energy is used by the cell to carry out critical functions. The by-product of this reaction is heat, carbon dioxide, and water. Anaerobic metabolism also results in the breakdown of glucose but without the availability of oxygen. Energy is still produced but the by-product of this reaction is lactic acid, which can be disruptive and damaging to cells if it is allowed to accumulate.

2. Ambient air is composed of a number of different gases, namely nitrogen (78%), oxygen (21%), argon (0.9%), and carbon dioxide (0.03%). FiO2 is defined as the “fraction of inspired oxygen” and so a patient breathing ambient air, or 21% oxygen, would have an FiO2 of 0.21. FDo2 is defined as the “fraction of delivered oxygen” such as may be administered through a ventilation device to a patient who is not able to breathe adequately on his own. For example, ventilating a patient with a bag-valve mask connected to 15 lpm could achieve an FDo2 in the range of 0.95 to 0.98.

3. The concentration of oxygen in the ambient air determines the amount of oxygen molecules that end up in the alveoli and are available for gas exchange. A lesser amount of oxygen in the ambient air means less oxygen reaches the blood and less is available for cells to use during metabolism.

4. An airway obstruction can occur at several anatomical levels in the upper airways. The nasopharynx has the potential to be obstructed by blood, secretions, vomitus, tumor swelling, bone fragments, or foreign bodies. The oropharynx and pharynx can become obstructed by the tongue, tissue swelling, hematomas, blood, vomitus, and foreign bodies. In the
larynx, an obstruction can occur from laryngeal spasm or structural failure such as in a fracture to the larynx.

5. The mechanical process of inhalation is primarily facilitated by the diaphragm, which contracts and moves slightly downward. In addition, the external intercostal muscles contract and lift the rib cage upward and outward. Together, these two effects expand the thorax and cause the pressure inside the chest to drop. Air naturally rushes in and inhalation occurs. By comparison, exhalation tends to be a passive process. The diaphragm and external intercostal muscles relax, the thorax decreases in size, the pressure in the chest cavity decreases, and air naturally rushes back out, causing an exhalation. We can, however, use certain accessory muscles to facilitate forced inhalation and exhalation.

6. The Boyle law simply says that the volume of gas is inversely proportionate to the pressure. In other words, increasing the size of a closed container will decrease the internal pressure inside the container. Likewise, decreasing the size of a container will increase the pressure inside. As it relates to ventilation, the Boyle law tells us that when the diaphragm contracts to increase the size of the chest cavity, the pressure inside will decrease. The result is that air will naturally rush in to equalize the pressure. This facilitates ventilation.

7. It is generally accepted that there are three respiratory control centers in the brainstem: the dorsal respiratory group, the ventral respiratory group, and the pontine respiratory center. The dorsal respiratory group (DRG) and ventral respiratory group (VRG) are located in the medulla oblongata in an area referred to as the medulla respiratory center. The pontine respiratory center, also referred to as the pneumotaxic center, is located in the pons in the brainstem. These centers receive sensory input and transmit impulses to the skeletal muscles controlling ventilation, causing them to either contract or relax, depending on the impulse. The ventral respiratory group (VRG) is a column of neurons that are located in the anterior portion of the medulla. The VRG contains both inspiratory and expiratory neurons that are responsible for initiating neural impulses that stimulate the external intercostal muscles and the diaphragm, causing them to contract, which results in inhalation. The dorsal respiratory group (DRG) located posterior to the VRG, relays its sensory information to the VRG to provide further input on depth and rate of respiration. However, the VRG is solely responsible for sending the nerve impulses to the spinal cord to be transmitted to the diaphragm and external intercostal muscles causing them to contract. The VRG and DRG function in every respiratory cycle, whether during quiet breathing or during forced breathing with the accessory muscles involved. In a typical respiratory cycle, the VRG inspiratory (VRGI) neurons stimulate the external intercostal muscles and diaphragm for 2 seconds, resulting in inhalation. The VRG expiratory (VRGE) neurons along with the pontine respiratory group inhibits the VRGI (inspiratory neurons), causing the nervous impulse transmission to the diaphragm and external intercostal muscles to cease for a total of 3 seconds. With the VRG, shut off, the external intercostal muscles and diaphragm relax, causing exhalation to occur. After 3 seconds, the VRG, becomes active, sending impulses to the respiratory muscles that cause inhalation to occur once again. During the entire time, the DRG is sending input to the VRG in regard to depth and rate of respiration. The process continues to repeat itself. With a 2 second on and 3 second off rhythm, it produces an average respiratory rate of 12 per minute in the adult patient.

8. The central chemoreceptors, located in the brainstem, are very sensitive to changes in carbon dioxide (CO₂) and pH. These two factors together give us a sense of the acid levels in the body, especially in the blood. If these chemoreceptors detect an increase in CO₂ or acid, they stimulate an increase in rate and depth of respiration to blow off more CO₂ thereby eliminating excess acid. Likewise, any decrease in CO₂ or acid will have the opposite effect. The peripheral chemoreceptors are located in the arch of the aortic vessel and the carotid arteries. These chemoreceptors are also sensitive to CO₂ and pH but are more sensitive to oxygen levels in arterial blood. As blood oxygen levels decrease, the peripheral chemoreceptors trigger the respiratory center to increase the rate and depth of respiration. But it takes a significant drop in oxygen levels for these to be triggered. Stimulation by both the central and peripheral chemoreceptors together has a greater influence on increasing the rate and depth of ventilation than stimulation from only one alone.

9. The ventilation/perfusion ratio describes the amount of alveolar ventilation compared to the amount of capillary perfusion supplying the alveoli. Ideally, each alveolus would be supplied with an adequate amount of ventilation and a matching amount of blood flow so that gas exchange across the alveolar-capillary membrane would be maximized. Even under normal conditions, this isn’t always the case and capillary perfusion typically exceeds alveolar ventilation. However, any injury or disruption on either side can significantly affect the ratio. For example, if the patient has difficulty breathing and ventilation is disrupted, cellular hypoxia may result even though capillary perfusion may be normal. Likewise, if the patient is bleeding and capillary perfusion is hampered, cellular hypoxia may result even though the patient had normal ventilation and was breathing effectively. In general, hypoxia results from a ventilation or perfusion disturbance.

10. Oxygen must be continuously delivered by the blood to the cells for normal cellular metabolism to occur. The vast majority of oxygen (~98%) is carried in the blood attached to hemoglobin, which are protein molecules found on the surface of red blood cells. Each hemoglobin molecule can carry up to four oxygen molecules. A small amount of oxygen (~2%) is simply dissolved in the plasma portion of blood.

11. Carbon dioxide is a by-product of metabolism that must be eliminated from the body. The blood carries it in a manner so that it can be eventually removed by the lungs. The majority of CO₂ (70%) is carried in the form of bicarbonate, which is formed when CO₂ combines with water and undergoes a chemical reaction. The remaining CO₂ (23%) is carried just like oxygen and is attached to hemoglobin, or dissolved in the plasma (7%).

12. Blood is composed of plasma and formed elements. The plasma, which represents 55% of blood volume, is primarily water and plasma proteins. Plasma functions to suspend the formed elements. The plasma proteins help maintain fluid balance, provide defense through antibodies, and assist in the coagulation of blood by providing clotting factors. The formed elements, which represent 45% of blood volume, are primarily cells: red blood cells, white blood cells, and platelets. Red blood cells carry oxygen, white blood cells protect against infection and eliminate dead and injured cells and debris, and platelets play a major role in blood clotting and the control of bleeding. Platelets are actually fragments of cells and are not considered actual blood cells.

13. Hydrostatic pressure is the force inside the vessel or capillary bed generated by the contraction of the heart and blood pressure. It’s a pressure that wants to naturally push fluid out of the vessel or capillary and into the interstitial space. Plasma oncotic pressure helps keep fluid inside the vessel because of the force created by the large plasma proteins in blood that attract water and other fluid substances.
The balance between these two pressures must be maintained for equilibrium of fluid balance.

14. Cardiac output is defined as the amount of blood ejected by the left ventricle per minute. It is determined by heart rate and stroke volume; if either factor were to rise or fall, the cardiac output would have a commensurate change. Systemic vascular resistance is defined as the resistance of blood flow through a vessel. Smaller-diameter vessels have more resistance inside the vessel, and larger-diameter vessels have less resistance inside the vessel. Because blood vessels have the capacity for vasconstriction (decreasing in size) and vasodilation (increasing in size), systemic vascular resistance may change depending on conditions. Vessel size and systemic vascular resistance influence the blood pressure of the patient. Specifically, systolic blood pressure is a measure of the cardiac output, and diastolic blood pressure is a measure of the systemic vascular resistance.

15. The sympathetic nervous system causes vasconstriction, which increases vessel resistance and pressure. Cardiac output and blood pressure would rise. Parasympathetic stimulation leads to vasodilation and a reduction in resistance and pressure. Cardiac output and blood pressure would fall.

16. Microcirculation is the flow of blood through some of the body’s smallest vessels: the arterioles, capillaries, and venules. This is where the exchange of gases, nutrients, and wastes occurs. Blood pressure and perfusion are regulated here through a number of factors including local, neural, and hormonal influences.

17. Baroreceptors are stretch-sensitive receptors located in the arch of the aorta and the carotid sinuses that detect changes in blood pressure. As pressure inside the vessel changes, the stretch receptors send impulses to the cardioregulatory center (controls heart rate and force of contraction) and the vasomotor center (controls vessel size and resistance) to regulate blood pressure.

18. Chemoreceptors are sensitive to the levels of oxygen, carbon dioxide, and pH (acid). If the chemoreceptors sense low levels of oxygen or high levels of CO₂ or acid, they will trigger the sympathetic nervous system to increase heart rate, contractility, and vasconstriction. All of these factors will increase blood pressure which will improve oxygen delivery and help eliminate more carbon dioxide.

CHAPTER 9 • Life Span Development

IN REVIEW

1. Infancy is the stage from birth to 1 year of age. As an infant ages, the heart rate becomes lower and the systolic blood pressure becomes higher. A key physiological characteristic at this stage is the infant’s head size, which is 25 percent of body weight. Over the 12 months, infants progress rapidly physiologically from reflex-oriented activities like sucking and rooting to crawling and nearly walking. Psychosocially, infants’ relationships primarily revolve around their parents and caregivers. Toddlers are considered the stage between 12 and 36 months in age, and preschoolers are considered the stage between 3 and 5 years in age. Like an infant, their heart rate and respiratory rate tend to decrease while their systolic blood pressure increases. Muscle mass increases—they become leaner—but weight gain slows down because of their level of activity. Patients in this age range have started to use language as their sole form of communication and often take language literally. School-age children are between 6 and 12 years of age. Their vital signs widen in range. Children in this age group are able to read and write and have developed better capacity to interact with adults and children outside their immediate family. Adolescence is the age range from 13 to 18 years. Vital signs tend to have a wide range, but they are becoming more like an adult’s. Most adolescents experience rapid growth spurts and go through puberty when their sexual organs mature and secondary sexual characteristics appear. Adolescents desire to be treated as adults even though most are not capable of making their own medical decisions. Body image and privacy may be a big concern in this age group. In early adulthood, the age range between 19 and 26, all body systems are operating at optimal performance. Because of their optimal physical condition, accidents are the leading cause of death in this age group. Adults entering this stage take on more responsibility and become more independent. Middle adulthood is the stage between 41 and 60 years of age. Body systems begin to experience more changes as a result of disease and lifestyle decisions. In late adulthood, age 61 and older, vital signs are often dependent on the patient’s physical and health status. Body systems continue to change and become less efficient than when they were at their peak. Independence may become an issue with many people in this age range turning to communities where daily living support is available.

2. The table below shows the vital signs for different age groups.

<table>
<thead>
<tr>
<th>Stage</th>
<th>Heart Rate</th>
<th>Respiratory Rate</th>
<th>Systolic BP</th>
<th>Body Temp</th>

<td>Use cutlery appropriately</td>
</tr>
<tr>
<td>Say “mama” and “dada”</td>
<td>Recognize name, faces, voices</td>
<td>Count ten or more objects</td>
</tr>
<tr>
<td>Finger feed</td>
<td>Sort objects by shape or color</td>
<td>Trace and draw pictures</td>
</tr>
</tbody>
</table>

4. In infants, toddlers, and preschoolers, physical changes often lead to confidence that results in achieving milestones like crawling, walking, and talking. School-age and adolescent patients undergo physical changes like puberty that may lead to self-consciousness, body image, and an interest in sex. During adolescence, most of the body systems continue to change and become less efficient than when they were at their peak. As we age, we become more concerned about our health and the potential for a loss of independence.
**CHAPTER 10 • Artificial Ventilation, and Oxygenation**

**IN REVIEW**

1. The two manual methods used to open an airway are the head-tilt, chin-lift and the jaw-thrust maneuver. Use the head-tilt, chin-lift when there is no suspicion of spinal injury. Tilt the head backward as the chin and jaw are lifted. Use the jaw-thrust maneuver when spinal injury is suspected. The patient's neck must be maintained in a neutral, in-line position. Only the mandible (jaw) is moved up and forward without extending the head or moving the neck.

2. The two airway adjuncts are the oropharyngeal and the nasopharyngeal airway. Both are used to prevent the tongue from blocking the airway. The oropharyngeal airway cannot be used when the patient has a gag reflex. The nasopharyngeal airway can often be tolerated by a patient with reduced responsiveness (who needs assistance in maintaining a patent airway) but who still has a gag reflex.

3. Assess for adequate breathing by the “look, listen, feel, and auscultate” approach. “Look” at the patient’s general appearance, respiratory rate, chest rise and fall, and presence of retractions; “listen” for patient speech and air movement in and out of the nose and mouth; “feel” for air escaping from the nose and mouth; and “auscultate” the patient’s breath sounds to determine if they are equal and present bilaterally.

4. A patient is breathing adequately when he has (1) a normal respiratory rate, (2) clear and equal breath sounds bilaterally, (3) adequate air movement heard and felt from the nose and mouth, and (4) good chest rise and fall with each ventilation.

5. Signs of inadequate breathing include abnormal work of breathing (retractions or nasal flaring), abnormal breath sounds (stridor or wheezing), reduced minute ventilation (decreased tidal volume or inadequate respiratory rate), inadequate chest wall movement (paradoxic movement or splitting), irregular patterns, and rapid respiratory rate with clinical improvement.

6. Methods of artificial ventilation available to the EMT are mouth-to-mask; bag-valve mask (BVM) operated by two people; flow-restricted, oxygen-powered ventilation device (manually triggered); and bag-valve mask (BVM) operated by one person.

7. In a patient with a suspected spinal injury, in-line stabilization must be established and maintained at all times while ventilating the patient.

8. Indications that the patient is being ventilated adequately are that the rate is sufficient, the tidal volume is consistent and causes the chest to rise adequately, adequate exhalation occurs without any air being trapped, the heart rate returns to normal, and color improves.

9. The appropriate procedure for initiating oxygen administration is as follows: (1) Check the cylinder to be sure it contains oxygen and remove the protective seal on the tank valve. (2) Quickly open, and then shut, the cylinder valve for 1 second to remove any dust or debris from the valve assembly. (3) Place the yoke of the regulator over the valve and align the pins, being sure the regulator washer is present and in the proper place; hand tighten the T-screw on the regulator. (4) Slowly open the main cylinder valve about one-half turn to charge the regulator and check the pressure gauge to be sure an adequate amount of oxygen is available. (5) Attach the oxygen mask or nasal cannula tubing to the nipple of the regulator. (6) Open the regulator flowmeter control and set the oxygen flow at the desired liters per minute. (7) With the oxygen flowing, apply the oxygen mask or nasal cannula to the patient.

10. The appropriate procedure for terminating oxygen administration is as follows: (1) Remove the oxygen mask or nasal cannula from the patient. (2) Turn off the oxygen regulator flowmeter control, and then turn off the cylinder valve. (3) Open the regulator valve to allow the oxygen trapped in the regulator to escape until the pressure gauge reads zero, then turn off completely the regulator flowmeter control.

**CHAPTER 11 • Baseline Vital Signs, Monitoring Devices, and History Taking**

**IN REVIEW**

1. The components of a standard vital sign assessment include checking breathing, pulse, skin signs, pupils, and blood pressure. Pulse oximetry is sometimes considered the sixth vital sign. In a stable patient, vital signs should be taken every 15 minutes and as often as necessary to ensure proper care. In an unstable patient, vital signs should be taken every 5 minutes. Reassess vital signs immediately following every medical intervention regardless of how soon it follows your previous assessment.

2. Breathing is assessed by observing the patient’s chest rise and fall. Breathing rate is determined by counting the number of breaths in a 30-second period and multiplying by two. Quality of breathing can be assessed while the rate is being counted. The normal respiratory rate range for an adult patient at rest is 8–24/minute, 15–30/minute for children, 25–50/minute for infants, and 30–60/minute for newborns.

3. Normal breathing involves average chest wall motion where the chest expands out at least 1 inch; accessory muscles of the abdomen are not used to breathe; the rate is within normal limits, and inhalations and exhalations are about the same length. In shallow breathing, there is only slight chest or abdominal wall motion, indicating inadequate tidal volume. In labored breathing, there may be grunting and stridor, nasal flaring, and gasping. The patient may be using accessory muscles, indicating extra work of breathing. In infants and children having abnormal breathing, there is often retraction of the skin around the collarbone and between the ribs. Noisy breathing typically presents with audible snoring, wheezing, gurgling, or crowing.

4. A radial pulse should be assessed in all patients 1 year or older. Use the brachial pulse in patients younger than 1 year because of the difficulty in locating the carotid pulse. When a peripheral pulse cannot be obtained, take the pulse at the carotid artery, but never assess it on both sides at the same time and avoid excessive pressure when palpating it in elderly patients.

5. To take a pulse, position the patient in a sitting or lying position and use the tips of two or three fingers—not the thumb—to palpate the artery, and count the number of beats in a 30-second period and then multiply by two. The average resting range is 60–80 beats/minute for an adult, 60–105 beats/minute for an adolescent, 60–120 beats/minute for a school-age child, 80–150 beats/minute for a preschooler, and 120–150 beats/minute for an infant.

6. Check for skin color in the nail beds, oral mucosa, and conjunctiva. In infants and children and in dark-skinned people, check the palms of the hands and the soles of the feet. Normally, skin color in these areas is pink. Abnormal colors include pale, blue-gray, red, yellow, and black-and-blue mottling.

7. To assess the pupils, briefly shine a light into the patient’s eyes and look for pupil size, equality, and reactivity. Normally, both pupils are the same size and constrict equally in response to light. Abnormal pupils may be
dilated (too large) or constricted (too small), or unequal in size, and neither or only one pupil may react to light.

8. Whether you’re taking a blood pressure by palpation or auscultation, you’ll generally use the same procedure for both methods such as choosing the proper size cuff, placing it, positioning the patient’s arm, and inflating/deflating the cuff. To palpate a blood pressure, inflate the cuff while palpating the radial pulse until you can no longer feel it. Continue to inflate it to 30 mmHg above that point. Slowly deflate the cuff and note when the radial pulse returns. This correlates to the systolic pressure. To auscultate a blood pressure, place the head of your stethoscope over the brachial artery, inflate the cuff, and listen for the return of the first sound. This is the systolic pressure. Continue releasing the air and note when you hear the last sound. This is the diastolic pressure. A normal blood pressure range for an adult male can be determined by adding the patient’s age to 100. A normal range for the diastolic pressure is 60-85 mmHg. An adult female’s blood pressure is typically 8-10 mmHg lower than an adult male.

9. Pulse oximetry is a method of detecting hypoxia by measuring oxygen saturation levels in the blood. The procedure is indicated in any situation where the patient’s oxygen status is a concern or when hypoxia may be even remotely suspected. It can, however, provide unreliable or false readings due to poor perfusion status, hypothermia, excessive patient movement, anemia, and even if the patient has a history of smoking. The device is used by clipping a small sensor onto the patient’s finger, toe, earlobe, or across the bridge of the nose. Turn on the device and match the pulse reading on the device to the patient’s actual heart rate. Infrared light shines through the tissue and detects hemoglobin saturation to provide an estimate of oxygenation.

10. SAMPLE is a mnemonic (memory aid) to help you remember the following patient history questions: S = signs and symptoms, A = allergies, M = medications, P = pertinent past history, L = last oral intake, and E = events leading to the injury or illness.

11. OPQRST is a mnemonic (memory aid) to help you remember a series of questions for assessing the patient’s chief complaint, major symptoms, or pain. O = onset (when and how did the symptoms begin?), P = provocation/palliation/position (what makes it worse/better?), Q = quality (how would you describe the pain?), R = radiation (where do you feel the pain?), S = severity (how bad is it?), and T = time (how long has it been going on?).

12. Many challenges can arise when gathering history. Some specific special challenges and some suggested strategies for overcoming them are (1) silent patients: watch for body language and try to determine the cause and rectify it whenever possible; (2) overly talkative patients: show patience, allow some free rein but interrupt as needed to gather information; (3) patients with multiple symptoms or complaints: try to clarify and filter information so you can determine the actual chief complaint; (4) anxious patients: be reassuring and allow the patient to express their feelings; (5) angry or hostile patients: remain calm, confident, and professional and refrain from becoming frustrated, defensive, or angry yourself; (6) intoxicated patients: be vigilant and ensure your own safety but remain nonjudgmental and provide assistance; (7) crying patients: respect their nonverbal clues by being patient, empathetic, and supportive; (8) depressed patients: listen carefully and remain nonjudgmental but watch for signs that the patient may need additional assistance or referrals beyond what you can provide; (9) patients with a confusing history or behavior: avoid spending an excessive amount of time trying to piece together their history; (10) patients with limited intelligence: work with the patient and family members together on gathering history; (11) patients with language barriers: find an interpreter through family members or bystanders or by calling a professional language translation line; (12) patients with hearing impairment: face the patient when speaking and use a translator if available; (13) patients with visual impairments: tell the patient everything you are doing and describe what is happening on the scene; (14) pediatric patients: depending on their age, use the parent or caregiver to fill in gaps of information; (15) elderly patients: be patient and allow the patient additional time to answer your questions.

CHAPTER 12 • Scene Size-up

IN REVIEW

1. Scene size-up is the EMT’s initial evaluation of a scene to which you have been called. Three goals of scene size-up are to identify possible hazards and ensure scene safety, to identify what led you to being called to the scene, and to determine whether any factors, such as the number of patients on the scene or other unusual factors, might require a call for additional assistance.

2. Use extra caution and diligence at potentially dangerous or unstable scenes. Do not enter unstable crash scenes, be extremely cautious around moving traffic, take extra precautions at crime scenes and near volatile crowds, keep your portable radio with you at all times, and call for help if you encounter something outside your area of training or expertise. Always retreat if the scene becomes hazardous.

3. Working on incident scenes next to moving traffic is one of the most common areas where EMS personnel work. To protect yourself, limit your time on scene to reduce your exposure to traffic, shut down traffic on the roadway if necessary to ensure your safety; place flares or cones far enough from the crash scene to give oncoming traffic plenty of warning of the crash scene, place apparatus and vehicles strategically so they protect the scene, wear bright safety reflective clothing or a vest at the crash scene to make you highly visible both day and night, do as much work as possible away from and out of the traffic flow, don’t turn your back to moving traffic, don’t jump highway dividers to provide emergency care while leaving yourself exposed to moving traffic, reduce any unnecessary scene lighting that may distract or may impair visibility of oncoming traffic, turn the wheels of the parked emergency vehicles so that they are pointed away from the scene, and avoid stopping and standing between vehicles.

4. Confined areas must be approached with extreme caution because of the potential for low oxygen and/or a toxic substance such as methane.

5. When approaching the possible scene of a crime, avoid the main sidewalk and instead walk on the grass; walk single file, with the person in front holding the flashlight, if used, to the side of his body, rearmost person carrying equipment; look for possible places of concealment or cover while approaching the house; change position while taking time to survey the building; stand to the knob side of the door when knocking; reassess the situation before entering; and always leave doors open when entering.

6. In doing the initial scene size-up, the nature of the patient’s problem needs to be characterized as either a trauma or a medical problem.

7. Mechanism of injury is defined as how the patient was injured. Specifically, it is the strength, direction, and nature of the forces applied to the patient’s body.

8. When assessing the scene of an automobile crash, look for clues to mechanism of injury like deformity greater than 20 inches outside the vehicle and intrusion into the
passenger compartment, axle displacement, rollover of the vehicle, impact marks on the windshield, a missing rear-view mirror, collapsed steering wheel, broken seat, side-door damage, deformed dashboard, and deformed pedals.

9. Inspect the scene to determine clues to the nature of a patient’s illness. Look for prescription and nonprescription medications, drugs, drug paraphernalia, alcohol, oxygen equipment, and environmental conditions.

10. The total number of patients must be confidently determined so that additional resources can be summoned early in the call in case the number of patients is beyond the capacity of the initial EMS team to handle.

CHAPTER 13 • Patient Assessment

IN REVIEW

1. The main purpose of the primary assessment is to identify and manage immediately life-threatening conditions to the airway, breathing, or circulation. However, a number of overall purposes of patient assessment are served during the primary assessment such as determining whether the patient is injured or ill, identifying and managing critical conditions, and determining priorities for further assessment and care. By comparison, the secondary assessment allows you to conduct a more thorough physical exam, take baseline vital signs, and obtain a more detailed history.

2. The main components of patient assessment are the scene size-up, primary assessment, secondary assessment, and the reassessment.

3. The steps of scene size-up are to (1) take Standard Precautions, (2) evaluate the scene for hazards and ensure scene safety, (3) determine the mechanism/nature of injury, (4) determine the number of patients, and (5) ascertain the need for additional resources.

4. The steps of the primary assessment are to form a general impression of the patient, assess the level of consciousness (mental status), assess the airway, assess breathing, assess circulation, and establish patient priorities. This should be conducted in approximately 60 seconds unless confronted with life-threatening problems that must be corrected along the way.

5. For a responsive medical patient, the secondary assessment is conducted in the order of (1) history, (2) focused medical assessment, and (3) baseline vital signs. This is because the most significant information about a medical condition will usually be obtained from what the patient tells you. For an unresponsive medical or trauma patient, the secondary assessment is conducted differently because the priorities are different; information from the physical exam is most important. The order is (1) rapid trauma or rapid medical assessment, (2) baseline vital signs, and (3) history.

6. A rapid head-to-toe assessment should be performed on unresponsive medical patients and on trauma patients who have a significant mechanism of injury, multiple injuries, altered mental status, or critical findings. A modified secondary assessment or focused exam should be performed on responsive medical patients or trauma patients who have no significant mechanism of injury, no multiple injuries, alert and oriented mental status, and no critical findings.

7. The following vital signs should be assessed during the secondary assessment and throughout the entire call: breathing (rate and tidal volume), pulse (rate, location, strength, and regularity), skin (temperature, color, and condition), capillary refill, blood pressure (systolic and diastolic), pupils (equality, size, and rate of reactivity), and SpO2.

8. OPQRST is a mnemonic (memory aid) to help you remember how to proceed through a series of questions to assess the patient’s chief complaint, major symptoms, or pain. They include: O = onset (when and how did the symptoms begin?), P = provocation/palliation/position (what makes it worse/better?), Q = quality (how would you describe the pain?), R = radiation (where do you feel the pain?), S = severity (how bad is it?), and T = time (how long has it been going on?). SAMPLE is a mnemonic to help you remember the following patient history questions: S = signs and symptoms, A = allergies, M = medications, P = pertinent past history, L = last oral intake, and E = events leading to the injury or illness.

9. At a minimum, the primary assessment and vital signs should be reassessed every 5 minutes for an unstable patient with critical injuries, and every 15 minutes for a stable patient.

CHAPTER 14 • Pharmacology and Medication Administration

IN REVIEW

1. Medications carried on EMS units are oxygen, oral glucose, activated charcoal, and aspirin.

2. EMTs may administer or assist with inhaled bronchodilators, nitrates, and epinephrine.

3. The routes by which EMTs may administer medications are sublingual, oral, by inhalation, and by injection.

4. Several common forms of medications that may be administered by the EMT are the compressed powder or tablet, liquid for injection, gel, suspension, fine powder for inhalation, gas, spray, and small-volume nebulizer.

5. Indication: the common reasons for using a medication to treat a specific condition. Contraindication: situations in which a medication should not be used. Dose: the amount of medication that is given to a patient at one time. Administration: the route and form by which a drug is given. Actions: the effect a drug has on the body. Side effect: the undesired effects of a medication.

6. (1) Obtain an order from medical direction; (2) select the proper medication; (3) verify the patient’s prescription; (4) check the expiration date; (5) check for discoloration or impurities; (6) verify the proper form, route, and dose; (7) use the “five rights” as a final check of the right patient, right medication, right route, right dose, and right date (time); and (8) document the administration of the medication and the patient’s response.

7. Following the administration of a medication, it is important to perform a reassessment. During the reassessment, repeat measurement of vital signs and assess for any changes in the patient’s condition. Assess mental status, airway patency, breathing rate and quality, pulse rate and quality, skin signs, blood pressure, medication side effects, and any change in chief complaint or the patient’s condition.

CHAPTER 15 • Shock and Resuscitation

IN REVIEW

1. Shock, or hypoperfusion, is defined as the insufficient supply of oxygen and other nutrients to some of the body’s cells that results from inadequate circulation of blood.

2. In order to maintain cellular perfusion, the body must be able to deliver an adequate amount of oxygen to the cells. To do so, (1) the patient must be breathing an adequate amount of oxygen with each breath, (2) the oxygen in the alveoli must be able to effectively diffuse across the alveolar/capillary membrane and enter the blood, (3) once diffused into blood, oxygen must bind to hemoglobin as its primary carrying vehicle, and (4) once it reaches the tissue level, oxygen must release from hemoglobin and diffuse across the capillary and into the cell. Depending on environmental conditions and/or
the patient's illness or injury, any of these steps may be hamp-ered and cell perfusion can be diminished.

3. The three etiologies of shock are inadequate volume, inade-quate pump function, and inadequate vessel tone. Inadequate volume is typically due to decreased blood or fluid volume from things like bleeding, diarrhea, burns, excessive urination, increased capillary leakage, and excessive vomiting. Inade-quate pump function is typically due to failure of the pump—the heart—such as may occur with a myocardial infarction (heart attack). Sometimes the pump may fail due to mechan-i-cal obstruction from swelling or pressure. Inadequate vessel tone is typically due to a change, or decrease, in peripheral vascular resistance (PVR). In order to have adequate blood pressure, the tone of the vessels must be maintained or the capacity of the vascular system will allow pooling of blood away from the core organs (brain and heart). A decrease in PVR may occur due to spinal cord injury.

4. There are four major categories of shock. Hypovolemic shock is caused by a loss of blood or fluid from the vas-cular space resulting in a low blood volume. Distributive shock is associated with a decrease in the intravascular vol-ume from massive systemic vasodilation and an increase in capillary permeability. Cardiogenic shock is poor perfusion resulting from an ineffective pump function of the heart. Obstructive shock is a poor perfusion state that results from a condition that obstructs forward blood flow.

5. Shock is broken down into specific types: (1) Hemorrhagic hypovolemic shock occurs due to whole blood loss from the intravascular space (from inside blood vessels), usually as a result of a traumatic injury or medical illness. (2) Nonhemor-rhagic hypovolemic shock occurs from the loss of fluid from the intravascular space while red blood cells and hemo-globin remain. The loss is primarily water, plasma proteins, and electrolytes, which reduces blood volume, pressure, and perfusion of cells. Because red blood cells are intact, oxygen-carrying capacity is preserved. (3) Burn shock is a specific form of nonhemorrhagic hypovolemic shock result-ing from a burn injury. Burns may interrupt the integrity of the capillaries and vessels and allow them to leak out plasma and plasma proteins. (4) Anaphylactic shock occurs because of massive and systemic vasodilation. Capillaries become very permeable and leak, and fluid gets pushed out into the interstitial space. (5) Septic shock is caused from an infection that releases bacteria or toxins into the blood. This causes the vessels throughout the body to become permeable and leak fluid into the interstitial space. The shock state is cre-at ed by massive vasodilatation which reduces the systemic vascular resistance, blood pressure, and perfusion. (6) Neu-rogenic shock results from a loss of sympathetic tone, caus-ing the blood vessels to dilate. For example, a spinal cord injury may damage the sympathetic nerve fibers that control the vessel tone below the level of injury. If the injury is high in the thoracic spinal cord or in the cervical region, enough vessel tone may be lost to cause a drop in systemic vascular resistance, blood pressure, and perfusion. There is no fluid loss from the intravascular space; the drop in perfusion is solely from widespread vasodilatation. (7) Cardiogenic shock is most often due to an acute myocardial infarction (heart at-tack), congestive heart failure, abnormal cardiac rhythm, or overdose on drugs that depress the pumping function of the heart such as beta-blockers or calcium channel-blockers. The depressed pump function reduces the force of the left ven-tricular contraction, stroke volume, cardiac output, systolic blood pressure, and perfusion.

6. The body immediately attempts to compensate for perfusion problems by stimulating the sympathetic nervous system and by releasing a cascade of hormones into the bloodstream. As a result, we see how these compensatory mechanisms relate to the different stages of shock: (1) Compensatory shock occurs when the body is still able to maintain a near normal blood pressure and perfusion of the vital organs. (2) De-compensatory shock occurs when the body’s compensatory mechanisms are no longer able to maintain a blood pressure and perfusion of the vital organs. If the shock state continues unopposed and is not managed effectively, the compensa-tory mechanisms either become exhausted or overwhelm the cells. The amount of oxygen delivered to the cell is less than what is needed for normal metabolism. In addition, the body is unable to effectively eliminate carbon dioxide and other waste products. Most of the emergency care of the patient in shock is geared toward maintaining or restoring oxygen and glucose delivery to the cells.

7. When shock occurs, the body attempts to compensate for the disturbance and return the perfusion and tissue func-tion back to a normal state. The body uses two responses, a neural response and a hormonal response, to compensate. (1) In the neural response, the sympathetic nervous system plays a significant role in stimulating the vessels and the heart in an attempt to restore the blood pressure in the arteries. The effects of the sympathetic stimulation, which occur immediately, are an increase in heart rate, an increase in the force of ventricular contraction, and the release of epinephrine and norepinephrine from the ad-renal gland. (2) In the hormonal response, epinephrine and norepinephrine stimulate alpha and beta receptors that primarily result in vasoconstriction and help increase systemic vascular resistance and blood pressure. The heart is also stimulated to increase rate and force of contraction. There are a number of other hormones released that are geared to reversing the shock state and restoring the pressure in the arteries and perfusion to the cells.

8. During a shock state, inadequate amounts of oxygen and glu-cose are delivered to cells. The amount of oxygen delivered to the cell is less than what is needed for normal metabolism. In addition, the body is unable to effectively eliminate carbon dioxide and other waste products. Most of the emergency care of the patient in shock is geared toward maintaining or restoring oxygen and glucose delivery to the cells.

9. The five links in the American Heart Association adult chain of survival are 1) immediate recognitions and activation; 2) early CPR; 3) defibrillation; 4) effective advanced life support; and 5) integrated post-cardiac-arrest care. The AHA pediatric chain of survival also has five links; however, the first three links emphasize slightly different elements of emergency cardiac care. This is based on the difference in the physiology and typical etiology of cardiac arrest in the pediatric patient. The links in the pediatric chain of survival are 1) prevention of arrest; 2) early high-quality CPR per-formed by bystanders; 3) rapid activation of EMS or other emergency medical responders; 4) effective advanced life support and rapid transport to an appropriate medical facil-ity; and 5) integrated post-cardiac-arrest care.

10. The heart rhythm most responsive to defibrillation is ven-tricular fibrillation (V-Fib). V-Fib is a disorganized cardiac rhythm that produces no pulse or cardiac output, and it is commonly associated with advanced coronary artery disease. It’s estimated that 50–60 percent of cardiac arrests will be in V-Fib during the first 8 minutes after becoming pulseless, so V-Fib is most commonly the rhythm that AED de-fibrillates. In addition, ventricular tachycardia is a heart rhythm that will also respond to defibrillation with the caveats described as follows. V-Tach is a very fast heart rhythm that results in such rapid pumping that the heart does not refill properly and cardiac output is sharply reduced. This rhythm can easily degenerate into ventricular fibrillation. The AED will respond to V-Tach, usually when the heart rate exceeds 180 beats a minute. However, you should be aware that some V-Tach patients remain responsive; since they are
not pulseless, they are not appropriate candidates for defibrillation. The AED should ONLY be applied to patients who are pulseless, not breathing (apneic), and unresponsive.

11. The AED is intended for nontraumatic cardiac arrest patients. These patients must be unresponsive, with no breathing and no pulse. If the patient is less than 8 years of age, an adult AED can be used preferably with a dose attenuating system to reduce the defibrillation energy being delivered to the child. If no dose attenuating system is available, proceed with the regular adult pads and defibrillation. The AED is not intended for traumatic cardiac arrest patients because their condition is typically the result of profound blood loss and not because they have a cardiac rhythm disturbance.

12. Immediate application of the AED is warranted as soon as it becomes available.

15. • Take Standard Precautions.
   • Perform an initial assessment of the patient.
   • Begin or resume CPR while the AED is ready for operation.
   • Attach the adhesive monitoring-defibrillation pads to the cables.
   • Apply the two defibrillation pads to the patient's bare chest.
   • Turn on power to the AED.
   • When the AED enters its analysis mode, stop any ongoing CPR and say “Clear!” making sure that no one is touching the patient.
   • Begin analysis of the patient’s heart rhythm.
   • If the AED indicates “Deliver Shock,” make sure that everyone is clear of the patient by visually checking all personnel and stating “I'm clear, you're clear, everyone is clear.” Press the shock button to deliver the shock.
   • Resume CPR for 2 minutes (or five sets of 30:2 compressions/ventilations).
   • After the first 2 minutes of CPR, pause to check the patient’s pulse for no longer than 10 seconds.
   • If the pulse is present, check the breathing.
   • If the patient is breathing adequately, deliver oxygen and transport.
   • If the patient is not breathing adequately, provide positive pressure ventilation with supplemental oxygen attached to the ventilation device and transport.
   • If no pulse is present, reanalyze the rhythm. If indicated, provide a second shock in the manner just described. If the AED gives a “No Shock” message, proceed to the following steps.
   • After delivering the second shock, resume CPR and transport as soon as possible.
   • A “No Shock” message can mean one of three things: The patient you thought was pulseless has a pulse after all, or the formerly pulseless patient has now regained a pulse, or finally the patient is pulseless but the AED is detecting a nonshockable rhythm. If the machine gives a “No Shock” message, immediately resume CPR for 2 minutes until the next reassessment.
   • If the pulse is present, check the breathing.
   • If the patient is breathing adequately, deliver oxygen and transport.
   • If the patient is not breathing adequately, provide positive pressure ventilation with supplemental oxygen and transport.
   • Transport after a total of two (or three) shocks are delivered (with an intervening period of CPR) or a total of two (or three) “No Shock” messages are received.

14. Start CPR if the AED is not immediately ready. When the AED is ready, stop CPR and initiate rhythm analysis. Deliver another single shock if warranted and then resume 2 minutes of CPR prior to checking a pulse. Deliver a second shock if there is no pulse and the AED advises another shock is warranted. If no shocks are indicated, perform CPR again for 2 minutes, then reanalyze until two or three “No Shock” messages have been received. Continue resuscitation as per local protocol and resume transport.

CHAPTER 16 • Respiratory Emergencies

IN REVIEW

1. Some of the common findings you might encounter with a patient having respiratory distress are a subjective complaint of shortness of breath, increased or decreased pulse rate, changes to the rate or depth of breathing, skin color changes, abnormal breathing sounds, difficulty speaking, retractions of the muscles in the upper thorax, an altered mental status, excessive abdominal muscle use to breathe, excessive coughing, and pulse oximetry readings below 95%.

2. It’s just as important to be able to recognize adequate breathing in all types and ages of patients as it is to recognize inadequate breathing. Look at the entire patient and assess tidal volume closely. In order to have adequate breathing, you must have both an adequate rate and an adequate tidal volume. Two adequates (both rate and tidal volume) = adequate breathing.

3. If either the rate or the tidal volume is inadequate, the breathing should be considered inadequate and the patient must be provided positive pressure ventilation. If both rate and tidal volume are inadequate, breathing is obviously inadequate and the patient must be given ventilatory assistance. One inadequate (either rate or tidal volume) = inadequate breathing. Two inadequates (both rate and tidal volume) = inadequate breathing.

4. Emergency care for a patient exhibiting signs and symptoms of breathing difficulty but still breathing adequately would include administering oxygen assessing the baseline vital signs; determining if the patient has a prescribed beta2 agonist inhaler and, if so, contacting medical direction for permission to administer the medication; completing a secondary assessment; and placing the patient in a position of comfort and commencing transport.

5. A patient exhibiting signs and symptoms of respiratory failure needs immediate intervention. Establish an open airway and insert an oropharyngeal or nasopharyngeal airway, if tolerated by the patient, in order to maintain the airway. Begin positive pressure ventilation with supplemental oxygen and continue to assess for signs of adequate ventilation. Expedite transport to the hospital.

6. Adequate positive pressure ventilation and oxygenation should improve the patient’s mental status. A decreasing heart rate in a patient with tachycardia may indicate improvement if the mental status is also improving and the respiratory distress is subsiding. Diaphoresis may improve and breath sounds may indicate improved air movement in the lungs, such as clearer and louder breath sounds on both sides of the chest. If ventilation were to remain inadequate, ensure an open and patent airway, ensure a tight seal of the face mask, and consider adjusting the rate and quality of ventilations being provided. If still unsuccessful, reassess for a foreign body obstruction.

7. To administer a bronchodilator by MDI, follow these steps: (1) Ensure you have the right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the inhaler and if any doses have already been administered prior to your arrival. (2) Obtain an order, either on-line or off-line, from medical direction. (3) Ensure the inhaler is at room temperature or warmer and
then shake vigorously for at least 30 seconds. (4) Remove the nonrebreather mask from the patient and instruct the patient to take the inhaler in his hand and hold it upright. If the patient is unable to hold the device, place your index finger on the top of the metal canister and your thumb on the bottom of the plastic container. (5) Have the patient exhale fully. (6) Have the patient place his lips around the mouthpiece of the inhaler or open his mouth and place the inhaler 1 to 1.5 inches from the front of the lips, or two finger widths. (7) Have the patient begin to slowly and deeply inhale over about 5 seconds as the canister is depressed. (8) Remove the inhaler and coach the patient to hold his breath for 10 seconds or as long as comfortable. (9) Have the patient exhale slowly through pursed lips. (10) Return the oxygen mask to the patient and reassess breathing status and vital signs. (11) Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between administrations or longer. If using a spacer, follow the same steps except for 6 and 7. In place of those steps, remove the spacer cap and attach the inhaler to the spacer and then depress the medication canister to fill the spacer with the medication. As soon as the canister is depressed, have the patient place his lips around the mouthpiece and inhale slowly and deeply. If the inhalation is too fast, the spacer may whistle. To administer a bronchodilator by small-volume nebulizer, follow these steps: (1) Ensure you have the right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the nebulizer and if any doses have already been administered prior to your arrival. (2) Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication. (3) Disassemble the medication chamber from the “T” piece by unscrewing it. While holding the medication reservoir upright, pour in the medication and reassemble the device. (4) Attach the tubing extending from the bottom of the drug reservoir to either the nebulizer compressor and turn it on, or, to an oxygen tank with the liter flow set to 8–10 lpm. You should note the misting coming from the “T” piece almost immediately. (5) Remove the nonrebreather mask from the patient and then instruct the patient to take the nebulizer in his hand and hold it upright. If the patient is unable to hold the device, you may have to do this for the patient, being sure to continuously hold it upright for optimal nebulization of the medication. (6) Have the patient exhale fully. (7) Instruct the patient to place his lips around the mouthpiece opening of the nebulizer, or another technique is to have the patient open his mouth and place the mouthpiece 1–1.5 inches from the front of the lips, estimated by two finger widths. (8) Have the patient begin to slowly and deeply breathe in the mist. (9) Instruct the patient to occasionally hold his breath, about every 2–3 breaths, after inhalation as long as he comfortably can, to assist with medication distribution throughout the respiratory tree. (10) Have the patient exhale normally and instruct the patient to occasionally cough during exhalation to facilitate removal of any mucus or secretions that may be present. (11) You may need to occasionally jiggle the nebulizer to dislodge any medication that collects on the sides of the reservoir. In about 5–10 minutes, the misting of medication should cease and the liquid medication you placed in the nebulizer will be gone. Return the oxygen mask to the patient. (12) Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the type of medication being administered or medical direction’s order.

8. Beta-agonist drugs are indicated when the patient exhibits signs and symptoms of breathing difficulty, when the patient has a physician-prescribed metered-dose inhaler or medication specifically prepared for nebulization, and when the EMT has received approval from medical direction, whether on-line or off-line, to administer the medication. Beta-agonist drugs are contraindicated when the patient is not responsive enough to use the MDI/nebulizer, when the drug is not prescribed for the patient, when permission has not been granted by medical direction, and when the patient has already taken the maximum number of allowed doses prior to your arrival.

9. In infants and children, early signs of respiratory distress must be recognized quickly because they often proceed quickly to respiratory failure. Look for anxiety, increased use of accessory muscles to breathe, sternal and intercostal retractions during inspiration, tachypnea (increased breathing rate), tachycardia (increased heart rate), nasal flaring, prolonged exhalation, frequent coughing, which is sometimes present rather than wheezing, and cyanosis to the extremities. The signs of inadequate breathing and respiratory failure may be similar in infants and children. These are late signs that indicate a priority patient and necessitate immediate intervention. Look for grunting, an altered mental status (may be completely unresponsive); bradycardia (slow heart rate); hypotension (low blood pressure); extremely fast, slow, or irregular breathing patterns; cyanosis to the core of the body and mucous membranes; any loss of muscle tone or limp appearance; diminished or absent breath sounds; head bobbing; seesaw or rocky breathing where the chest is drawn inward while the abdomen moves outward; a decreased response to pain; and inadequate tidal volume.

10. In infants and children, the upper airway can be obstructed by foreign bodies or can be obstructed due to swelling from certain diseases and medical conditions. Distinguishing between these possibilities is the only way to determine appropriate treatment. The history is especially important when airway blockage is suspected, since it may identify preexisting diseases that may be causing the airway closure, or events that may have led to a foreign body obstruction. If the blockage was sudden and there was something around that the child could have swallowed and there is no history or other sign of disease, treat the patient for an upper airway foreign body obstruction. If the blockage came on gradually, the child has other signs of being ill, or the child has a history of respiratory or other disease, and no one saw the child swallow anything, avoid inserting anything into the airway. Instead, provide oxygen or positive pressure ventilation with supplemental oxygen as necessary.

CHAPTER 17 • Cardiovascular Emergencies

IN REVIEW

1. The cardiovascular system, also known as the circulatory system, is made up of the heart, blood vessels, and blood. It delivers oxygen and nutrients to the body’s cells and carries away carbon dioxide and other wastes.

2. Capillary walls are so thin that oxygen and nutrients carried in the blood are able to move out of the capillaries and into the body’s cells. Capillaries then carry away carbon dioxide and waste products given off by the cells via deoxygenated blood to be excreted from the body.

3. Perfusion is defined as the delivery of oxygen and other nutrients to the cells of all organ systems, which results from the constant adequate circulation of blood through the capillaries. Shock, or hypoperfusion, is defined as an insufficient supply of oxygen and other nutrients to some of the body’s cells that results from inadequate circulation of blood.

4. Signs and symptoms of cardiac compromise include chest discomfort or pain that radiates to the chest, neck, jaw, arm,
or back. The patient may also complain of epigastric pain similar to indigestion. A sudden onset of sweating is often a significant finding by itself. The patient may have cool, pale skin and have difficulty in breathing. You may also note light-headedness or dizziness, anxiety or irritability, feelings of impending doom, an abnormal or irregular pulse rate, an abnormal blood pressure, and nausea and/or vomiting.

5. Ensure a patent airway and provide positive pressure ventilation with oxygen connected to the device if the breathing is inadequate. If the respiratory rate and tidal volume are both adequate, consider supplemental oxygen. According to the AHA 2010 guidelines, administer supplemental oxygen if the patient is dypneic, hypoxemic, has obvious signs of heart failure, has an SpO₂ reading of <94% or the SpO₂ is unknown. Administer oxygen via a nasal cannula at 2 to 4 lpm and titrate the concentration and liter flow to achieve and maintain an SpO₂ of ≥94%. The AHA 2010 guidelines indicate that there is not sufficient evidence to support the use of supplemental oxygen as a routine in patients who do not present with dyspnea, hypoxemia, heart failure, or an SpO₂ of <94%. Do not overoxygenate the patient. Place the patient in a position of comfort. If the patient has a prescription for nitroglycerin, administer one tablet every 3–5 minutes up to a total of three tablets. Follow your local protocol. Be sure the systolic blood pressure is above 90 mmHg and remains above 90 mmHg following each nitroglycerin administration. If local protocol allows, administer 160–325 mg of aspirin. Notify the receiving hospital early of suspected MIs. Continue to assess the patient en route to the medical facility. Contact ALS for further assistance if available. If the patient becomes pulseless and apneic (no pulse, no respirations), immediately begin cardiac resuscitation and apply the automated external defibrillator.

6. The dosage of aspirin is 160–325 mg as soon as possible after the onset of the chest discomfort and symptoms of heart attack. It is recommended that 160–325 mg of a nonenteric aspirin be chewed and swallowed. First complete a history and physical exam. Obtain approval from medical direction, either on-line or off-line, to administer the aspirin. Be sure that the patient is alert and oriented and then have the patient chew a 160–325 mg nonenteric tablet. Reassess the patient and record the vital signs.

7. Nitroglycerin is indicated when all of the following conditions are met: (1) The patient exhibits signs or symptoms of chest pain. (2) The patient has physician-prescribed nitroglycerin. (3) Approval has been obtained from medical direction, whether on-line or off-line, to administer the medication.

2. EMTs must pay particular attention to the patient’s airway and breathing because alterations in mental status may cause the patient to lose his ability to maintain his own airway. The jaw and tongue can relax, fall back, and block the airway. Unresponsive patients typically have no cough or gag reflex and won’t be able to clear their airway of secretions, blood, and vomitus.

3. The three most common findings in patients suffering a stroke are facial droop, arm drift, and speech disturbances. Other signs and symptoms include an altered mental status ranging from dizziness or sudden confusion to complete unresponsiveness; a sudden onset of paralysis or weakness to the face, arm, hand, or leg, especially to one side of the body; numbness or loss of sensation on one side of the body; loss of control of the bladder or bowel; unequal pupils; deterioration or loss of vision in one or both eyes, or double vision; eyes turned away from the side of the body that is paralyzed; nausea and vomiting; a sudden onset of severe headache; seizure activity; complaint of a stiff neck (a late symptom); sensory or receptive aphasia; expressive or motor aphasia; uncoordination of the extremities, usually on one side; poor balance, clumsiness, or difficulty in walking; heart or loss to one side; light or sound sensitivity; and vertigo.

4. Steps in the emergency care of a patient suffering from an altered mental status or stroke are as follows: (1) Maintain a patent airway. (2) Suction secretions and vomitus as needed. (3) Be prepared to assist ventilations as needed. (4) Maintain the SpO₂ reading at or above 94% and to eliminate any signs of hypoxia. If the patient becomes alert and oriented and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO₂ is ≤94% or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO₂ reading of ≥94%. If signs of severe hypoxemia are present, a nonrebreather mask at 15 lpm could be used. (5) If the patient is responsive, position him in a supine position. If the patient wants to be placed in a semi-Fowler’s position, do not elevate the head and chest greater than 30 degrees. If the patient is unresponsive or unable to protect his own airway, place him in a left lateral recumbent position. (6) Check the blood glucose level if your protocol permits. (7) Protect any paralyzed extremities. (8) Expedite transport.

5. Patients who experience a transient ischemic attack (TIA) develop most of the same signs and symptoms as those experiencing a stroke. The key difference between a stroke and a TIA is that the signs and symptoms of a TIA typically disappear within 10–15 minutes but almost always within 1 hour of onset. TIAs always resolve within 24 hours without causing any permanent neurological disability. Ischemia, which refers to an oxygen deficit in the tissues, affects the brain and causes the stroke-like signs and symptoms to appear. Reversal of the ischemia leads to disappearance of the stroke-like signs and symptoms. Emergency medical care is the same for both conditions.

6. Headaches can be categorized as vascular, cluster, tension, and organic, traction, or inflammatory in nature. Vascular headaches occur as a result of dilation or distention of vessels or inflammation within the cranium. Migraine headaches are in this category. Cluster headaches are similar to migraines because they are believed to have a vascular origin. The pain is usually found only on one side of the head or face in the temporal region or around the eye and is excruciating. Tension headaches are thought to be caused by contraction of the muscles found in the neck and scalp. The pain is usually described as being “tight” or “vise-like.” Organic, traction, or

CHAPTER 18 • Altered Mental Status, Stroke, and Headache

IN REVIEW

1. A change in the patient’s mental status is an indication that the central nervous system has been affected in some manner. Causes may include trauma, where the brain is injured from a blunt force or penetrating object, or nontraumatic causes such as an alteration in the patient’s blood sugar or blood oxygen level. Alterations in mental status usually fall into one of two general categories: structural or toxic-metabolic. Examples of structural causes are brain tumors and hemorrhage. Toxic-metabolic causes occur from conditions like severe hypoxia, abnormal blood glucose conditions, liver and kidney failure, and poisoning. EMTs see many examples in the field of conditions that may cause an altered mental status, such as shock, alcohol and narcotics use, patients recovering from seizure, infection, cardiac rhythm disturbances, and stroke.
inflammatory headaches are a result of tumors, infection, stroke, or inflammatory disorders within the cranium such as meningitis, hemorrhagic stroke, and tumor.

7. You should suspect a serious underlying condition if the patient’s headache was associated with any of the following signs or symptoms: an altered mental status; motor or sensory deficits; behavioral changes; seizure activity; an abrupt onset of pain never experienced before by the patient; pain that worsens with coughing, sneezing, or bending over; signs of fever or stiff neck; and any change in the quality of a chronic headache.

CHAPTER 19 • Seizures and Syncope

IN REVIEW

1. The airway may be compromised in actively seizing or postictal patients because their mental status is altered. The patient often cannot maintain his own airway. Large amounts of saliva are often produced during the seizure, and the tongue is commonly bitten and bleeding.

2. The following are pertinent questions to ask a responsive patient, relative, or bystander who witnessed the seizure:
   - Was the patient awake during the seizures?
   - Was the muscle activity a twitching or jerking motion?
   - Was it isolated to one part of the body or generalized?
   - When did the seizure start? How long did it last?
   - Did the patient experience an aura before the seizure?
   - Did the patient hit his head or fall? Did the patient bite his tongue or mouth? Was there a loss of bowel or bladder control?
   - Is there any recent history of fever, headache, or stiff neck?
   - Is the patient allergic to any medications?
   - What medications does the patient take? Did the patient take his seizure medication as prescribed?
   - Does the patient have a history of epilepsy, previous seizures, diabetes, stroke, or heart disease?
   - When was the last time the patient had a seizure?
   - Was this a typical type of seizure for him?
   - When did the patient last have something to eat or drink?
   - What was the patient doing immediately prior to the seizure activity?

3. The signs and symptoms of generalized tonic-clonic seizures typically occur in five stages: (1) The aura serves as a warning that a seizure is about to begin and involves some type of sensory perception by the patient. The patient typically loses consciousness—and may fall—sometime after the aura. (2) The patient’s muscles become contracted and taut during the tonic phase leading to extreme muscular rigidity. (3) In the hypertonic phase, the patient has extreme muscular rigidity with hyperextension of the back. (4) Muscle spasms then alternate with relaxation during the clonic phase, typically producing violent and jerky seizure activity. During the convulsions, incontinence may occur and the patient may bite his lips, tongue, or mouth. (5) In the postictal phase, the patient is no longer convulsing and is in the recovery phase. The patient’s mental status is altered and ranges from unresponsiveness to confusion and disorientation. This phase generally lasts 10–30 minutes.

4. Focus on controlling the patient’s airway and breathing and manage immediate life threats. Position the patient in a lateral recumbent position. If a spinal injury is suspected, properly immobilize the patient in a supine position.

Maintain a patent airway and suction any secretions, blood, or vomitus. Assist ventilations as needed and prevent injury to the patient. Consider oxygen therapy and transport.

5. Status epilepticus is defined as a seizure lasting longer than 5 minutes or seizures occurring consecutively without a period of responsiveness between them. This is a serious medical emergency that may be life threatening.

6. Conditions and injuries that commonly cause seizures include epilepsy, high fever, infection, poisoning, hypoglycemia, hyperglycemia, head injury, shock, hypoxia, stroke, drug or alcohol withdrawal, dysrhythmias, hypertension, complications of pregnancy (eclampsia), and blood electrolyte imbalances. Seizures may also be termed “idiopathic” which means that the cause is simply unknown.

7. Syncope, or fainting, is a sudden and temporary loss of consciousness. Syncope usually occurs when the patient is standing up or when the patient suddenly stands up from a sitting position. The collapse that follows puts the body in a horizontal position, reducing the pull of gravity and allowing blood circulation to the brain to improve. As a result, the patient typically recovers rapidly. Bystanders may confuse a syncope episode with a seizure because the patient may experience a short period of jerky muscle movement during the episode. The difference is that with syncope the episode usually begins in a standing position, the patient remembers feeling faint or light-headed, the patient becomes responsive almost immediately after becoming supine, and the skin is usually pale and moist.

CHAPTER 20 • Acute Diabetic Emergencies

IN REVIEW

1. Hypoglycemia occurs when the amount of glucose in the blood falls below normal limits. Unlike other cells that can burn fat and protein for energy, brain cells only use glucose as an energy source. If blood glucose levels drop, brain cell dysfunction occurs and the mental status of the patient will deteriorate. If the blood glucose levels are not restored, brain cells will eventually begin to die.

2. Many of the signs and symptoms seen in hypoglycemia are actually associated with the release of the hormone epinephrine, which gets secreted into the bloodstream as blood glucose levels drop. Signs and symptoms can therefore be separated into those caused by the epinephrine release and those caused by the brain cell dysfunction from low sugar levels. Epinephrine release causes diaphoresis; tremors; weakness; hunger; tachycardia; dizziness; pale, cool, and clammy skin; and a warm sensation. The signs and symptoms of brain cell dysfunction are confusion, drowsiness, disorientation, unresponsiveness, seizure, and stroke-like symptoms.

3. It’s extremely important that the patient is given sugar to increase the blood glucose as quickly as possible to prevent brain cells from dying. How you accomplish that depends on the patient’s level of consciousness. If the patient is responsive, able to swallow, and able to obey your commands, (1) ensure the airway is patent, (2) assess the blood glucose level if your protocol permits, and (3) administer one tube of oral glucose. If the patient is unresponsive, unable to swallow, or unable to obey your commands, you cannot administer glucose orally. Instead, your treatment for this patient will be to (1) establish an open airway, (2) provide oxygen if the breathing is adequate or provide positive pressure ventilation if the breathing is inadequate, (3) contact advanced life support, and (4) assess the blood glucose level.
4. A patient with an altered mental status may not be able to protect his own airway, meaning his tongue may relax back and cause an obstruction and/or he may be unable to clear his airway should secretions or vomitus enter the mouth or throat. Patients with hypoglycemia may have self-administered oral glucose prior to your arrival or will get oral glucose as part of your treatment plan. Because of the viscous nature of this medication, it’s important to continuously monitor the patient’s airway to avoid accidental blockage or aspiration of the oral glucose.

5. Oral glucose is indicated as long as all of the following criteria are met: (1) The patient has an altered mental status, (2) the patient has a history of diabetes controlled by medication or a blood glucose level less than 60 mg/dL, and (3) the patient is able to swallow.

6. Oral glucose should not be administered to a patient who is either unresponsive or unable to swallow the medication.

7. There are actually three ways to administer the medication. The first way is to hold back the patient’s cheek and squeeze small portions of the contents of the tube into the mouth between the cheek and gum. The second way is to place small portions of the oral glucose on a tongue depressor, pull back the cheek, and slide the tongue depressor to deposit the medication between the cheek and gum. The third, and perhaps more obvious method, is to have the patient squeeze the glucose himself into his mouth. This ensures he is alert enough to swallow it.

8. First, it is important to determine whether medical direction and local protocol allow the EMT to test the patient’s glucose level on a blood glucose meter. Furthermore, oral glucose may be administered only on the orders of medical direction, either on-line or as an off-line standing order or protocol.

9. Insulin, a hormone secreted from the pancreas, plays a critical role in facilitating the movement of glucose out of the blood and into the cells for metabolism. In diabetic ketoacidosis, the patient has an inadequate amount of insulin, leading to a buildup of glucose in the blood because sugar is not being moved into the cells to be used for energy and metabolism. Without a supply of glucose, the body’s cells start burning fat as an alternative. This produces a by-product called ketones, which form into a strong acid. As more fat is burned instead of glucose, the acid levels in the body increase to dangerous levels. At the same time, the excess glucose in the blood is spilling into the urine from the kidneys and drawing a large amount of water with it, causing dehydration. The acidosis and dehydration together produce diabetic ketoacidosis.

10. Signs and symptoms of patients with diabetic ketoacidosis include warm, dry, flushed skin, fruity or acetone odor on the breath, blood glucose levels often greater than 350 mg/dL, rapid deep respirations (also known as Kussmaul breathing), altered mental status, polyuria (excessive urination), polyphagia (excessive hunger), polydipsia (excessive thirst), dizziness, poor skin turgor, altered mental status, confusion, weakness, dry oral mucosa, dry and warm skin, polyuria (excessive urination), and nausea and vomiting.

11. These patients are typically dehydrated and acidicotic and the treatment is aimed at reducing the blood glucose and rehydrating the patient. It may be prudent to contact an ALS unit to begin rehydration. Your care will include establishing a patent airway and considering oxygen if the breathing is adequate or providing positive pressure ventilations if the breathing is inadequate. If your protocol allows, determine the blood glucose level. If you are unsure about the condition, administer oral glucose if the patient is able to swallow. It is always better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so. Finally, contact medical direction for further orders.

12. The pathophysiology of hyperglycemic hyperosmolar nonketotic syndrome (HHNS) is very similar to diabetic ketoacidosis. HHNS is a hyperglycemic condition that causes the blood glucose level to increase drastically. Because the amount of glucose in the blood is so high, the kidneys attempt to regulate by spilling off large amounts of it into the urine. This draws large amounts of water with it and the patient will become profoundly dehydrated. One difference is that these patients still produce and secrete some insulin so some glucose continues to be delivered to the cells, and fat metabolism and ketone production is less of an issue.

13. Patients with hyperglycemic hyperosmolar nonketotic syndrome (HHNS) present with tachycardia, fever, positive orthostatic tilt test, dehydration, polydipsia (excessive thirst), dizziness, poor skin turgor, altered mental status, confusion, weakness, dry oral mucosa, dry and warm skin, polyuria (excessive urination), and nausea and vomiting.

14. Like the DKA patient, the HHNS patient needs to be rehydrated with fluids. It may be necessary to call for advanced life support for this purpose. Your care will include establishing a patent airway and considering oxygen if the breathing is adequate or providing positive pressure ventilations if the breathing is inadequate. If your protocol allows, determine the blood glucose level. If you are unsure about the condition, administer oral glucose if the patient is able to swallow. It is always better to err on the side of hypoglycemia and administer glucose to the patient if the condition is unclear or if your orders instruct you to do so. Finally, contact medical direction for further orders.

CHAPTER 21 • Anaphylactic Reactions

IN REVIEW

1. A cascade of events occurs when a patient is exposed to an antigen that stimulates the immune system to respond. But sometimes the immune system overestimates the danger of the antigen and produces an overwhelming chemical response, leading to life-threatening symptoms. The components of that chemical response, also known as chemical mediators, are what specifically cause life-threatening symptoms. Histamine is an example of a chemical mediator that can cause bronchoconstriction, vasodilation, increased capillary permeability (leaky capillaries), and an increased production of mucus. This results in patients developing dyspnea, wheezing, hypotension, weak pulses, and tachycardia.

2. The first time the body is exposed to a particular antigen, the immune system recognizes it as foreign, kills it, but also forms antibodies in response so it can better fight off the antigen should it ever be encountered again. It’s at this point, when antibodies are being formed in response to the first exposure, that sensitization really occurs because the body is prepared to respond to a subsequent exposure. However, in those people prone to allergic reactions and anaphylaxis, their second (or perhaps subsequent) exposure to the antigen will actually generate an overwhelming response by the immune system instead of an efficient response.

3. Antigens may enter the body by injection (bites, stings, needles, or infusions), ingestion (swallows the substance), inhalation (breathes the substance), or direct contact (absorption through the skin).

4. Of all the causes of anaphylactic reaction, injection, especially intramuscular or intravenous injection, is the most common route and penicillin is the most common cause. Keep that in mind the next time you’re interviewing your
patient about his medical history. It may save his life! Some of the other major causes of anaphylactic reaction are (1) venom from insect bites or stings, such as wasps, hornets, yellow jackets, fire ants, mosquitoes, and spiders (snake venom also fits in this category); (2) foods like nuts, milk, eggs, shellfish, chocolate, and berries; (3) plants that produce pollen, especially ragweed and grasses; (4) medications like penicillin, antibiotics, local anesthetics, aspirin, seizure medications, and muscle relaxants; (5) other substances like glue and latex (many hospitals and EMS systems are using nonlatex gloves and medical supplies because of the danger of patient reaction); and (6) exercise, which is thought to accentuate anaphylactic response when certain foods have been ingested close to the time of exercise.

5. Anaphylaxis may cause the patient to develop stridor or crowing sounds from swelling in the upper airway. Increased mucus production and swelling of the tongue can also obstruct the airway. Wheezing is often prominent. Inserting an airway adjunct may not help if the swelling is at the level of the larynx. If a patient is severely disoriented, unresponsive, or breathing inadequately, immediately begin positive pressure ventilation with supplemental oxygen. If the breathing is adequate, place the patient on a nonrebreather mask with an oxygen flow of 15 liters per minute. Delivery of ventilations may be difficult because of bronchoconstriction, inflammation, increased mucus production, and resistance in the lower airway, so squeezing the BVM may be difficult. You may need to deactivate the pop-off relief valve on the BVM in order to deliver a sufficient tidal volume. Endotracheal intubation may be required, so consider calling ALS backup early if they’ll be needed to help you support your patient.

6. • Skin: warm, tingling feeling in the face, mouth, chest, feet, and hands (early); intense itching, especially of hands and feet (hallmark symptom); hives (hallmark sign); red, flushed skin; swelling to the face, lips, neck, hands, feet, and tongue; cyanosis in severe cases.
• Respiratory system: patient complains of a lump in the throat, tightness in the chest, high-pitched cough, tachypnea (increased breathing rate), labored and noisy breathing, hoarseness or impaired ability to talk, excessive amounts of mucus coughed up, partially or completely occluded airway, difficulty in breathing.
• Cardiovascular system: tachycardia (increased heart rate), hypotension (decreased blood pressure), irregular pulse, absent radial pulse (severe shock).
• Central nervous system: increased anxiety, unresponsiveness, disorientation, restlessness, seizures, headache.
• Gastrointestinal system: nausea/vomiting, abdominal cramping, diarrhea, difficulty in swallowing, loss of bowel control.
• Genitourinary system: urgency to urinate, cramping of the uterus.
• Generalized signs/symptoms: itchy and watery eyes, runny or stuffy nose, sense of impending doom, complaints of “not feeling well,” general weakness or discomfort.

7. The two key categories of signs and symptoms that specifically indicate a severe anaphylactic reaction are airway/respiratory compromise and shock.

8. Treatment for a mild anaphylactic reaction includes maintaining an open airway, providing oxygen, and transporting as soon as possible. Your major concern is that the mild reaction may rapidly progress to a moderate to severe anaphylactic reaction. Patients experience a moderate to severe anaphylactic reaction require immediate and aggressive intervention, including maintenance of a patent airway, suctioning of secretions, and high-concentration oxygen therapy. Be prepared to assist ventilations. Administer epinephrine by a prescribed auto-injector if available and call early for advanced life support when indicated.

9. Epinephrine is the drug of choice for the emergency treatment of a moderate to severe anaphylactic reaction. All of the following criteria must be met before an EMT administers epinephrine by auto-injector to the patient:
1. The patient exhibits signs and symptoms of a moderate to severe anaphylactic reaction, including respiratory distress and/or shock (hypoperfusion), (2) the medication is prescribed to the patient, and (3) the EMT has received an order from medical direction for administration, either on-line or off-line. There are no contraindications for the administration of epinephrine in a life-threatening anaphylactic reaction.

10. To administer the epinephrine by auto-injector: (1) Obtain an order from medical direction, either on-line or off-line. (2) Obtain the patient’s prescribed auto-injector. Check the medication to be sure that the prescription is written for the patient experiencing the anaphylactic reaction and that the medication has not expired, has not become discolored, and does not contain particulates or sediments. Medical direction may order administration of epinephrine that is not prescribed to the patient if the system carries the epinephrine auto-injector on the EMS unit. (3) Remove the safety cap(s) from the auto-injector. (4) Place the tip of the auto-injector against the lateral aspect of the patient’s thigh midway between the hip and knee. (5) Push the injector firmly against the thigh until the spring-loaded needle is deployed and the medication is injected. (6) Hold the auto-injector in place until all of the medication has been injected. (7) Dispose of the single-dose auto-injector in a biohazard container designed for sharp objects.

11. Epinephrine mimics the sympathetic nervous system to constrict blood vessels, improve blood pressure, reduce the leakage from capillaries, relax smooth muscle in the bronchioles to improve breathing, and alleviate the wheezing and dyspnea. The patient may complain of side effects such as increased heart rate; pale skin, especially at the site of injection; dizziness; chest pain; headache; nausea and vomiting; and excitability and anxiousness.

CHAPTER 22 • Toxicologic Emergencies

IN REVIEW
1. Most calls to poison control centers involve children, especially toddlers who inadvertently swallow poisonous substances while exploring their environment.

2. Poisons enter the body by way of ingestion, inhalation, injection, or absorption.

3. Poisoning patients can deteriorate quickly and so it is important to reassess the patient often. Be sure to closely monitor the breathing status and be prepared to ventilate if necessary. Persons poisoned by ingestion may vomit, which may further complicate the airway.

4. You can often gather clues from the environment, the patient, or bystanders to determine whether a poisoning has taken place. Look for clues like empty bottles, spilled chemicals, and overturned plants, or interview others at the scene to determine the nature of the incident.

5. The emergency medical care steps for a poisoning or overdose patient are to take Standard Precautions and establish and maintain a patent airway. Consider oxygen and be prepared to assist ventilations. Position the patient (on left side if altered mental status, on spine board if spinal injury is suspected, otherwise in position of comfort). Contact the poison control center and/or medical direction for treatment. Bring
bottles, labels, plant parts, vomitus, or other evidence of the poisonous substance to the hospital. Consider ALS transport.

6. Even though the literature has suggested activated charcoal reduces absorption of the ingested poison, there is no evidence that suggests a better patient outcome. Thus, activated charcoal is rarely administered by emergency medical service personnel in ingested poisons. Activated charcoal should be only used for a patient who has ingested poisons by mouth, upon specific orders from medical direction and/or the poison control center. Activated charcoal should not be administered to patients who have an altered mental status because of possible aspiration, to patients who have swallowed acids or alkalis (such as hydrochloric acid, bleach, ammonia, or isolated ethanol ingestion), or to patients who are unable to swallow. Unless directed otherwise by medical direction, give both adults and children 1 gram of activated charcoal per kilogram (1 g/kg) of body weight. The usual adult dose is 30–100 grams. The usual dose for infants and children is 12.5–25 grams. To administer activated charcoal, follow these steps: (1) Consult medical direction or the poison control center, according to local protocol, before administering activated charcoal to any patient. (2) Shake the container of activated charcoal thoroughly; if it is too thick to shake, remove the cap and stir it until well mixed. The activated charcoal settles to the bottom of the bottle and needs to be evenly distributed. (3) Activated charcoal looks like mud. The patient may be more willing to drink it if he can’t see it, such as through a straw from a covered opaque container. (4) If the activated charcoal settles, shake or stir it again before letting the patient finish the dose. (5) Record the time and the patient response. (6) If the patient vomits, notify medical direction to authorize one repeat of the dose.

7. The emergency medical care steps for an ingested poisoning or overdose patient are to take Standard Precautions, establish and maintain a patent airway, consider oxygen or provide ventilation if breathing is inadequate, prevent further injury, and consult medical direction during transport. Be sure to use gloves to remove any remaining pills, tablets, capsules, or other fragments from the patient’s mouth, taking care not to injure yourself, and bring the suspected poisons to the receiving facility.

8. The emergency care steps for inhaled poisons are to quickly get the patient out of the toxic environment, place the patient in a supine position or position of comfort, ensure an open and patent airway, start positive pressure ventilation with supplemental oxygen if the patient is not breathing or has inadequate breathing, or administer oxygen by nonrebreather mask at 15 lpm for all inhaled poisonings regardless of the SpO2 reading. Bring all containers, bottles, labels, or other clues about the poisoning agent to the receiving facility (safely).

9. The emergency care steps for injected poisons are to maintain the patient’s airway and begin positive pressure ventilations with supplemental oxygen if the patient’s respirations are inadequate. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. Be alert for vomiting and position the patient in a lateral recumbent position to help prevent aspiration. In the case of a bite or sting, protect yourself from injury and protect the patient from repeated injection. Bring all containers, bottles, labels, or other evidence of poisonous substances to the receiving facility.

10. (a) The emergency care steps for absorbed poisons to the skin are to protect your hands with gloves, move the patient from the source of the poison, and remove the patient’s contaminated clothing and jewelry. Carefully monitor the airway and respiratory status. Begin positive pressure ventilations with supplemental oxygen if the patient’s respirations are inadequate. If breathing is adequate, administer oxygen based on the SpO2 reading and patient signs and symptoms. If the SpO2 reading is greater than 94% and no signs or symptoms of hypoxia or respiratory distress are present, oxygen may not be necessary. Brush any dry chemicals or solid toxins from the patient’s skin, taking extreme care not to abrade the skin or spread the contamination. Contact medical direction to determine whether to flush the contaminated area. (b) If poison has been splashed into the eye, irrigate the affected eye with clean water for at least 20 minutes. If possible, continue irrigation while en route to the receiving facility. Position the patient so water runs away from the unaffected eye, taking care not to spread the contamination.

11. Because drug and alcohol emergencies may mimic other medical conditions, especially stroke or hypothyroidism, you should inspect the area immediately around the patient for evidence of drug or alcohol use. Empty or partially filled pill bottles or boxes, syringes, empty liquor bottles, prescriptions, hospital discharge orders, or physician’s notes might help you identify what drug the patient has taken. Keep all such evidence with the patient since it will be useful for the staff at the poison control center or the emergency department. The odor of alcohol on the patient’s breath or clothing may provide a clue to alcohol abuse, but don’t confuse the fruity or acetone odor that is related to a diabetic emergency with the smell of alcohol. Ask friends, family members, or bystanders what they know about the incident.

12. Calls involving drugs or alcohol often involve physical abuse, violent acts, or sudden changes in behavior that may result in violence toward the EMT. You must practice extra care in making sure the scene is safe. In these situations, it may be prudent to call for police backup early so they are on scene with you in case violence erupts. Constantly remain attentive to the dynamics of the scene and the patient. Be very careful to note the presence of any potential weapons and not to get stuck with a drug abuser’s needle, as most people who share needles also share infectious diseases. Make sure you have taken the appropriate Standard (body substance isolation) Precautions, since alcoholics and drug abusers may have a higher incidence of bloodborne and airborne diseases.

13. The six indicators that a drug or alcohol patient is a high priority for transport are as follows: (1) unresponsiveness, (2) inadequate breathing, (3) fever, (4) abnormal heart rate (slow, fast, weak, or irregular), (5) vomiting with an altered mental status, and (6) seizures.

14. The signs and symptoms of alcohol- and drug-related emergencies vary widely depending on the substance or drug that was abused. Many times the patient abuses more than one substance or drug.

15. Emergency care for an alcohol or a drug emergency includes these steps: (1) Establish and maintain a clear airway. (2) Consider oxygen administration and provide ventilations with supplemental oxygen if breathing is inadequate. (3) Position the patient. (4) Maintain proper body temperature. (5) Assess blood glucose level if your protocol permits. (6) Restrain the patient only if necessary.

CHAPTER 23 • Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies

IN REVIEW

1. The organs contained within the abdominal cavity are the stomach, spleen, liver, gallbladder, small intestine, and part of the large intestine. The kidneys and pancreas are located behind the lining of the abdominal cavity in a cavity called the retroperitoneal space.
2. The quadrants of the abdominal cavity and the organs in each are as follows: Left upper quadrant (LUQ) contains most of the stomach, the spleen, the pancreas, and part of the large intestine. The left kidney is behind the abdominal lining. Right upper quadrant (RUQ) contains most of the liver, the gallbladder, and part of the large intestine. The right kidney is behind the abdominal lining. Right lower quadrant (RLQ) contains the appendix and part of the large intestine. Left lower quadrant (LLQ) contains part of the large intestine.

3. The signs and symptoms of acute abdomen are pain or tenderness, fear and anxiety, a guarded position, rapid and shallow breathing, a rapid pulse from pain or shock, a low or high blood pressure depending on the stage, nausea, vomiting and diarrhea, signs of a rigid abdomen or guarding, a distended abdomen, fever and chills, belching or flatulence, changes in bowel habits or urination, any other signs or symptoms of shock, and other signs of internal bleeding such as vomiting blood or blood in the stool.

4. Factors for high transport priority are poor general appearance, unresponsiveness, responsiveness but not following commands, shock (hypoperfusion), and severe pain.

5. To conduct a physical examination of a patient with acute abdominal pain, determine if the patient is restless or quiet and whether the pain is increased upon movement. Inspect the abdomen to determine if it is distended, and gently palpate the abdominal quadrant with the most painful area last. Assess whether the abdomen feels soft or rigid. Normally, the abdomen should be soft and non-tender. If rigid, determine if guarding is involuntary or voluntary. Assess if the abdomen is tender or nontender. When palpating, note any masses that may be present. Ask if there is pain in other body areas and document the quadrant in which any pain is located.

6. The steps for emergency medical care of a patient with acute abdominal pain are as follows: (1) Keep the airway patent. (2) Place the patient in a position of comfort. If the patient is vomiting or has an altered mental status, place him in a lateral recumbent position. (3) If breathing is adequate, consider oxygen administration based on the SpO2 reading and patient recumbent position. (4) If breathing is inadequate, consider the quadrant in which any pain is located. Ask if there is pain in other body areas and document the quadrant in which any pain is located. (5) Provide emotional support and calmly reassure the patient. (6) Treat for shock if signs of hypoperfusion are present. (7) Initiate a quick and efficient transport and consider ALS based on your protocols.

7. The internal organs of the female reproductive system are the vagina, uterus, ovaries, and fallopian tubes.

8. Common gynecologic conditions that may cause abdominal pain include menstrual pain, vaginal bleeding, sexual assault, ovarian cysts, endometritis, endometriosis, pelvic inflammatory disease, and sexually transmitted diseases.

9. Sexual assault is an act of violence and a crime. It is important to provide emergency care that addresses both the physical needs and the emotional support required by these patients. It is also very important that the victims of sexual assaults are evaluated at the hospital and that any evidence related to the crime is preserved as much as possible. Guidelines for managing these patients include: (1) Ask the patient not to change clothes, bathe, comb, or clean any part of the body. If the clothing was changed, collect, bag it separately, and take it with you. (2) Do not cut through any holes or tears in the patient's clothing. Handle the clothing as little as possible. (3) Do not touch or change anything at the crime scene unless it impedes emergency medical care. (4) Do not clean wounds, if possible. Treat wounds like you would other soft tissue injuries. (5) Do not examine the genital area unless there is a life-threatening hemorrhage. If there is minor bleeding it can be absorbed by a pad. Make sure all bloody articles are collected and transported with the patient. (6) Provide a safe environment for the patient. Always maintain patient confidentiality and only ask questions pertinent to assessment and emergency medical care.

10. The urinary system is composed of the kidneys, ureters, urinary bladder, and urethra.

11. Some of the more common genitourinary emergencies include urinary tract infections, kidney stones, and kidney failure.

12. During your assessment, be sure to note any swelling, redness, pain, unusual odor or color, or bleeding around the site. Before you move and transport the patient you should drain the bag. Record how much urine was in the bag and the time that you emptied it. Make sure there are no kinks in the device and that it's free from anything it could get caught on before you move the patient. After transferring the patient to the cot or bed, make sure that you lower the bag so the urine can freely flow into it.

13. In hemodialysis, a dialysis machine is connected to an access site on the patient and the patient's blood flows through the access site and into the machine to have the waste removed. Hemodialysis is commonly performed at an outpatient dialysis facility, but can be performed in other locations. In peritoneal dialysis, a special fluid used for dialysis (dialysate) is run through a tube into the patient's abdomen. The peritoneal membrane functions as the semipermeable membrane during peritoneal dialysis. The fluid remains in the abdomen for several hours so it can absorb the wastes and then is drained out of the body through a different tube. Peritoneal dialysis is commonly performed at home and is often performed while the patient is sleeping at night.

**CHAPTER 24 • Environmental Emergencies**

**IN REVIEW**

1. The five processes through which the body loses heat are radiation, convection, conduction, evaporation, and respiration.

2. In hypothermia, a person's body loses more heat than it produces or gains, leading to a reduced core temperature. In hyperthermia, a person's body produces or gains more heat than it loses, leading to an increased core temperature.

3. The signs and symptoms of generalized hypothermia include the following: (1) Cool abdominal skin. (2) Decreasing mental status correlating with the degree of hypothermia such as amnesia, memory lapses, and incoherence; mood changes; impaired judgment; reduced ability to communicate; dizziness; loss of coordination, apparent exhaustion or inability to get up after rest, uncontrollable fits of shivering at first with little or no shivering as hypothermia progresses, and reduced sensation or loss of sensation. (4) Changing vital signs such as respiratory changes with rapid breathing at first and then shallow and slow, later proceeding to absent near the end. Pulse changes include a rapid pulse at first, slow and barely palpable pulse later, and irregular or absent pulse near the end. (5) Changes in skin color, from red in early stages, changing to pale; then cyanotic, and finally to gray, waxen, and hard; skin that is cold to the touch. (6) Slowly responding pupils that are typically dilated. (7) Low to absent blood pressure.

4. General guidelines for care include the following: (1) Remove the patient immediately from the cold environment, if possible. (2) Never initiate the thawing procedures if there is any danger of refreezing. Keeping the tissue...
frozen is less dangerous than submitting it to refreezing. (3) Consider oxygen administration based on the SpO₂ patient complaint, and signs and symptoms. The SpO₂ reading may provide an inaccurate reading or no reading due to the severe peripheral constriction of vessels and lack of adequate perfusion from the cold in the extremities. (4) Prevent further injury to the injured part.

5. For a patient whose skin is moist and pale, with normal-to-cool skin temperature, provide the following care: (1) Move the patient to a cool place. (2) Consider oxygen administration based on the SpO₂ patient complaint, and signs and symptoms. Provide positive pressure ventilation if needed. (3) Remove as much of the patient’s clothing as you can; loosen what you cannot remove. (4) Cool the patient by applying cold, wet compresses and/or by misting the patient with water and then fanning lightly. (5) Place the patient in a supine position. Consider raising the feet and legs 8–12 inches in an attempt to improve blood circulation to the brain and other core organs by reducing pooling in the lower extremities. (6) If the patient is fully responsive and not nauseated, have him drink cool water. If the patient is unresponsive or has an altered mental status or is vomiting, do NOT give fluids. For a patient with hot skin who is either moist or dry, immediate intervention is necessary. Cooling the patient takes priority over everything other than airway, breathing, and circulatory management. Provide the following care: (1) Remove the patient from the heat and place him in a cool environment. (2) Remove as much of the patient’s clothing as is possible or reasonable. (3) Consider oxygen administration based on the SpO₂ patient complaint, and signs and symptoms. (4) Immediately begin to cool the patient. Generally, one method alone will not effectively cool the patient, so use a combination of the following four methods: pour tepid water over the patient’s body; and/or place cold packs in the patient’s groin, at each side of the neck, in the armpits, and behind each knee; and/or fan the patient aggressively or direct an electric fan side of the neck, in the armpits, and behind each knee; and/or fan the patient aggressively or direct an electric fan into the axillas, over the lower abdomen, and behind each knee. (5) Be prepared to manage seizures or prevent the aspiration of vomitus. (6) Transport immediately, continuing to administer oxygen and cooling methods during transport.

6. Conditions that would predispose a patient to experience a cold emergency are ambient temperature, wind chill and moisture, age (very young or old), preexisting medical conditions, alcohol, drugs, poisons, duration of exposure, the patient’s clothing, and the activity level of the patient.

7. Conditions that would predispose a patient to experience a heat emergency are the climate, exercise and strenuous activity, extremes in age, preexisting illnesses and medical conditions, use of certain drugs or medications, and lack of acclimation.

8. Active rewarming is a technique of aggressively applying heat to warm a patient's body. Active rewarming may include wrapping the patient in warmed blankets; placing heat packs and hot water bottles on the patient’s groin, in the armpits, and on the chest; and turning up the heat in the patient compartment of the ambulance. Passive rewarming is taking measures to prevent further heat loss and giving the patient’s body the optimum chance to rewarm itself. Passive rewarming can include wrapping the patient in blankets and turning up the heat in the patient compartment of the ambulance.

9. Nervous system: altered mental status; retrograde amnesia; anterograde amnesia; weakness; pain, tingling, and numbness; pale, cool, and clammy skin; temporary paralysis; dizziness; loss of pupillary function; seizures; vertigo.

10. Proceed with care for the lightning strike patient as follows: (1) Ensure the scene is safe; do not become a lightning strike patient yourself. (2) If the patient’s clothes are on fire, put out the fire. (3) Establish in-line manual stabilization. (4) Establish an airway if the patient has an altered mental status. (5) If the patient is in cardiac arrest, immediately begin CPR and attach the AED. Provide aggressive ventilation with a high concentration of oxygen. (6) If the patient has a pulse but is not breathing or not breathing adequately, begin aggressive positive pressure ventilation at 10–12 per minute. Supply high concentrations of oxygen while ventilating. (7) Completely immobilize the patient to a backboard. (8) Transport while continuously monitoring the patient’s condition.

11. Signs and symptoms associated with stings and bites include a history of the bite, pain, redness, swelling, weakness, dizziness, chill, fever, nausea, vomiting, bite marks, and a stinger embedded in the tissue. Be alert for signs and symptoms of developing anaphylactic shock.

12. The general emergency care for a patient suffering from a bite or sting is as follows: Remove the stinger, if still present, by gently scraping against it. Wash the area, and remove any jewelry or other constricting objects. Lower the injection site slightly below the heart. Apply a cold pack to an insect bite or sting but not to snakebites or marine-life stings; apply a constricting band for snakebite if advised by medical direction or local protocol. Observe and provide care for allergic reaction if it develops. Keep the patient calm, limit the patient’s physical activity, and keep the patient warm. Transport.

13. General signs and symptoms of altitude illness are a general ill feeling, a loss of appetite, headache, sleep disturbances, and respiratory distress upon exertion. Patients experiencing acute mountain sickness (AMS) develop symptoms ranging from fatigue to vomiting and altered mental status. Patients experiencing high-altitude pulmonary edema (HAPE) may develop tachycardia, tachypnea, cyanosis, and crackles or wheezes in at least one lobe of the lung. Patients experiencing high-altitude cerebral edema (HACE) often develop ataxia, seizures, and coma.

14. The primary treatment is to stop the ascent and considering moving the patient down to a lower altitude. Administration of supplemental oxygen will relieve the signs and symptoms. In severe cases, it may be necessary to provide positive pressure ventilation with oxygen connected to the ventilation device.

CHAPTER 25 • Submersion Incidents: Drowning and Diving Emergencies

IN REVIEW

1. Children most often drown when the parent or primary caregiver leaves the child alone for less than 5 minutes. In the adult patient, drowning may occur due to alcohol and drug use, hypoglycemia, heart attack from exertion, cardiac dysrhythmias, syncope, seizure disorders, depression or a suicide attempt, anxiety or a panic disorder, arthritis, Parkinson’s disease or another neuromuscular disorder that
CHAPTER 26 • Behavioral Emergencies

IN REVIEW

1. Clues that the problem may be physical rather than psychological include a sudden onset of symptoms (most behavioral problems develop more gradually); if the patient has hallucinations, they are visual but not auditory; the patient has memory loss or impairment (in most behavioral problems, the memory remains intact and the patient is usually alert, being oriented to person, place, and time); the patient’s pupils are dilated, constricted, or unequal, or they respond differently to light; or the patient has excessive salivation, is incontinent, and/or has unusual odors on his breath.

2. Some of the causes that can lead to violence in the behavioral patient include real or perceived patient mismanagement, psychosis, alcohol or drug intoxication, fear, panic, and head injury.

3. When performing an assessment on a patient who has attempted or threatened suicide, make the injury or medical condition related to the suicide attempt your primary concern, listen carefully, accept all the patient's complaints and feelings, do not trust “rapid recoveries” (transport the patient even if he seems to be better), be specific in your actions (do something tangible for the patient such as arranging for a member of the clergy to meet the patient at the hospital), never show disgust or horror when caring for the patient, do not deny that a suicide attempt occurred, and never try to shock a patient out of a suicidal act.

4. When performing an assessment on a patient who has been violent or seems to offer the potential for violence, get a history from bystanders or family, study the patient's posture, listen to the patient, monitor the patient's physical activity, be firm and clear in your directions to the patient, and be prepared to use restraints, if necessary.

5. One or more of these signs and symptoms may indicate a behavioral emergency: fear, anxiety, confusion, behavioral changes, anger, mania, depression, withdrawal, loss of contact with reality, sleeplessness, loss of appetite, loss of sex drive, constipation, crying, tension, and irritability.

6. When providing care for a patient with a behavioral emergency, be alert at all times to the possibility that the patient may become violent and do harm to you, others at the scene, or himself. Your safety is of utmost importance. Assess the patient for trauma or a medical condition and calm the patient and stay with him; never leave a suicidal patient alone. If it’s necessary to protect yourself or others, or the patient from harming himself, use restraints. Transport the patient to a facility where he can get the physical and psychological treatment that is needed.

7. Always restrain a patient in a supine position using “humane restraints” such as padded soft leather or cloth restraints rather than metal handcuffs.

8. Factors that would be considered in determining whether the force used with a patient was reasonable are size and strength of the patient, type of behavior patient exhibits, patient’s mental state, and method of restraint.

9. You must be able to demonstrate that the patient’s threats to hurt himself or others are real to transport a patient without his consent.

10. You can protect yourself against false accusations by thoroughly documenting the entire patient encounter, involving the medical chain of command and law enforcement, documenting witnesses, and, if possible, having witnesses sign the written report of the event.

CHAPTER 27 • Trauma Overview: The Trauma Patient and the Trauma System

IN REVIEW

1. Mass, velocity, acceleration, and deceleration affect the kinetic energy and force of impact. Velocity is a more significant factor than mass. When mass is doubled, kinetic
energy is doubled; when velocity is doubled, kinetic energy is squared. When the rate of either acceleration or deceleration increases, so does the force that is exerted.

2. First the vehicle strikes an object (vehicle collision). Next, the patient comes to a quick stop on parts of the inside of the vehicle (body collision). Finally, the patient’s internal organs strike the internal body and the tissues that support them (organ collision).

3. In motorcycle collisions, the following collisions are typical: (a) head-on impact, when the cycle tends to tip forward due to the location of its center of gravity; (b) angular impact, when the rider strikes an object at an angle; (c) ejection, when the rider clears the handlebars and strikes the object of the collision, the ground, or both; and (d) “laying the bike down,” when the bike is laid on its side with the rider’s inside leg dragging on the pavement or ground.

4. (a) In a feet-first fall, energy travels up the skeletal system, possibly causing fracture of the heels, ankles, knees, hips, pelvis, and/or spine. (b) In a landing on outstretched hands, energy travels up the arms with possible fracture to the wrist, elbow, and/or shoulder. (c) In a head-first fall, energy may travel through the arms to the shoulder; the head and spine may be hyperextended, flexed, or compressed; and there may be injuries to the torso and legs as the body is thrown forward or backward.

5. Sometimes called pathway expansion, cavitation is the cavity in the body tissues formed by a pressure wave resulting from the kinetic energy of a bullet. The cavity formed is larger than the diameter of the projectile itself. A knife does not produce cavitation because it is a low-velocity weapon. A bullet fired from a handgun (medium velocity) or M-16 rifle (high velocity) would produce cavitation.

6. In a blast, the cause of primary-phase injuries is the pressure wave from the blast; the cause of secondary-phase injuries is flying debris propelled by the blast; and the cause of tertiary-phase injuries is the impact of the patient being thrown by the blast.

7. Mechanisms that should cause the EMT to have a high index of suspicion of significant injury are death of another occupant in the vehicle, an unresponsive patient or patient with an altered mental status, intrusion of greater than 12 inches for the occupant site or greater than 18 inches anywhere to the vehicle, and ejection from the motor vehicle.

8. The common designation of trauma centers are Level I (can manage all types of trauma 24 hours a day, 7 days a week), Level II (can manage most trauma with surgical capabilities 24 hours a day, 7 days a week), Level III (has some surgical capability and specially trained emergency department personnel to manage trauma), and Level IV (is typically a small community hospital in a remote area capable of stabilizing seriously injured trauma patients and then transferring them to a higher-level trauma center).

9. According to the National Trauma Triage Protocol published by the Centers for Disease Control (CDC), the Field Triage Decision Scheme suggests that any patient with a Glasgow Coma Score of less than 14, a systolic blood pressure of less than 90, or a respiratory rate of less than 10 or greater than 25 should be taken to a trauma center.

10. The Field Triage Decision Scheme suggests that any patient with the following anatomical injury criteria be transported to a trauma center:
   • All penetrating injuries to head, neck, torso, and extremities proximal to elbow and knee.
   • Fracture.
   • Two or more proximal bone fractures.
   • Crushed, degloved, or mangled extremity.
   • Amputation proximal to wrist or ankle.

11. The Field Triage Decision Scheme suggests that any patient with the following mechanism of injury criteria be transported to a trauma center:
   • Falls (adults >20 feet, and children >10 feet or 2–3 times the height of the child).
   • High-risk auto crash, including intrusion >12 inches occupant site or >18 inches any site; ejection from automobile; death in same passenger compartment; and vehicle telemetry data consistent with high risk injury.
   • Auto versus pedestrian/bicyclist thrown, run over, or significant (>20 mph) impact.
   • Motorcycle crash >20 mph.

CHAPTER 28 • Bleeding and Soft Tissue Trauma

IN REVIEW

1. Arterial bleeding is bright red, spurting blood. Venous bleeding tends to be dark red, steadily flowing blood. Capillary bleeding is dark red, slowly oozing blood.

2. The primary mechanism of controlling external bleeding is by direct pressure. This is usually accomplished by placing a sterile gauze pad or dressing over the injury site and applying fingertip pressure directly to the point of bleeding. Large, gaping wounds may require packing with sterile gauze and the application of direct hand pressure, if fingertip pressure fails. If severe bleeding persists while direct pressure is being applied over dressings, remove dressings and apply direct pressure to the point of bleeding, typically directly to the vessel that is bleeding.

3. If bleeding is not controlled with direct pressure, the next step is to apply a tourniquet as follows: (1) Use a device that is 4 inches wide and four to six layers thick. Many commercial tourniquets are now available. (2) Wrap it around the extremity at a point just proximal to the bleeding but as distal on the extremity and as close to the injury as possible. Do not cover the wound with the tourniquet. (3) Tighten the tourniquet until the hemorrhage ceases. (4) Secure the tightening rod or device. (5) Write the time of tourniquet application on tape and secure it to the tourniquet (example is TK 13:32). Never cover the tourniquet or site of bleeding. Continuously reassess the wound for recurrent bleeding. (6) Notify the receiving medical facility that a tourniquet has been applied. (7) Document the use of the tourniquet and the time it was applied in the prehospital care report.

4. In some cases, an inflated blood pressure cuff may be used as a tourniquet until bleeding stops.

5. The two most common sources of internal bleeding are injured or damaged organs and fractured extremities, especially the femur, hip, or pelvis.

6. Take Standard Precautions and maintain an open airway and adequate breathing. Administer oxygen and provide...
artificial ventilations as necessary. Control external bleeding with direct pressure. If direct pressure is unsuccessful in controlling the bleeding, apply a tourniquet. Splint any extremity that you suspect is fractured. Initial splinting can be achieved by the long backboard when expeditious transport is critical. Provide immediate transport to critical or unstable patients and those with signs and symptoms of hypovolemic shock. Provide emergency care for shock.

7. The signs and symptoms of shock are mental status changes such as restlessness and anxiety. Watch for perfusion problems such as pale, cool, clammy skin; weak, thready, or absent peripheral pulses; and delayed capillary refill. It often takes as much as a 15 percent blood loss to affect the vital signs, but watch for an increased pulse rate (early sign); a weak and thready pulse (early sign); an increased breathing rate (early sign) that may be deep or shallow, labored, and irregular; a decreased blood pressure (late sign); and a narrow pulse pressure. Other signs and symptoms include dilated pupils (sluggish reaction), marked thirst, nausea and vomiting, and pallor with cyanosis to the lips.

8. Emergency medical care of hypovolemic shock is as follows: (1) Maintain Standard Precautions. (2) Maintain an open airway. If breathing is adequate, administer oxygen via nonrebreather mask at 15 lpm. If breathing is inadequate, begin positive pressure ventilation with supplemental oxygen connected to the ventilation device. (3) Control any external bleeding using the techniques described in this chapter. (4) Apply and inflate the pneumatic antishock garment (PASG) in accordance with local protocols and if approved by medical direction. Carefully follow appropriate indications for PASG use. (5) Place the patient in a supine position. (6) Splint suspected bone or joint injuries. In the hypovolemic shock patient, transport is critical. Thus, the fractures will be initially stabilized by the long backboard. (7) Use a blanket to cover any patient suspected of suffering hypovolemic shock to prevent loss of body heat. Warm the patient compartment to 85°F during transport to prevent body heat loss. Remove any wet or blood-soaked clothes. (8) Transport the patient immediately.

9. Three types of closed soft tissue injuries are (1) a contusion, or bruise; (2) a hematoma, similar to a contusion except it usually involves damage to a larger blood vessel and a larger amount of tissue; and (3) a crush injury, which may be closed or open.

10. The general signs and symptoms of closed soft tissue injuries include swelling, pain, and discoloration at the injury site, with the potential of internal bleeding and signs and symptoms of bleeding and hypovolemic shock if the underlying organs are injured.

11. The general emergency medical care for closed soft tissue injuries includes taking Standard Precautions; ensuring an open airway and adequate breathing; treating for shock (hypoperfusion), if necessary; and splinting painful, swollen, deformed extremities.

12. Six types of open soft tissue injuries are abrasions, lacerations, avulsions, penetrations/punctures, amputations, and crush injuries. Abrasions are generally caused by scraping, rubbing, or shearing away the outermost layer of the skin (epidermis). Lacerations are breaks in the skin caused by forceful impact with a sharp object. An avulsion is a loose flap of skin and soft tissue that has been torn loose or pulled completely off. A penetration or puncture wound generally is the result of a sharp, pointed object being pushed or driven into the soft tissue. Amputations involve a disruption in the continuity of an extremity or other body part as the result of ripping or tearing forces. Crush injuries are usually the result of blunt trauma or crushing forces.

13. The signs and symptoms of open soft tissue injuries include a break in the skin and external bleeding, localized swelling, pain and discoloration at the injury site, and possible signs and symptoms of internal bleeding and hypovolemic shock.

14. The general emergency medical care for open soft tissue injuries includes taking Standard Precautions, ensuring an open airway and adequate breathing, exposing the wound, controlling bleeding with direct pressure, preventing further contamination, dressing and bandaging the wound, keeping the patient calm and quiet, treating for hypovolemic shock, and transporting.

15. Special considerations that must be taken when providing emergency medical care to patients with the following injuries are:
- Penetrating chest wounds: use a commercial seal (Asherman chest seal) or an occlusive dressing to prevent air from entering the chest cavity through the wound; leave one side untaped to allow air to escape as the patient exhales. The patient may assume a position of comfort if there is no suspected spinal injury; however, spinal injury should be suspected with any significant mechanism of injury to the chest.
- Abdominal evisceration: avoid touching or trying to replace the abdominal organs; cover the exposed organs with a moistened sterile dressing, an occlusive dressing, additional layers of bulky dressings, and a bandage; flex the patient’s hips and knees if they are uninjured and if spinal injury is not suspected. However, suspect spinal injury with any significant mechanism of injury to the abdomen. Do not use the abdominal portion of the PASG if it is used in your system.
- Impaled object: manually secure the object, expose the wound area, control bleeding, and use a bulky dressing to help stabilize the object during transport.
- Amputated part: wrap the part in a dry, sterile gauze dressing, then wrap or bag it in plastic, keep it cool, and transport the part with the patient.
- Large open injury to the neck: cover the wound with a gloved hand, apply an occlusive dressing covered by a regular dressing, apply pressure to control bleeding, apply a pressure bandage, and provide care for suspected spinal injury.

16. A dressing covers an open wound to aid in the control of bleeding and to prevent further damage or contamination. In most cases, the dressing should be sterile. Common types of dressings include universal or multitrauma dressings, gauze pads, adhesive-type dressings, and occlusive dressings.

17. A bandage is used to hold or secure a dressing in place. Common types of bandages include self-adhering bandages, gauze rolls, triangular bandages, and air splints.

18. A pressure dressing is used to maintain control of bleeding. To apply a pressure dressing, cover the wound with several sterile gauze dressings or a bulky dressing. Apply hand pressure over the wound until the bleeding is controlled. Bandage firmly to create enough pressure to maintain control of the bleeding. Check distal pulses to be sure the bandage is not too tight. If blood soaks through the original dressing and bandage, remove them and apply fingertip pressure. When bleeding is under control, apply dressings and bandage over the wound again.

CHAPTER 29 • Burns

IN REVIEW

1. Superficial burns involve only the epidermis and are characterized by pink or red, dry skin and slight swelling. Partial-thickness burns involve not only the epidermis but portions of the dermis as well. Depending on severity, they...
are characterized by thin-walled blisters and pink, moist, soft and tender skin or thick-walled blisters that often rupture with red and blanched white skin and poor capillary refill at the burn site. The patient can still feel pain. Full-thickness burns are characterized by dry, hard, tough, and leathery skin that may appear white-waxy to dark brown or black and charred (eschar). These are usually painless due to nerve-end damage.

2. The rule of nines is a standardized way to identify the amount of skin surface that is burned. In an adult, the head and neck, each upper extremity, the chest, the abdomen, the upper back, the lower back, the anterior of each lower extremity, and the posterior of each lower extremity each represent 9%. The genital region represents a 1% body surface area (BSA). In infants the head and neck are counted as 18%, the chest and abdomen as 18%, the entire back as 18%, each upper extremity as 9%, and each lower extremity as 14%. For children over the age of 1 year, add 0.5% to each leg and subtract 1% for the head for each year beyond age 1.

3. Using the rule of nines, (a) a 4-year-old child with superficial burn injuries to the front and back of both legs as well as the chest, abdomen, and back has a BSA burned of 67%; (b) an adult with partial-thickness burn injuries to the front of one lower extremity and the front and back of the other has a BSA burned of 27%.

4. The burn severity classification for patient (a) is critical, and for patient (b) is moderate.

5. Basic emergency medical care steps for a burn injury are as follows: (1) remove the patient from the source of the burn and stop the burning process with water or saline; (2) establish and maintain airway and breathing and administer oxygen or provide positive pressure ventilation with supplemental oxygen as necessary; (3) classify the severity of the burn and transport immediately if critical; (4) cover the burned area with a dry, sterile dressing or burn sheet; (5) keep the patient warm and treat other injuries as needed; and (6) transport to an appropriate facility according to local protocols.

6. When dressing a burn, avoid using any material that shreds or leaves particles; never apply any type of ointments, lotions, or antiseptics; and never attempt to break or drain blisters.

7. Always protect yourself from exposure to hazardous materials. Wear gloves and eye protection at a minimum. Brush off dry powders prior to flushing with water, and immediately begin to flush with large amounts of water. Continue flushing the contaminated area for at least 20 minutes while en route to the receiving facility, taking care not to contaminate uninjured areas when flushing.

8. Never attempt to remove the patient from the electrical source unless properly trained to do so. If the patient is still in contact with the electrical source (or you are unsure), do not touch the patient. Consider oxygen administration or provide positive pressure ventilation with supplemental oxygen if indicated. Monitor the patient for cardiac arrest, be prepared to provide CPR, and have AED available, if possible. Assess the patient for muscle tenderness with or without twitching or seizure activity. Treat all soft tissue injuries associated with the burn and look for both entrance and exit injuries. Transport as soon as possible.

2. In a closed bone injury the skin over the fracture site is intact. In an open bone injury an open wound is associated with the fracture.

3. You might suspect a bone or joint injury with any of the following signs: pain, tenderness, deformity, discoloration, paresthesia distal to the fracture site, loss of feeling distal to the fracture site, paresis (weakness), paralysis, and an inability to move the extremity. A decreased pulse amplitude, increased capillary refill time, paresthesia, or pale, cool skin distal to the fracture site may indicate vessel injury.

4. Splinting reduces pain and minimizes complications. Splinting prevents damage from the movement of any bone fragments, bone ends, or dislocated joints, reducing the chance for further injury.

5. The emergency medical care steps for treating a bone or joint injury are to take Standard Precautions, administer oxygen if indicated based on the SpO2 reading, patient complaints, and signs and symptoms, maintain spinal stabilization if spine injury is suspected, splint bone and joint injuries, apply cold packs, elevate the extremity if spinal injury is not suspected, and transport. Assess pulse, motor, and sensory function distal to the injury site both before and after splinting.

6. The general rules for splinting a bone or joint injury are the following: Assess distal pulse, motor function, and sensation both before and after splinting. Immobilize the joints both above and below a long bone injury or the bones above and below a joint injury. Remove or cut away clothing and jewelry. Cover all wounds, including open fractures, with a sterile dressing. If there is a severe deformity or the distal extremity is cyanotic or lacks pulses, align with gentle traction before splinting. Do not align if pain, resistance, or crepitus increase. Generally do not align a wrist, an elbow, a knee, or a shoulder. Never try to push bone ends back underneath the skin. Pad splints. Maintain manual traction until after the splint is applied. When in doubt, splint the injury. If the patient shows signs of shock, align the patient in the normal anatomical position. Treat for shock and transport immediately without taking the time to apply a splint. If the femur or pelvis is suspected to be fractured, splinting should be considered as a bleeding control measure. Splint the femur or pelvis at the scene only if enough resources are present so that a delay in transport does not occur.

7. Complications that can arise from improper splinting of a bone or joint are nerve tissue and blood vessel compression under the splint; transport delay in patients with life-threatening conditions; reduction of distal circulation; possible aggravation of bone or joint injuries; and damage to tissues, nerves, blood vessels, or muscles due to excessive movement.

8. In general, you should not use a traction splint if the injury is within 1–2 inches of the knee or ankle, the knee itself has been injured, the hip has been injured, the pelvis has been injured, there is partial amputation or avulsion with bone separation, and the distal limb is connected only by marginal tissue.

CHAPTER 30 • Musculoskeletal Trauma and Nontraumatic Fractures

IN REVIEW

1. The musculoskeletal system functions to give the body shape, protect the internal organs, provide for movement, store salts and other materials needed for metabolism, and produce red blood cells necessary for oxygen transport.

2. In a closed bone injury the skin over the fracture site is intact. In an open bone injury an open wound is associated with the fracture.

3. You might suspect a bone or joint injury with any of the following signs: pain, tenderness, deformity, discoloration, paresthesia distal to the fracture site, loss of feeling distal to the fracture site, paresis (weakness), paralysis, and an inability to move the extremity. A decreased pulse amplitude, increased capillary refill time, paresthesia, or pale, cool skin distal to the fracture site may indicate vessel injury.

4. Splinting reduces pain and minimizes complications. Splinting prevents damage from the movement of any bone fragments, bone ends, or dislocated joints, reducing the chance for further injury.

5. The emergency medical care steps for treating a bone or joint injury are to take Standard Precautions, administer oxygen if indicated based on the SpO2 reading, patient complaints, and signs and symptoms, maintain spinal stabilization if spine injury is suspected, splint bone and joint injuries, apply cold packs, elevate the extremity if spinal injury is not suspected, and transport. Assess pulse, motor, and sensory function distal to the injury site both before and after splinting.

6. The general rules for splinting a bone or joint injury are the following: Assess distal pulse, motor function, and sensation both before and after splinting. Immobilize the joints both above and below a long bone injury or the bones above and below a joint injury. Remove or cut away clothing and jewelry. Cover all wounds, including open fractures, with a sterile dressing. If there is a severe deformity or the distal extremity is cyanotic or lacks pulses, align with gentle traction before splinting. Do not align if pain, resistance, or crepitus increase. Generally do not align a wrist, an elbow, a knee, or a shoulder. Never try to push bone ends back underneath the skin. Pad splints. Maintain manual traction until after the splint is applied. When in doubt, splint the injury. If the patient shows signs of shock, align the patient in the normal anatomical position. Treat for shock and transport immediately without taking the time to apply a splint. If the femur or pelvis is suspected to be fractured, splinting should be considered as a bleeding control measure. Splint the femur or pelvis at the scene only if enough resources are present so that a delay in transport does not occur.

7. Complications that can arise from improper splinting of a bone or joint are nerve tissue and blood vessel compression under the splint; transport delay in patients with life-threatening conditions; reduction of distal circulation; possible aggravation of bone or joint injuries; and damage to tissues, nerves, blood vessels, or muscles due to excessive movement.

8. In general, you should not use a traction splint if the injury is within 1–2 inches of the knee or ankle, the knee itself has been injured, the hip has been injured, the pelvis has been injured, there is partial amputation or avulsion with bone separation, and the distal limb is connected only by marginal tissue.

CHAPTER 31 • Head Trauma

IN REVIEW

1. The central nervous system is composed of the brain and the spinal cord.

2. The meninges are layers of tissue that enclose and protect the brain. They are the dura mater, the arachnoid layer, and the pia mater.

3. The three parts of the brain are the cerebrum, the cerebellum, and the brainstem.

4. An open head injury involves a break in the skull, such as that caused by impact with a windshield or by an impaired
object. It involves direct local damage to the involved tissue, but it can also result in brain damage due to infection, laceration of the brain tissue, or punctures of the brain by objects that invade the cranium after penetrating the skull. In cases of closed head injury the scalp may be lacerated but the skull remains intact and there will be no opening to the brain. Brain damage within the intact skull can be extensive. The amount of injury depends mainly on the mechanism of injury and the force involved.

5. Other injuries that may be present include airway problems, cervical spine injury, and both internal and external bleeding.

6. Major types of brain injury include concussion, contusion, subdural hematoma, epidural hematoma, laceration, and brain herniation.

7. Determining a baseline level of responsiveness is important in cases of head injury because the level of responsiveness may deteriorate and indicate a sign of a serious problem.

8. A history is important in cases of head injury because the history can provide vital information about the mechanism, course, and seriousness of the injury.

9. The signs and symptoms of head injury include altered mental status; decreasing mental status; irregular breathing patterns; increasing blood pressure and decreasing pulse (also known as Cushing reflex); obvious signs of injury or pain to the head; blood or cerebrospinal fluid leaking from the ears or nose; discoloration around the eyes in the absence of eye trauma (raccoon sign); discoloration behind ears (Battle sign); poor or absent motor or sensory function; nausea and/or vomiting; unequal pupil size with altered mental status; seizures; visible damage to the skull (through laceration in the scalp); pain, tenderness, or swelling at the site of injury; and nonpurposeful response to painful stimuli.

10. The steps of emergency medical treatment in cases of head injury are: (1) Take Standard Precautions before handling the patient. (2) Maintain manual, in-line spinal stabilization. (3) Maintain a patent airway with adequate breathing and adequate oxygenation or provide positive pressure ventilation with supplemental oxygen. Maintain the SpO2 monitor at 94% or greater if possible. (4) Consider controlled hyperventilation at a rate of 20 breaths per minute only if signs of severe head injury and brain herniation are present. (5) Monitor the airway, breathing, pulse, and mental status for deterioration. (6) Control bleeding. (7) Be prepared to manage seizure activity. (8) Transport immediately.

11. Signs and symptoms specific to brain herniation are dilated or sluggishly pupil on one side, weakness or paralysis, severe alteration in consciousness, abnormal posturing, abnormal ventilatory patterns, and Cushing reflex (an increased systemic blood pressure and decreased heart rate).

CHAPTER 32 • Spinal Column and Spinal Cord Trauma

IN REVIEW

1. The vertebrae of the spinal column sheathe and protect the spinal cord, which carries nerve impulses from the brain to other parts of the body through nerve bundles.

2. The most common mechanisms of spine injury are compression, flexion, extension, rotation, lateral bending, distraction, and penetration.

3. The signs and symptoms of potential spine injury are tenderness in the area of injury, especially along the spinal column; localized pain; pain independent of movement or palpation along the spine or in the lower legs; obvious deformity of the spine; soft tissue injuries; numbness, weakness, or tingling in the arms and/or legs; loss of sensation or paralysis of the extremities; incontinence; priapism; and impaired or diaphragmatic breathing.

4. In cases of suspected spine injury, you must apply manual, in-line stabilization from initial patient contact until the patient is fully immobilized with a head/cervical immobilization device and straps to a backboard.

5. To manage the airway in a patient with a suspected spine injury, after in-line spinal stabilization is applied, open the airway with a jaw-thrust maneuver. Insert an oropharyngeal or nasopharyngeal airway, if necessary. Suction the airway instead of turning the patient’s head for drainage. Because breathing problems are common in such cases, be prepared to provide positive pressure ventilation.

6. The cervical spine immobilization collar prevents the head from moving in relation to the spine and reduces compression of the cervical spine during movement of the patient; it does not immobilize the patient.

7. To assess motor function, check upper extremities by having a patient grip your fingers with both hands; check lower extremities by having him push both his feet against your hands. To assess sensory function, touch the patient’s hands and feet lightly out of his sight; if the patient can’t detect the touches, pinch the hand and/or foot.

8. For seated patients with suspected spine injuries, the patient is first immobilized to the short device to prevent aggravation of the injury as he is moved to a supine position for full immobilization to a long device.

9. Rapid extrication is appropriate only in situations where the scene is not safe, where the patient’s condition is so unstable that you need to move and transport him immediately, or where the patient blocks access to others more seriously injured.

10. A helmet should be left on the patient if it fits well and there’s little movement of the patient’s head inside the helmet, there are no impending airway or breathing problems, there is no difficulty in accessing the airway if problems arise, there is no interference with patient immobilization, or removing the helmet would cause further injury.

11. The patient presents with the inability to move or feel sensations of pain, light touch, and crude pressure below the level of injury. The patient will also likely present with a loss of bowel and bladder control as the autonomic function is blocked.

12. The patient may present with conflicting or confusing signs of spinal cord injury. The patient may be able to move in some areas of the body and not move in other areas of the body, or the patient may retain the sensation of pain to some areas of the body but not to other areas of the body. Unlike a complete spinal cord injury where there is complete loss of motor and sensory function below the level of injury, the incomplete spinal cord injury will produce only loss of some function in some areas of the body.

CHAPTER 33 • Eye, Face, and Neck Trauma

IN REVIEW

1. Emergency care that may need to be undertaken during the primary assessment of eye, face, or neck injuries includes spinal stabilization, care for airway and breathing, and control of severe bleeding. Patients with chemical burns to the eye, an impaled object in the eye, an extruded eyeball, or severe injuries to the neck must be considered a high priority for immediate transport.

2. ALS backup may be needed for injuries to the eyes, face, and neck because advanced airway procedures may be required.

3. When you conduct the physical exam of a patient with an eye injury, assess the eyes separately and together with
a small penlight to evaluate the orbits, lids, conjunctivae, globe, and pupils (for size, shape, equality, and reactivity to light). Ask the patient to follow movements of your finger in all directions to check for abnormal gaze, paralysis of gaze, or pain on movement.

4. The basic treatment guidelines for all eye injuries are as follows: (1) If the eye is swollen shut, avoid any unnecessary manipulation in examining the eye. (2) Do not try to force the eyelid open unless you have to wash out chemicals. (3) Consult medical direction or local protocol before irrigating. (4) Do not put saline or medicine in an injured eye. (5) Do not remove blood or blood clots from the eye. (6) Have the patient lie down and keep quiet. (7) Limit use of the uninjured eye by covering it along with the injured eye. (8) Give the patient nothing by mouth. (9) Transport every patient with an eye injury for evaluation by a physician. (10) Never apply direct pressure to an injured eye.

5. (a) For a foreign object located on the white of the eye, pull down the lower lid while the patient looks up or pull up the upper lid while the patient looks down. Then remove the foreign object with a piece of sterile gauze. (b) For a foreign object located under the upper eyelid, draw the upper lid down over a cotton swab or similar object, and remove the object with the corner of a piece of sterile gauze. (c) For a foreign object lodged in the eyeball, do not attempt removal. Place a bandage over both eyes and transport.

6. In all chemical burns of the eye, begin immediate, continuous irrigation for at least 20 minutes (at least 60 minutes for an alkali burn) with water or saline with water running from the inside corner to the outside. Continue irrigation en route to the hospital.

7. Remove contact lenses if there has been a chemical burn to the eye, if the patient is unresponsive and is wearing hard contact lenses, and if transport time will be lengthy or delayed. Do not remove contact lenses if the eyeball is injured (other than a chemical burn) or if transport time is short.

8. The general emergency medical care guidelines for injuries to the face, mouth, and jaw are the following: Use Standard Precautions; manually stabilize the spine; establish a patent airway; consider oxygen administration or provide positive pressure ventilation with supplemental oxygen as necessary; control severe bleeding; cover any exposed nerves, tendons, or blood vessels with a moist, sterile dressing; if a tooth has been lost, try to find it, rinse it with saline, and transport in sterile saline-soaked gauze; treat for shock; and transport. Consider requesting ALS backup if advanced airway procedures may be needed.

9. For a foreign object in the nose or ear, reassure the patient (and parents if the patient is a child) and transport the patient to the hospital for removal of the object.

10. In addition to obvious lacerations or wounds, signs and symptoms of an injured neck include obvious swelling or bruising, difficulty speaking, loss of the voice, airway obstruction that is not obviously due to other sources, crepitation heard during speaking or breathing as air escapes from an injured larynx, and displacement of the trachea to one side.

CHAPTER 34 • Chest Trauma

1. Two general categories of injuries to the chest are open and closed. An open chest injury is the result of a penetrating chest wound, which can cause damage to tissues and organs along the path of penetration or (in the case of a bullet) cause extensive internal damage throughout the chest cavity. A closed chest injury occurs when blunt trauma is applied to the chest but no open wound results. An injury to the lung, heart, great vessels (aorta and vena cava), respiratory tract, diaphragm, and esophagus can result from blunt injury.

2. Signs and symptoms associated with major chest trauma are cyanosis to the fingertips or face; dyspnea; breathing rate that is faster or slower than normal; shallow breathing, contusions, lacerations, punctures, swelling, or other obvious signs of trauma; coughing up frothy blood; signs of shock (hypoperfusion); decreasing blood pressure with an increasing pulse that becomes weaker; tracheal deviation; paradoxical movement of a segment of the chest wall; open wound that may or may not produce a sucking sound; distended jugular veins; absent or decreased breath sounds upon auscultation; pain at the injury site, especially pain that increases with inhalation and exhalation; failure of the chest to rise during inhalation; peripheral pulses that become extremely weak or become absent during inhalation; and a systolic blood pressure that drops by 10 mmHg or more during inhalation.

3. General guidelines for emergency medical care of trauma to the chest are as follows: Maintain an open airway. Administer oxygen based on Spo2 reading, patient complaint and signs and symptoms, and patient condition. Reevaluate breathing status, remaining alert for sudden and rapid deterioration. If, at any time, signs of inadequate breathing appear, immediately begin positive pressure ventilation with supplemental oxygen. Stabilize any impaled object. Completely immobilize the patient if spinal injury is suspected. Treat the patient for shock if signs and symptoms are present.

4. (a) For an imaged object to the chest, stabilize the object in place with bulky gauze and bandages. (b) An open wound to the chest should be immediately sealed with a gloved hand, and then with an occlusive dressing. Tape the dressing on three sides to allow air from the thoracic cavity to escape during exhalation (or on four sides, lifting a corner to relieve pressure as necessary). Continually assess the patient's respiratory status. (c) A flail segment (paradoxical movement) should be splinted in an inward position by placing a hand over the unstable flail segment; or by placing bulky dressings, a pillow, or towels over the unstable segment; or by securing the patient's arm to the body. If the patient's breathing is inadequate, initiate positive pressure ventilation.

5. A pneumothorax occurs when air enters the pleural space, causing collapse of the lung. An open pneumothorax is an open wound to the chest that allows air to enter the pleural space and causes the lung to collapse. A tension pneumothorax occurs when the pleural space fills with blood, causing the lung to collapse. A tension pneumothorax occurs when an open wound in the chest occurs and a buildup of air and pressure on the injured side of the thoracic cavity becomes so severe that it begins to shift the heart, lungs, and large blood vessels toward the body's uninjured side, resulting in compression of those organs.

CHAPTER 35 • Abdominal and Genitourinary Trauma

IN REVIEW

1. Signs and symptoms associated with trauma to the abdomen are contusions, abrasions, lacerations, punctures, other signs of blunt or penetrating trauma; pain that may initially be mild, then worsening; tenderness on palpation to areas other than the injury site; rigid abdominal muscles; patient lying with legs drawn up to the chest
an attempt to reduce the pain; distended abdomen; discoloration around the umbilicus or to the flank (late finding); rapid, shallow breathing; signs of shock; nausea and vomiting (the vomitus may contain blood); abdominal cramping possibly present; pain may radiate to either shoulder; and weakness.

2. General guidelines for emergency medical care of both open and closed abdominal injuries include the following: Take appropriate spinal precautions. Maintain an open airway, performing a jaw-thrust maneuver and inserting an oropharyngeal or nasopharyngeal airway if the patient’s airway, performing a jaw-thrust maneuver and inserting an oropharyngeal or nasopharyngeal airway if the patient’s condition deteriorates. Consider oxygen administration based on the SpO2 reading, patient complaints, and signs and symptoms. Reassess the breathing status and, if inadequate, begin positive pressure ventilation. Treat for shock (hypoperfusion). Control any external bleeding. Position the patient in a supine position with legs flexed at the knees. Stabilize any impaled objects. Apply a pneumatic antishock garment (PASG) if indicated and allowed by local protocol. Transport as quickly as possible.

3. Emergency medical care for an abdominal evisceration is to follow the general guidelines for abdominal injury, except dress the evisceration in the following way: Expose the wound, cutting away clothing as necessary. Position the patient on his back and flex the legs up toward the chest if spinal injury is not suspected. Prepare a clean, sterile dressing by soaking it with saline or sterile water. Apply the dressing over the protruding organs. Do not use absorbent cotton or any other material that might cling to the organs when wet, such as paper towels or toilet tissue. Cover the moist dressing with an occlusive dressing to retain moisture when wet, such as paper towels or toilet tissue. Cover the moist dressing with an occlusive dressing to retain moisture and warmth. Consider oxygen administration based on the SpO2 reading, patient complaints, and signs and symptoms.

4. General emergency care for injuries to male genitalia is as follows: Treat as a soft tissue injury, and control bleeding with direct pressure. Apply cold compresses to the scrotum to reduce pain and swelling. If the penis has been avulsed or amputated, apply direct pressure to control bleeding. Locate the amputated or avulsed part, wrap it in sterile dressing moistened with sterile saline, place it in a plastic bag, and keep it cool by placing it on a cold pack or ice that has been wrapped in a towel. Consider oxygen administration based on the SpO2 reading, patient complaints, and signs and symptoms. Carefully assess for signs and symptoms of shock. Transport the patient with any amputated parts. General emergency care for injuries to female genitalia is as follows: Control bleeding with direct pressure, using moistened compresses such as a sanitary napkin. Do not pack or place dressings inside the vagina. Carefully assess for signs and symptoms of shock. Consider oxygen administration based on the SpO2 reading, patient complaints, and signs and symptoms. Transport.

**CHAPTER 36 • Multisystem Trauma and Trauma in Special Patient Populations**

**IN REVIEW**

1. The following golden principles relating to prehospital multisystem trauma care are essential to keep in mind when you manage patients with multisystem trauma: ensure safety of the rescue personnel and the patient, determine additional resources needed, understand kinematics, identify and manage life threats, manage the airway while maintaining spinal stabilization, support ventilation and oxygenation, control external hemorrhage and treat for shock, perform a secondary assessment and obtain a medical history, splint musculoskeletal injuries and maintain spinal immobilization on a long spine board, and make transport decisions.

2. Realize that you have two patients when dealing with a pregnant trauma patient: the mother and the fetus. Because it’s difficult to assess the fetus, it is important to treat the mother aggressively, especially if there is severe trauma. Some considerations for a pregnant trauma patient include: • Full spinal immobilization is required for pregnant patients suspected of having spinal injuries but you will need to tilt the board to the left to prevent supine hypotensive syndrome. • Airway, ventilation, and oxygenation are critical to the pregnant trauma patient. Anticipate vomiting and have suction readily available. Assist the patient’s ventilations if they are inadequate. Administer oxygen by nonrebreather mask if the breathing is adequate or via the bag-valve mask in the inadequate breathing patient. Administer supplemental oxygen to maintain the SpO2 reading as high as possible. Attempt to achieve 100% oxygen concentration delivery. • Assess the patient’s circulation and check for major bleeding. If vaginal bleeding is present, absorb the blood flow with a pad and do not pack the vagina. Anticipate, prevent, and treat shock. • Perform a visual exam at the vaginal opening to assess for crowning or bleeding. If labor occurs as a result of the trauma, you will want additional resources to help you manage both the mother and the newborn. • Consider ALS intercept or air medical transport for major traumas involving pregnant patients. Inform the trauma center as soon as possible that the patient involved in the trauma is pregnant.

3. Physiological changes in older patients make them more susceptible to trauma. Circulation changes can lead to the inability to maintain vital signs during hemorrhage, and their blood pressure may drop sooner. There is a higher risk of cerebral bleeding following head trauma, and skeletal changes can cause curvature of the upper spine that may require padding during supine spinal immobilization. Many elderly patients have osteoporosis, making them more susceptible to fractures. Decreased muscle size in the abdomen may mask abdominal trauma in the elderly. Soft tissue injuries are also common in the elderly, because their skin is thinner.

4. The following conditions may result in cognitive impairments: Alzheimer’s disease, vascular dementia, Down syndrome, autistic disorders, brain injuries, and strokes.

5. Patients with cognitive impairments are often poor historians of their past medical history or events of the trauma, and the psychological implications of trauma may be different in this population. You should understand that many of these patients may not know what is happening even before the trauma. They may be confused or upset and their pain perception may be altered. This may alter some of the normal responses associated with injury.

6. Because of the cardiovascular changes in the pregnant patient, the signs of maternal hypotension resulting from traumatic bleeding may be delayed or masked. Elderly patients who were hypertensive prior to an injury may have normal blood pressures when they are in shock.

7. Pediatric patients have anatomical and physiological differences that make them more susceptible to certain traumatic forces. The child’s body surface area is greater than adults and therefore can lose heat faster. Pediatric patients have heavy heads and weak neck muscles that increase their risk of head and cervical spinal injuries. Their internal organ placement makes them more susceptible to injuries such as those involving the spleen and liver. Infants and children also have greater chest wall flexibility than adults which can
allow for injuries with few external signs of trauma. You must look closely for signs and symptoms of a flail chest in pediatric trauma patients, and maintain a high index of suspicion that severe underlying trauma exists. The growth plates in children are not fully developed and trauma to these plates may impact the bones’ normal growth. Children also have higher energy requirements and can fatigue faster than adults.

8. Preexisting medical conditions may affect the traumatic injuries sustained by the elderly. Multiple medications are more common in this age group and may also affect the patient assessment and patient outcome. Medications can especially affect the patient's vital signs and blood clotting capabilities.

CHAPTER 37 • Obstetrics and Care of the Newborn

IN REVIEW

1. Signs and symptoms of predelivery emergency include: abdominal pain, nausea, vomiting, vaginal bleeding, passage of tissue, weakness, dizziness, altered mental status, seizures, excessive swelling of the face and/or extremities, abdominal trauma, and shock (hypoperfusion). General guidelines for emergency medical care of predelivery emergencies are as follows: Ensure adequate airway, breathing, and circulation. Care for bleeding from the vagina. Treat for shock (hypoperfusion) if indicated. Provide emergency medical care as for the nonpregnant patient based on any other signs and symptoms. Transport the patient on her left side.

2. Delivery is imminent if the mother complains of the feeling that she needs to defecate; crowning has occurred; contractions are 2 minutes apart or closer, are intense, and last from 60 to 90 seconds; the patient feels the infant’s head moving down the birth canal (sensation of bowel movement); the patient has a strong urge to push; and the patient’s abdomen is very hard.

3. Position a patient in active labor on a firm surface with knees drawn up and spread apart, and feet flat on the surface beneath her. Elevate the patient’s buttocks several inches with a folded blanket, sheet, towels, or other clean objects, buttocks several feet in from the edge of the surface. Support the mother’s head, neck, and shoulders with pillows or folded blankets. To create a sterile field around the vaginal opening, use sheets from the OB kit, sterile towels, or paper barriers. Remove the patient’s clothing or push it up above her waist. Place one or two sanitary napkins over the vaginal opening. Then lower the patient’s legs and help her hold them together. Elevate her feet, if necessary.

4. The emergency medical care for a patient in active labor for a normal delivery is as follows: (1) Position the patient supine. (2) Create a sterile field around the vaginal opening. (3) Monitor the patient for vomiting. Be ready to suction. (4) Continuously assess for crowning. (5) Place your gloved fingers on the bony part of the infant’s skull when it crowns. Exert very gentle pressure to prevent an explosive delivery. Avoid touching and exerting pressure on the infant’s face and on any soft spot (fontanelle) on the head. With a sterile dressing, exert gentle pressure horizontally across the perineum to reduce the risk of traumatic tears. (6) Tear the amniotic sac if it is not already ruptured and move it away from the infant’s head and face. (7) Remove the umbilical cord from around the infant’s neck, if necessary. (8) As soon as the head is delivered and before the rest of the infant is delivered, suction the infant’s mouth and nostrils only if obvious obstruction to ventilation is present.

Routine suction is no longer recommended. (9) As the torso and full body are born, support the newborn with both hands. Receive the newborn in a clean or sterile towel. (10) Grasp the feet as they are born. (11) Wipe blood and mucus from the infant’s mouth and nose with sterile gauze. (12) Dry the infant with towels and place it in a blanket on its back or side with the neck in a neutral position. Keep the infant level with the mother’s vagina until the umbilical cord is cut. Do everything you can to keep the baby warm. (13) Assign one partner to care for the mother, the other to monitor and care for the newborn. (14) Clamp, tie, and cut the umbilical cord when pulsations cease. Periodically check the end of the cord for bleeding, and control any that may occur. (15) Expect the placenta to be delivered within 10 to 20 minutes of the infant. (16) Wrap the delivered placenta in a towel and place it in a plastic bag for transport to the hospital. (17) Place one or two sanitary napkins over the vaginal opening. Then lower the patient’s legs and help her hold them together. Elevate her feet, if necessary. (18) Record the time of delivery and transport the mother, infant, and placenta to the hospital. Keep both the mother and the infant warm. Transport gently.

5. An abnormal delivery can be recognized by observing one or more of the following: any fetal presentation other than the normal crowning of the fetal head, abnormal color or smell of the amniotic fluid, labor before 38 weeks of pregnancy, and recurrence of contractions after the first infant is born.

6. • For a prolapsed cord, instruct the patient NOT to push. This avoids additional compression of the umbilical cord. During contractions, instruct the patient to “pant like a dog” to prevent her from contracting her abdominal muscles and pushing. It is important that you coach the patient during the contractions because her desire is to push. Position the patient with her head down in a knee-chest position with the stretcher in a Trendelenburg position if possible. Insert a sterile, gloved hand into the vagina, and push the presenting part of the fetus away from the pulsating cord. Follow local protocol and seek medical direction. Cover the umbilical cord with a sterile towel moistened with saline solution. Transport the patient rapidly, maintaining pressure on the presenting part and monitoring pulsations in the cord.

• For a breech birth, position the mother with her buttocks at the edge of a firm surface or bed and have her hold her legs in a flexed position. As the infant delivers, do not pull on the legs, but support them. Allow the entire body to be delivered as you simply support it. Continue with care for the neonate as in the normal delivery.

• For a limb presentation, do not attempt a field delivery under any circumstance. Transport immediately, because a cesarean section will be required to deliver the fetus. Administer oxygen to the mother, and place the mother in a knee-chest position with her pelvis elevated. Never pull on the infant by its arm or leg. Have the mother pant if she has the urge to push with contractions.

• For a multiple birth, be prepared to care for more than one infant. Be prepared for one or more placentas and more than one resuscitation. If the second infant is not breech, handle the delivery as you would for a single infant. Expect and manage hemorrhage following the second birth. If the second infant has not delivered within 10 minutes of the first, transport to the hospital for delivery of the second infant.

• For meconium staining, aggressively suction the airway until clear to avoid aspiration. Do this as soon as the head emerges from the birth canal and before the body delivers. Do not stimulate the infant to breathe before suctioning. Transport as soon as possible, maintaining the airway throughout.
• For a premature birth, dry the infant and keep it warm. Prevent bleeding from the umbilical cord. Blow oxygen across the infant's face. Prevent contamination and do not let anyone breathe into the infant's face.

7. Approximately 80 percent of newborns require no resuscitation beyond keeping them warm and suctioning the airway. If their responses are slightly depressed, most will respond to oxygen blown by the face or to bag-valve-mask ventilations with supplemental oxygen. Providing warmth is one of the best possible interventions.

8. The indications and procedures for neonatal resuscitation are as follows: (1) If the infant has an inadequate SpO₂ reading, direct a flow of oxygen across the face. (2) Provide ventilations by bag-valve mask with supplemental oxygen at the rate of 40–60 per minute if the infant's breathing is shallow, slow, gasping, or absent following brief stimulation; the heart rate is less than 100/minute. Reassess after 30 seconds. If the breathing and/or heart rate have not improved, continue ventilations and reassess every 30 seconds. (3) If, despite adequate ventilations, the infant's heart rate drops to less than 60 beats per minute, continue ventilations and begin chest compressions at a rate of 120/minute.

CHAPTER 38 • Pediatrics

IN REVIEW

1. Differences in anatomy and physiology of the infant and child as compared to adult patients are numerous. However, the most significant to the EMT typically concern the airway. Infants have proportionally larger tongues, making it easier to occlude the airway. The diameter of a newborn's trachea is only about 4–5 mm, which means life-threatening swelling occurs faster than in an adult. Pressure on the soft tissue under the chin can easily displace the tongue back into the pharynx, leading to airway obstruction. Newborns and infants are obligate nose breathers, which means an obstructed nose can cause respiratory distress. The smallest area of the upper airway is at the level of the cricoid cartilage, and not at the level of the vocal cords as seen in an adult. The epiglottis is much higher in the airway than in an adult, leading to a higher incidence of aspiration, especially when the neck is hyperextended.

2. The patient in early respiratory distress presents with adequate respiratory depth and minute volume but has an above-normal respiratory rate; nasal flaring; intercostal, supraclavicular, and subcostal retractions on inspiration; neck muscle use; audible breathing noises such as stridor, wheezing, or grunting; and “seesaw” respirations. Decompensated respiratory failure presents with signs of early respiratory distress and any of the following: respiratory rate over 60/minute, cyanosis, decreased muscle tone, severe use of accessory muscles to aid in respirations, poor peripheral perfusion, altered mental status (in relation to the patient’s developmental stage), grunting, or head bobbing.

3. Signs of a complete airway obstruction include no crying or talking, an ineffective or absent cough, an altered mental status including a possible loss of responsiveness, and cyanosis.

4. End organ perfusion is adequate if the patient has acceptable or normal capillary refill, pulse rate and strength, strength of peripheral versus core pulses, warmth and color of the hands and feet, urinary output, and mental status.

5. The risk of seizures is high among children up to age 2. In fact, 3 to 5 percent of all children in the United States will have experienced a febrile (caused by fever) seizure by the time they reach their 5th birthday. Any condition that would produce seizures in adults also causes them in kids. Those are epilepsy, head injury, meningitis, oxygen deficiency, drug overdose, and low blood sugar (hypoglycemia). If the child has a single seizure, ensure airway patency, position the patient on his side (if there is no possibility of spine trauma), make sure he doesn’t injure himself, be prepared to suction, provide oxygen and ventilate as appropriate, and transport. If seizures last longer than 10 minutes or recur without a recovery period (status epilepticus), provide positive pressure ventilation with supplemental oxygen. Transport rapidly, monitoring the airway.

6. Patterns of injury most likely to occur when pediatric patients are victims of trauma are as follows: In motor vehicle crashes, unrestrained infants and children are likely to have head and neck injuries, while restrained pediatric patients will have abdominal and lumbar spine injuries. Pediatric patients struck while riding bicycles are likely to suffer head, spinal, and/or abdominal injuries, whereas those struck by vehicles as pedestrians will probably have head injuries, chest injuries, and lower extremity injuries. In falls from height or diving into water, suspect head and neck injuries. When pediatric patients suffer burns, expect them to be more severe since their skin is not as thick or durable as adult skin, and inhalation of smoke; toxic fumes, or superheated air can cause airway swelling more rapidly and severely in pediatric patients. In sports injuries, suspect head and neck injuries. Finally, maintain a high index of suspicion for child abuse when the injury does not match the child’s or the caregiver’s description of what happened.

7. Indicators of possible child abuse and neglect include multiple abrasions, lacerations, incisions, bruises, or broken bones; multiple injuries or bruises in various stages of healing; injuries on both the front and back or on both sides of the child; unusual wounds (such as circular burns); a fearful child; injuries to the genitals; injuries to the central nervous system that occur when the infant or child is violently shaken; situations in which the injuries do not match the mechanism of injury described by the caregivers or the patient; lack of adult supervision; untreated chronic illnesses; and malnourishment, an unsafe living environment, and a delay in reporting injuries.

8. You should talk out your feelings with colleagues, friends, or your partner or spouse. Take advantage of professional services provided by your EMS service. Emotions that are ignored or suppressed will lead to burnout.

CHAPTER 39 • Geriatrics

IN REVIEW

1. Changes in the elderly person’s body increase the susceptibility to trauma in a number of ways, such as:

• Cardiovascular system: Degenerative processes decrease the ability of the heart to pump blood and stenosis may restrict blood flow through the heart. Older hearts have less ability to raise their rate to meet an increased demand from physical activity, stress, or illness, which means that the heart rate may not increase in response to shock. Arteries lose their elasticity and tear easily, resulting in additional bleeding. The blood vessels also do not react as fast or as efficiently in response to stimulation from the central nervous system.

• Respiratory system: Due to changes in the respiratory musculature and a change in the normal elasticity and recoil of the thorax, the thorax is not as effective in moving the air in and out of the lungs. A progressive decrease in gas diffusion across the alveolar membrane causes poorer oxygenation, which leads to poorer compensation in traumatic chest injuries. The body’s response to hypoxia
is blunted. Damaged cough and gag reflexes decrease the ability to clear substances from the airway.

- Musculoskeletal system: Osteoporosis causes the bones to weaken and become brittle, thereby increasing the likelihood of fracturing. The disks that are located between each vertebra in the spine start to narrow, causing kyphosis, which can complicate normal immobilization techniques. Joints begin to lose their flexibility, and there is a general and progressive loss of skeletal muscle mass. In all, skeletal fractures take longer to heal and may precipitate secondary medical emergencies.

2. Never just assume that elderly patients will be difficult to communicate with. Approach them as you would any patient. However, two challenges that are often caused by sensory degeneration in the elderly are diminished eyesight and diminished hearing. With eyesight challenges, try to place yourself where the patient can see you and always explain what is happening. If the patient has eyeglasses, be sure he is wearing them. With hearing challenges, try to speak louder, not higher. If the patient has a hearing aid, assist him in using it. One strategy is to try to speak into a stethoscope placed into the patient’s ears. Also, try note-taking or even see if the patient can read lips.

3. Questions you should ask the elderly patient in order to help obtain an accurate history include: Have you had any trouble breathing? Have you had a cough lately? If so, have you been coughing up anything like mucus or blood? Have you had any chest pain? Did you get dizzy? If so, what were you doing when this occurred? Have you fainted? Have you had any headaches lately? Have you been eating and drinking normally? Have there been any changes in your bowel or bladder habits? Have you fallen lately?

4. A secondary assessment should always be performed on all geriatric patients as an extra precaution because geriatric patients may be unable or unwilling to reveal all of their problems in describing their chief complaint. In addition, a geriatric patient’s condition can deteriorate rapidly and you need to gather the information at the outset.

5. Emergency care guidelines for positioning and packaging the geriatric patient include: (1) If the emergency run is medical in nature and the patient is alert and able to protect his own airway, place the patient in a position that is comfortable for him. (2) If the patient has an altered mental status and is unable to protect his own airway, the patient should be placed on his left side to avoid aspiration. (3) If spinal injury is suspected, the patient needs immediate stabilization of the cervical spine during initial airway assessment. The patient should also be immobilized to a long spine board, using appropriate immobilization devices. (4) The patient with severe curvature should not be forced into the usual immobilization position but should be immobilized using blankets or other devices that can accommodate the spinal curvature.

6. An assessment finding of denial of chest pain in the geriatric patient differs from the same finding in a younger adult patient because a geriatric patient has depressed pain perception and may be suffering a “silent heart attack.” It’s important to be alert for other signs and symptoms such as weakness or fatigue, breathing difficulty, aching shoulders, or indigestion. These should be considered signs of possible cardiac difficulty or heart attack. It’s also possible that the patient may be experiencing pain but does not want to admit it for fear of hospitalization.

7. Factors that make the elderly more likely to fall include altered mental status, slower reflexes, failing eyesight and hearing, activities that exceed physical limitations, arthritis, and general loss of muscle tone and strength.

8. Possible causes of altered mental status in the geriatric patient include stroke, TIA, seizures, syncope, drug toxicity, and dementia or Alzheimer’s disease. Treatment considerations include the following: Never assume that a geriatric patient’s altered mental status is “normal” for him or that it is “senility.” Inquire of family members or others who know the patient if the mental status is, indeed, normal for him or if it represents a significant change. Remember also that the noise of a radio, a siren, or strange voices may add to the patient’s confusion. Attempt to explain or reduce the noise. Never take personally the uncooperativeness or hostility that may result from patients with dementia.

9. Geriatric patients are predisposed to environmental heat or cold emergencies because the aging process diminishes the body’s ability to maintain heat when cold, or dissipate heat when hot. These factors include a smaller insulating layer of fat, reduced muscle mass, the body’s metabolic rate slowing with age, impaired reflexes, decreasing blood flow (especially to the extremities), and a reduced shivering response. Also, because of impaired perception, geriatric patients simply may not realize how cold or hot it is. It is also likely that elderly patients on a fixed income may be unable to afford keeping their homes adequately heated or cooled.

10. Signs and symptoms of geriatric abuse include bruises, bite marks, bleeding beneath the scalp (indicative of hair-pulling), lacerations on the face, trauma to the ears, broken bones, deformities of the chest, cigarette burns, and rope marks. If you suspect abuse, pay attention to inconsistencies while interviewing the patient, the patient’s family, and the patient’s caregiver(s). Do not confront the care provider or family with your suspicion of abuse. Instead make your suspicion known to the receiving hospital’s staff or follow local protocols or state law with regard to reporting suspected abuse.

CHAPTER 40 • Patients with Special Challenges

IN REVIEW

1. There are many medical and traumatic conditions that can cause the loss of function to a body system. These changes can range from mild hearing loss to substantial impairment like an inability to breathe spontaneously. Some of the more common sensory problems encountered in the prehospital environment are hearing impairment (loss or diminishment in the ability to hear sounds), vision impairment (usually due to disease, injury, or degenerative disorders), and speech derangement (disorders in articulation, voice production, language, and fluency).

2. Bariatric (obese) patients often experience hypertension, coronary artery disease, congestive heart failure (CHF), stroke, obstructive sleep apnea, asthma, chronic obstructive pulmonary disease (COPD), diabetes, esophageal reflux, liver disease, osteoarthritis, gout, back injuries, immobility, depression, and suicide.

3. If the patient’s tracheostomy tube is partially or totally occluded due to bleeding or heavy secretions, use a whistle-tip (soft) suction catheter to clear the airway. Apply suction and slowly withdraw the catheter while twisting it between your fingers. Do not suction for longer than 10–15 seconds in an adult, and 5 seconds in a pediatric patient. Oxygenate between suctioning attempts, and rinse the catheter with sterile water between attempts. If the patient has a primary care provider available on scene, they’re often more skilled in tracheal suctioning and can be asked for help.

4. Brain injuries may result in permanent problems with breathing and leave the patient dependent on a ventilator and unresponsive to external stimuli. Because of their reliance on such equipment, these patients often develop...
upper respiratory infections and pneumonia. Be aware of this equipment during patient transfer and always remember to maintain an open and patent airway and ensure the patient’s breathing remains adequate throughout your call.

5. Ventilators may fail due to an electrical supply interruption or failure of some internal component or circuit. However, the real problem may not be with the ventilator at all and instead may be due to a change in the patient’s condition. Do not confuse high pressure or SpO2 alarms for ventilator malfunction. Always assess the condition of the patient as well as the condition of the ventilator.

6. A vascular access device (VAD) is a medical device that is used when a patient is in need of ongoing intravenous medications. They’re typically placed when the patient needs medication administration for longer than 7 to 10 days, but they can also be used on a longer-term basis as well.

7. Patients diagnosed with COPD or sleep apnea are typically provided with continuous positive airway pressure (CPAP) machines. The patient wears a mask that covers the mouth and/or nose and the machine provides constant pressure during the ventilatory cycle to keep the small bronchiole airways open during exhalation. This results in improved oxygenation and ventilation and reduces the patient’s work of breathing.

8. The EMT should first remove the ventilator circuit, and place a BVM on the 15/22 mm adapter of the tracheostomy tube and attempt one or two ventilations. If the ventilations do go in easily and you see chest wall movement, the problem is likely either ventilator failure or a problem with the ventilation circuit. If you can find and fix the problem with the ventilator, or your protocol allows you to adjust the patient’s settings (rate and tidal volume) to meet the patient’s needs, the ventilator may be reapplied during transport to the hospital. If you do not see immediate rise and fall of the chest, and/or the BVM is hard to squeeze, and/or you don’t hear alveolar breath sounds, the problem may lie with the patient. First reassess the airway, clear it as appropriate, and reattempt to ventilate. If there is still a problem, assess for clinical findings such as bronchoconstriction, pneumothorax, tension pneumothorax, severe pneumonia, and any other respiratory syndromes that may be contributing to the airway resistance. Contact ALS and continue with manual ventilations while en route to the hospital.

9. EMTs encounter a variety of devices in the field related to gastrointestinal and genitourinary conditions, often in chronically ill patients at home or in extended care facilities. Feeding tubes are medical devices that provide nutrition to patients who cannot chew and/or swallow due to gastrointestinal and genitourinary conditions, often in chronically ill patients at home or in extended care facilities. They’re typically placed when the patient needs medication administration for longer than 7 to 10 days, but they can also be used on a longer-term basis as well.

10. If the intraventricular shunt becomes occluded and cerebrospinal fluid (CSF) is unable to normally flow through and drain from the brain, it will accumulate and intracranial pressure (ICP) will elevate to potentially dangerous levels. With even a slight elevation in ICP, the patient may complain of headache, vertigo, nausea, and weakness. As ICP rises, the compression on the brain results in vomiting, mental status changes, sensory and motor dysfunction, seizures, and respiratory depression. If the pressure becomes too high, the brain will have nowhere to expand against the rigid skull except to herniate through the base of the skull (its opening is called the foramen magnum). The patient may display Cushing response, unresponsiveness, and pupillary changes.

CHAPTER 41 • The Combat Veteran

IN REVIEW

1. The EMT’s primary responsibility is to assess the patient for any life threats associated with an acute injury or illness. The EMT then is responsible for recognizing the patient as possibly suffering from PTSD.

2. In addition to combat veterans, the knowledge of PTSD is applicable to patients who are in law enforcement or who are firefighters, EMS personnel, and any other individuals who, because they are exposed to high stress situations involving immediate death, serious injury or horrific trauma, are prone to developing PTSD.

3. If you yourself start to develop symptoms of PTSD, your first imperative is to recognize the signs and symptoms you are experiencing as those of PTSD. Second, acknowledge that you are experiencing PTSD. Finally, seek help from a mental health professional.

4. PTSD is often missed as a problem because it can present with many signs and symptoms that also occur in other medical conditions. It is important during your assessment to first make sure that the patient is not suffering from a traumatic injury or medical illness, but also be aware of the possibility of PTSD as a cause of the patient’s signs and symptoms.

5. The four main features of PTSD are response, relives, avoids, and anxiety or anger.

6. Signs and symptoms common to both PTSD and TBI are severe headaches, drug or alcohol use, sleep disturbances, depression, anxiety, anger, memory problems, easily frustrated, relationship problems, easily fatigued, bothered by certain smells, and automatic actions.

7. Signs and symptoms associated with TBI or concussion and not PTSD are numbness, impulsive behavior, head and neck pain, trouble reading, lack of focus, clumsy, can’t find the right words when speaking, trouble understanding others, getting lost, disoriented, trouble swallowing, confusion, trouble hearing, blurred vision, dizziness, and loss of sense of smell.

8. Since 2000, it has been reported that approximately 300,000 soldiers have been diagnosed with TBI or concussion resulting from an IED.

9. Approximately 40% of veterans use alcohol or drugs to help them cope.

10. There is no cure for PTSD. Treatment is aimed at relieving the signs and symptoms.

11. The definitive care for PTSD involves the veteran seeking treatment from a mental health professional. If you encounter a veteran that you suspect is suffering from PTSD, it is important to transport that patient so that he or she can get the appropriate treatment.

12. The treatment for TBI differs in that from PTSD. Veterans with TBI must be treated by a neurologist for the physical injury to the brain.

13. Other resources include the Veteran’s Administration (VA), which provides services to veterans. It may be necessary to encourage the patient to seek assistance from the VA. Some areas have crisis intervention teams that could respond to the scene and provide the necessary assistance and referral of patients.

14. High cholesterol, hypertension, and diabetes are diseases that have a greater prevalence in the veteran population than in the general population of the same age.

15. The combat veteran’s suicide rate is 30 percent greater than for their non-combat peers.

16. Other patients who may experience unfocused pain and other signs and symptoms common to the returning veteran include rape victims, POWs, and sexually abused children.
17. Triggers that may exacerbate a situation for many veterans include diesel fumes, dust, and helicopters, and others commonly associated with military vehicles and war zone environments.

CHAPTER 42 • Ambulance Operations and Air Medical Response

IN REVIEW

1. You have certain privileges under the law as the operator of an emergency vehicle, such as exceeding the speed limit, driving the wrong way on a one-way street or opposite side of the road, turning in any direction at an intersection, parking anywhere, leaving the ambulance in the middle of a street or intersection, cautiously proceeding through a red light, and passing in a no-passing zone. Qualifications for these privileges include having a valid driver's license, having gone through a training program, responding to a true emergency, using warning devices, and exercising due regard for the safety of others.

2. Using a police or other emergency vehicle escort en route to a response or the hospital should be a last resort. It is dangerous, not only to the escort, but also to the EMT driver, to the patient in the ambulance, and to others on the road. Use an escort only if you are unfamiliar with how to get to the hospital or if you do not think that you can find the patient's location. Allow for a safe distance between the escort vehicle and your ambulance.

3. There are three main causes of intersection collisions:
   1. A motorist approaches the intersection just as the light is changing and because of impatience, passes through the intersection. (2) There are two emergency vehicles when motorists expect only one. (3) Vehicles waiting at an intersection may block your view of pedestrians in the crosswalk.

4. Using a siren can lead ambulance operators to assume that the driver of another vehicle can hear them, it can cause other drivers to panic and suddenly brake or swerve, and it often causes emotional stress for the patient. Sirens have even been shown to cause a hypnotic effect on the ambulance driver with increase of speed. Finally, it can reduce the ability to hear other emergency vehicles.

5. The phases of an ambulance run are the prerun preparation, dispatch, en route to the scene, at the scene, en route to the receiving facility, at the receiving facility, and post run.

6. The minimum information an ambulance crew should receive from dispatch before beginning a run includes the location of the call, the nature of the call, the location of the patient(s), the number of patients, the severity of the problem, any special conditions or problems, and whether any other units are en route.

7. The procedures for turning a patient over to a receiving facility are as follows: notify dispatch of your arrival at the facility, make an official transfer of care to an appropriate health care provider, transfer all records and information about the patient to the appropriate personnel, give a complete oral report (introduce patient by name; describe the chief complaint, updated vital sign readings, history, and administration of treatment), assist in lifting and moving the patient, turn over valuables, exchange supplies and equipment, and complete a written prehospital care report. Before leaving, ask staff if they have any more questions or if you will be needed further.

8. Cleaning and restocking of an ambulance after a run should begin at the hospital, continue en route to the station, and finish at the station in order to be ready as quickly as possible for return to service.

9. The infection control procedures that should be followed are to dispose of sharps; wash hands; clean, disinfect, or sterilize contaminated equipment; launder soiled clothing and linens; and dispose of infectious wastes.

10. In many cases, local and state guidelines exist regarding the use of air medical transport, and may even provide specific criteria for when it can be used. Some city, county, or regional ordinances may require that the fire department be present when landing a helicopter. Make sure that you are familiar with any guidelines or policies in your area. To establish a safe landing zone for a helicopter, follow these guidelines:
   - Make sure the landing area is clear of obstructions. It should ideally be a flat square with 60-foot sides by day for a small helicopter, but larger—about 100-foot sides—by night. Pick up loose debris that might blow up into the rotor system. Choose a landing site at least 150 feet away from collision vehicles, if possible, so that noise and rotor wash will not be a problem for rescuers.
   - If the landing site is a divided highway, stop the traffic going in both directions, even though the aircraft will land on only one side of the highway.
   - Consider the wind direction. Helicopters take off and land into the wind by preference, rather than making vertical descents and ascents. Establish radio communications with the incoming flight crew and warn them of any power lines, poles, antennas, trees, or other obstructions.
   - Mark each corner of the landing area with a highly visible device. Use a flag or surveyor's tape by day and a flashing or rotating light at night. Use flares either by day or night but only if there is no danger of fire. A beam of light should not be directed upward. If possible, put a fifth warning device on the upwind side to designate the wind direction.
   - If conditions are dusty or dry enough to create a fire hazard, have the area wet down, if possible.
   - Keep the patient and crew clear of the air downwash area. Spectators should be at least 200 feet away. EMT personnel should be at least 100 feet away during landing.
   - Assign one person to guide the pilot in. He should wear eye and ear protection and should stand near the wind direction marker with his back to the wind, facing the touchdown area, arms raised overhead to indicate the landing direction.

CHAPTER 43 • Gaining Access and Patient Extrication

IN REVIEW

1. The first priority in any emergency is personal safety—the safety of yourself and your partner.

2. The primary role of the EMT in a rescue situation is gaining access to the patient as quickly as can be safely accomplished in order to perform patient assessment and emergency care, even as the rescue operation proceeds. In some situations, it may be necessary that you perform simple extrication patient to remove the patient from the vehicle. More complex extrication situations require advanced training and tools. Your two major priorities in a rescue situation are (1) to keep yourself and your partner safe and (2) to prevent further harm to the patient.

3. The first step you should take on arriving at the site of a motor vehicle collision is sizing up the scene to identify real and potential hazards. Perform a 360-degree assessment. Evaluate the need for additional help.

4. To locate all the patients involved in an emergency such as a motor vehicle collision, you should search thoroughly,
both at the site of the emergency and in the immediate vicinity. Question witnesses, bystanders, and other patients. Look for clues such as a child's coat in the backseat of a car. When in doubt, have the police contact relatives in an attempt to learn who might have been in the vehicle.

5. It is important to approach a motor vehicle collision from the front to prevent patients from turning their heads to see you, thereby possibly aggravating a spinal injury.

6. Patient care always precedes removal from the vehicle unless delay would endanger the life of the patient, EMS personnel, or other rescuers.

7. Protect the patient from glass and other flying debris by covering him with a heavy blanket, tarp, or salvage cover, and in some cases with an object such as a short spine board between the working area and the patient.

8. The minimum level of personal protective equipment required at a motor vehicle collision site includes eye and head protection, disposable gloves, a high-visibility vest when on or near the roadway, heavy gloves as necessary, and any additional protection needed to prevent direct contact with blood or body fluid.

9. Always assume a downed power line is electrically alive. The area must be secured to avoid accidental contact, and you should request special assistance from the local electric service company. If patients are still in the vehicle, tell them to stay there. If the situation is immediately threatening to life or the electric company is unable to respond, rescue personnel specially trained in handling electrical emergencies may move the downed line using special equipment and techniques designed for that purpose.

10. A vehicle is considered stable when it is in a secured position and can no longer move, rock, or bounce. To stabilize a vehicle in danger of rolling until rescue crews can properly and completely stabilize it, shut off the engine, set the parking brake, shift the automatic to "park" or the manual to any gear, and place firm objects such as a spare tire in front of and behind a wheel to minimize vehicle movement.

CHAPTER 44 • Hazardous Materials

IN REVIEW

1. A number of visual clues can indicate the probable presence of a hazardous material, such as smoking or self-igniting materials, extraordinary fire conditions, boiling or spattering of materials that have not been heated, wavy or unusually colored vapors over a container of liquid material, characteristically colored vapor clouds, frost near a container leak (indicative of liquid coolants), and the unusual condition of containers (peeling or discoloration of finishes, unexpected deterioration, deformity, or the unexpected operation of pressure-relief valves).

2. As soon as you recognize or suspect a hazardous materials emergency, radio immediately for help and then secure the scene and limit the exposure of rescuers and bystanders.

3. You should never attempt a hazardous materials rescue unless you have had the necessary specialized training to the hazardous materials technician level or better and proper training in the use of self-contained breathing apparatus. Even then, it is unlikely that the person who performs the rescue of the patient (in full protective gear) will be the same person who provides medical care.

4. Specific actions to protect bystanders are securing the scene, cordon off the whole area, and appointing people to keep bystanders away.

5. While waiting for help to arrive, you should protect yourself and bystanders by keeping uphill, upwind, and away from the danger.

6. Resources for identifying and handling a hazardous materials emergency are available through state and local agencies, including specialized hazmat teams, and can be found in the Emergency Response Guidebook and other print references, or can be obtained from CHEMTREC or Chemtrec, Inc., through their toll-free numbers, or from a regional poison control center.

7. To protect yourself, others, and your vehicle from contamination, do the following. Wear all proper protective clothing including SCBA and make sure all other rescuers do the same. Establish "safety zones" to keep contamination from spreading. Prior to transport, cover the benches, floor, and other exposed areas with thick plastic sheeting secured with duct tape. Decontaminate all patients before transport. Before removing them from the scene, seal all contaminated clothing and equipment in plastic bags or metal containers with tightly fitting lids. Decontaminate yourself by washing with mild detergent or green soap and plenty of running water for at least 20 minutes or until the burning stops. Following rescue, decontaminate equipment and the vehicle by washing them thoroughly inside and out.

8. The “safety zones” are the hot or contamination zone, the warm or control zone, and the cold or safe zone. In the hot zone, which is immediately adjacent to the accident site and where contamination can still occur, perform the actual rescue, initial (gross) decontamination, and necessary treatment for life-threatening conditions. In the warm zone, which is immediately adjacent to the hot zone, continue to wear appropriate protective gear. Administer lifesaving emergency care to the patient. When the patient is stabilized, perform complete decontamination. Perform a rapid trauma assessment. In the cold zone, shed all contaminated protective gear. Take vital signs and a history, complete emergency care of the patient, and prepare for transport.

9. Information necessary for trained personnel to decide on a course of action includes nature of the problem, identification of the hazardous materials, the kind and condition of containers, existing weather conditions, whether or not there is presence of fire, time that has elapsed since the emergency occurred, what already has been done by people at the scene, the number of patients, and the potential danger to more people.

10. The required elements of an incident management plan are one command officer who is responsible for all rescue decisions, a clear chain of command, one established system of communications, and predesignated receiving facilities.

CHAPTER 45 • Multiple-Casualty Incidents and Incident Management

IN REVIEW

1. An MCI is any event that places a great demand on personnel and equipment resources. The number of patients required to declare an MCI varies on the jurisdiction and the availability of resources.

2. The incident commander is responsible for coordinating all aspects of the incident and, upon arrival, will begin to organize and delegate the responsibilities of the various established branches depending on the scale of the multiple-casualty incident.

3. Upon arrival, the EMT should report to the mobile command unit for instructions. If you are the first unit to arrive, you may be incident commander temporarily until it can be transferred to the most qualified individual later. If you are one of the first EMTs on scene, you will probably be asked to perform triage. However, you may also be called on to provide treatment or assist with moving equipment.
4. Triage unit. This unit sorts patients by criticality and assigns priorities for emergency care and transport.
   - Treatment unit. Emergency care is provided to patients in this unit. This is done based on the priority assigned to the patient by the triage unit.
   - Transport unit. In this unit, patients are moved to ambulances or helicopters for transportation to a medical facility, and communications are organized to notify the receiving medical facilities.
   - Staging unit. Ambulances, helicopters, and additional equipment are held in this area until they are assigned to a particular task. Sometimes a supply unit is established as part of or separately from the staging unit to gather and distribute supplies and equipment required by all units.
   - Morgue unit. Deceased casualties are moved to this unit where they are held and processed.

5. The initial triage of a patient is performed very quickly. For example, in the START system, you simply assess respiratory status, perfusion status, and mental status.

6. Appropriate triage levels (in a system with three levels of triage) are as follows: (a) a patient with inadequate breathing—highest priority, or priority 1; (b) a patient who is in cardiac arrest with insufficient EMS personnel to provide care—lowest priority, or priority 3; (c) a patient found with a painful, swollen, and deformed forearm—lowest priority, or priority 3; (d) a patient with a lacerated back—second priority, or priority 2.

7. It is important to use a patient identification or tagging system because tagging the sick or injured helps arriving EMTs quickly and efficiently identify treatment priorities. Also, arriving EMTs know untagged patients will still need initial triage. The criteria for a successful patient identification system are that the tagging system should be easy to understand, standardized, and easily affixed to the patient.

8. To effectively transport patients in a multiple-casualty incident, highest-priority patients should be transported first, immediately after treatment, and evenly distributed among available hospitals. As each ambulance leaves, the transportation officer should radio the hospital to advise which ambulance is en route and briefly describe the injuries involved with an estimated time of arrival. Individual EMTs should not try to communicate with the hospital unless an emergency develops during transport. When the only patients left at the site are ambulatory, load them onto a bus with properly equipped EMTs and follow an ambulance to a hospital.

9. Any of the following guidelines may help to reduce stress: Try not to get overwhelmed by the immensity of the incident, and care for patients one by one. Rest at regular intervals upon reporting back to the staffing area for assignment, maybe as often as once every 1–2 hours (but follow local protocol). Make sure that each rescue worker is fully aware of his exact assignment. Have several workers in the staffing area circulate among the rescue workers and watch for signs of physical exhaustion or stress. Require workers with problems to return to the staffing area and rest for a longer period than usual. Make sure that rescue workers are assigned to tasks appropriate for their skills and experience. Provide plenty of nourishing drinks and food. Encourage rescue workers to talk among themselves. Make sure that rescuers have the opportunity to talk with trained counselors after the incident.

CHAPTER 46 • EMS Response to Terrorism
Involving Weapons of Mass Destruction

IN REVIEW

1. Weapons of mass destruction include chemical, biological, radiological, and explosive. A useful mnemonic is “B-NICE” where B = biological, N = nuclear, I = incendiary, C = chemical, and E = explosive.

2. Personal safety is the first priority for all EMS personnel and there are many safety issues that must be addressed when responding to these scenes. They include positioning of the vehicle and responders uphill, upwind, and at a safe distance to prevent responders from becoming victims. Responders must also be aware of the potential for secondary devices. Responders must be wearing appropriate personal protective equipment (PPE) for the type of potential exposure to prevent contamination. Responders should also be prepared to recognize the signs and symptoms associated with WMD to ensure appropriate treatment and transport of all patients.

3. A conventional weapon is an explosive used to create massive destruction through the explosion. An incendiary device is designed to cause injury by burning at high temperature. It is used to create a large amount of fire volume meant to burn persons and property. While there may be an explosion, it is not the primary objective.

4. Explosion will primarily cause a shock wave that is especially harmful to hollow organs like the lungs, causing a pneumothorax. The secondary effect of the explosion causes penetrating and blunt force trauma to all parts of the body from flying projectiles. Injury patterns from the secondary effect of the blast are dependent on the patient's proximity to and position at the time of the blast. The tertiary effects of the explosion cause further blunt force trauma, as the body itself becomes a projectile. Other objects can also come to rest on the patient, causing additional injury. Expect penetrating trauma and crush injuries in this patient.

5. The primary effect from an explosion is the shock wave that immediately follows the blast. The secondary effect of the explosion is from the shrapnel and other projectiles contacting the victim. The injury patterns from the explosion is from the victim being propelled by the blast and then striking an object or the ground.

6. Nerve agents block the action of acetylcholinesterase. This allows an accumulation of acetylcholine, which will then cause continued, uncontrolled, and uncoordinated contraction of muscle fibers that continue until the muscle fatigues and then begins to die. Volatile agents are both a liquid and a vapor hazard.
   - Vesicants cause damage to any area of the body exposed to the chemical. The agents were previously known as “blister agents” because they cause blistering, burning, and tissue death on contact. These agents tend to be liquid hazards at low temperatures and vapor hazards at warmer temperatures.
   - Cyanide prevents the cells of the body from utilizing oxygen. This quickly affects the brain and heart. Cyanide is a high vapor hazard and can also be ingested through contaminated food products.
   - Pulmonary agents cause damage to the lungs, especially the smaller airways and the alveoli. They act primarily to cause lung injury and are commonly referred to as “choking” agents.
   - Riot-control agents are aerosolized solids like pepper spray. These agents cause extreme irritation on contact, which can include the respiratory tract if inhaled.
   - Toxic industrial chemicals can vary in the type of effects they may cause, but they are transported and stored throughout the country in large, highly concentrated amounts. These chemicals can act like pulmonary agents, cyanide, or even nerve agents.

7. Nerve agents require supportive care. This includes maintaining an airway through intubation and suctioning,
They also require an antidote to combat the nerve agent, including the potential for antiseizure medication. This patient also needs wounds dressed to prevent further contamination and absorption of the nerve agent.

- Vesicants require immediate and thorough irrigation of all contaminated surfaces with water or a chemical decontamination kit. After irrigation, burns should be dressed with dry sterile dressings.
- Cyanide exposure requires early respiratory support to include positive pressure ventilation and intubation. These patients may also require an antidote of amyl nitrite to reverse the effects of the cyanide.
- Pulmonary agents require respiratory support to include high-concentration oxygen, suctioning, and possible intubation.
- Riot-control agents require supportive care and typically involve removing the patient from the environment and irrigating the eyes with water or saline. Patients may also need oxygen therapy if suffering respiratory distress.
- Toxic industrial chemicals require a variety of medical interventions based on the presenting signs and symptoms.

8. • Pneumonia-like agents include anthrax, plague, and tularemia. These agents cause shortness of breath, fever, and malaise.
• Encephalitis-like agents include smallpox and Venezuelan equine encephalitis. These agents cause headaches, fever, malaise, and altered mental status.
• Biological toxins include botulinum, ricin, and other toxins. While these toxins cannot be transmitted from one person to another, they are still some of the most dangerous compounds in the world.
• Other agents include cholera, viral hemorrhagic fevers, and brucellosis. These viruses are deadly and are still seen in epidemic proportions in developing nations.

9. The care of patients exposed to biological agents is primarily supportive. Recognition is extremely important to advanced management of the patient. This includes maintaining an adequate airway with the potential for intubation. Respiratory support may be necessary with supplemental oxygen and positive pressure ventilation, if needed. These patients also need antibiotic and fluid therapy, so appropriate medical treatment must be sought.

10. • Gamma and X-ray radiation are the same. This is a powerful type of radiation that is the most penetrating type and can travel long distances. This radiation is the major external hazard associated with nuclear detonation and reactor accidents.
• Neutron radiation is very damaging and easily passes through the body. It typically occurs in a nuclear chain reaction. The threat is greatest near a nuclear reactor or bomb explosion.
• Beta radiation is low-speed, low-energy radiation. It is common in fallout decay and is a serious threat from ingestion of contaminated food and from inhalation of airborne particles.
• Alpha radiation is very heavy and slow moving. It is a serious internal hazard because it causes a great amount of damage over its short course of travel.

11. The detonation of a nuclear device can cause three types of injuries: injuries from radiation, injuries from the blast, and injuries from the thermal burns.

12. Your primary concern is for your own and the patients’ safety. A radiation exposure patient requires maintenance of the airway and ventilatory status. Be cognizant of upper airway burns. Ensure a patent airway, which may necessitate tracheal intubation. Respiratory support may include oxygen therapy as well as positive pressure ventilation. Manage burns as you would normally manage a thermal burn. Use sterile dressings and sterile burn sheets to cover the burned areas. Manage blunt trauma as you normally would in a trauma patient.
abandonment  the act of discontinuing emergency care without ensuring that another health care professional with equivalent or better training will take over.

abdominal aorta  the portion of the descending aorta that extends from the thoracic portion of the aorta to the distal point where the aorta divides into the iliac arteries. Arteries branching from the abdominal aorta supply the abdominal organs.

abdominal aortic aneurysm (AAA)  a weakened, ballooned, and enlarged area of the wall of the abdominal aorta.

abdominal cavity  the space located below the diaphragm that extends to the top of the pelvis.

abdominal evisceration  abdominal organ protrusion through an open wound to the abdomen.

abdominal quadrants  the four parts of the abdomen as divided by imaginary horizontal and vertical lines through the umbilicus.

abrasion  an open injury to the outermost layer of the skin (epidermis) caused by scraping away, rubbing, or shearing away of the tissue.

abruptio placenta  the premature separation of the placenta from the uterus wall.

absorbed poison  usually a chemical or substance from a poisonous plant that enters through the skin.

absorption  passage of a substance through skin or mucous membranes upon contact.

abuse  causing deliberate harm to another person. See also emotional abuse, physical abuse, sexual abuse.

acceleration/deceleration injury  a head injury typical of a car crash in which the head comes to a sudden stop, but the brain continues to move back and forth inside the skull, resulting in bruising to the brain.

acetabulum  (AS-i-TAB-u-lum) the rounded cavity or socket on the external surface of the pelvis that receives the head of the femur.

acetylcholine (ACh)  a neurotransmitter that is distributed throughout the body and is necessary for normal function of the parasympathetic nervous system.

acetylcholinesterase (ACHE)  an enzyme that breaks down the neurotransmitter acetylcholine. Nerve agents inhibit the action of this enzyme, allowing acetylcholine to accumulate.

acromion (ah-KRO-me-on)  the lateral triangular projection of the scapula that forms the point of the shoulder.

action  the effect a drug has on the body. The therapeutic effect is the intended positive response by the body. The mechanism of action is how the drug works to create its effect on the body. For example, an action of nitroglycerin is dilation of the blood vessels.

activated charcoal  a distilled charcoal in powder form that can adsorb many times its weight in contaminants to prevent their absorption by the body; no longer commonly administered in the emergency care of patients who have ingested a poison.

active rewarming  technique of aggressively applying external sources of heat to a patient to rewarms his body.

acute with rapid onset  rapid and severe onset of symptoms of a medical condition.

acutely  rapidly and severely.

acute abdomen  a sharp, severe abdominal pain with rapid onset. Acute abdomen can have a number of causes. Also called acute abdominal distress.

acute coronary syndrome (ACS)  a group of signs and symptoms resulting from any of a variety of conditions that can affect the heart in which the coronary arteries are narrowed or occluded by fat deposits, clots, or scar tissue.

acute renal failure (ARF)  a rapid loss of renal function that results in poor urine production, electrolyte disturbance, and fluid balance disturbance.

Adams’s apple  a swelling of the larynx, usually a thyroid cartilage.

administration  the route and form by which a drug is given.

adolescent  a child 12 to 18 years of age.

advance directive  instructions, written in advance, such as a do not resuscitate (DNR) order, a living will, or a durable power of attorney.

Advanced Emergency Medical Technician (AEMT)  the level of EMS practitioner who performs the responsibilities of an EMT with the addition of the use of advanced airway devices, monitoring of blood glucose levels, initiation of intravenous and intraosseous infusions, and administration of a select number of medications.

aerobic (eh-ROB-ik) metabolism  chemical and physical changes that take place within the cells in the presence of oxygen.

afterbirth  the placenta and other tissues that are expelled after the delivery of the fetus.

afterload  the force of contraction that the left ventricle has to generate to overcome the resistance in the aorta to eject the blood.

ageism  stereotyping or discrimination against old people.

agitated delirium  a mental and physiologic state of arousal that is usually characterized by extreme strength and endurance, tolerance to pain, hostility, and hyperactive behavior; may result in sudden cardiac death; also called excited delirium.

agonal respirations  gasping-type respirations that have no pattern and occur very infrequently; a sign of impending cardiac or respiratory arrest. Also called agonial breathing.

air embolism  an air bubble that enters the bloodstream and obstructs a blood vessel.

airway resistance  the restriction of airflow that is related to the diameter of the airways.

allergen  a substance (antigen) that enters the body by ingestion, injection, inhalation, or absorption and triggers an allergic reaction. See also causative allergen.

allergic reaction  a misdirected and excessive response by the immune system to a foreign substance or an allergen.

alpha radiation  a very heavy and slow-moving particle that travels only inches in air and is stopped by clothing or the outer layer of the skin. It is a very serious internal contaminant and can be ingested or inhaled.

Alzheimer’s disease  disease characterized by cerebral function loss as seen with diseases that affect the brain.

American with Disabilities Act (ADA)  a federal law passed in 1990 that protects individuals with a documented disability from being denied initial or continued employment based on their disability.

amniotic sac  a thin, transparent membrane that forms the sac that holds the fetus suspended in amniotic fluid. Also called bag of waters.

amputation  an open injury caused by the ripping or tearing away of a limb, body part, or organ.

anaerobic (AN-eh-ROB-ik) metabolism  chemical and physical changes that take place within the cells without the presence of oxygen.

anaphylactic reaction  a reactive release of chemical mediators that produce bronchoconstriction, vasodilation, capillary permeability, and increased mucus production leading to airway and respiratory compromise and hypoperfusion. Also called anaphylaxis.

anaphylactic shock  a shock (hypoperfusion) state that results from dilated and leaking blood vessels related to severe allergic reaction. Also called anaphylaxis or anaphylactic reaction.

anaphylactoid (non-IgE-mediated) reaction  a reaction to a foreign substance that resembles an anaphylactic reaction that may occur on first exposure to the substance, without immune system sensitization.

anaphylaxis  another term for anaphylactic reaction. See anaphylactic reaction.

anaerobic metabolism  another term for anaerobic metabolism.

anaesthesia  inability to remember circumstances after an incident.

antibodies  special proteins produced by the immune system that search out antigens and combine with and help to destroy them.

antidote  a substance that neutralizes the effects of a poison or a toxic substance.

antigen  a foreign substance that enters the body and triggers an immune response. See also allergen.
anxiety a state of painful uneasiness often characterized by agitation and restlessness.

aorta (ay-OR-uh) the major artery from the heart.
apnea absence of breathing; respiratory arrest.
apnea monitor device that monitors breathing and emits a warning signal if breathing stops.
appendicitis inflammation of the appendix.
aqueous humor that with the cornea helps to maintain the shape of the eye.
arachnoid middle layer of protective brain tissue (meninges).
arteriole (ar-TE-re-ol) the smallest branch of an artery, which at its distal end leads into a capillary.
artherosclerosis disease process that causes the loss of elasticity in the walls of the arteries that supplies blood to the rest of the body.
artery blood vessel that carries blood away from the heart.
aspiration breathing a foreign substance into the lungs.
aspiration pneumonia inflammation of the lungs caused by the aspiration of vomitus or other foreign material.
aspire a common household medication that will keep platelets from clumping together to form clots; also used as a pain reliever, as an anti-inflammatory agent, and to reduce fever; often administered to the patient suspected of having a heart attack.
assault a willful threat to inflict harm on a person.
assystole a heart rhythm indicating absence of any electrical activity in the heart. Also known as flatline.
atria (AY-treen-uh) the two upper chambers of the heart. Pl. of atrium.
aura an unusual sensory sensation that may precede a seizure episode by hours or only a few seconds.
auscultation listening for sounds within the body with a stethoscope.
automatic transport ventilator (ATV) a positive pressure ventilation device that delivers ventilation automatically.
automaticity the ability of cells within the cardiac conduction system to generate a cardiac impulse on their own.
autonomic nervous system part of the nervous system that influences involuntary muscles and glands.
AVPU mnemonic for alert, responds to verbal stimulus, responds to painful stimulus, unresponsive; to characterize levels of responsiveness.
avulsion an open injury characterized by a loose flap of skin and soft tissue that has been torn loose or pulled completely off.

bag-valve-mask (BVM) device a positive pressure ventilation device that consists of a bag with a nonrebreather valve and a mask. The bag-valve device is connected to the mask or other airway. The bag is squeezed to deliver a ventilation to the patient.
bandage any material used to secure a dressing in place.
bariatrics medical management of obese patients.
bareoreceptors stretch-sensitive receptors located in the aortic arch and carotid bodies that constantly measure the blood pressure.
base station the central dispatch and coordination area of an EMS communications system that ideally is in contact with all other elements of the system.
baseline vital signs the first set of vital sign measurements to which subsequent measurements can be compared.
basilar skull floor of the skull.
battery the act of touching a person unlawfully without his consent.
Battle sign discoloration of the mastoid suggesting basilar skull fracture.
battery the way a person acts or performs.
battery an emergency a situation in which a person exhibits abnormal behavior.
beta radiation a low-speed, low-energy particle that is easily stopped by air or water.
bilateral symmetrically on both sides.

bilevel positive airway pressure (BiPAP) a form of noninvasive positive pressure ventilation. The BiPAP device delivers a continuous flow of air under pressure. It differs from the CPAP device in that it provides different pressures: higher during inspiration, lower during expiration.
biopsy to take a small piece of tissue for examination.
algesic a drug that relieves pain.
blood pressure the force exerted by the blood on the interior walls of the blood vessels.
broken heart the mucus and blood that are expelled from the vagina when a fetus is expelled.
blood pressure the major artery of the upper arm.
bradycardia a heart rate less than 60 beats per minute.

bradypnea a breathing rate that is slower than the normal rate.

brain herniation compression and pushing of the brain through the foramen magnum.

brainstem the funnel-shaped inferior part of the brain that controls automatic functions of the body. It is made up of the pons, the midbrain, and the medulla, which is the brain's connection to the spinal cord.
breech birth a common abnormality of delivery in which the fetal buttocks or both lower extremities are low in the uterus and are the first to be delivered.
bronchial (BRONG-ke) the two main branches leading from the trachea to the lungs, providing the passageway for air movement. Pl. of bronchi.
bronchioles (BRONG-ke-olz) small branches of the bronchi.
bronchoconstriction constriction of the smooth muscle of the bronchi and bronchioles causing a narrowing of the airway passageway.
bronchodilator a drug that relaxes the smooth muscle of the bronchi and bronchioles and reverses bronchoconstriction.
bronchospasm spasm or constriction of the smooth muscle of the bronchi and bronchioles.
Brown-Séquard syndrome loss of different functions on opposite sides of the body from injury to one side of the spinal cord.
burnout a condition resulting from chronic job stress, characterized by a state of irritability and fatigue that can markedly decrease effectiveness.
calcaneus (kal-KAY-ne-us) the heel bone.
capillary (KAP-i-lair-eh) tiny blood vessel that connects an arteriole to a venule.
capillary refill the amount of time it takes for capillaries that have been compressed to refill with blood.
cardiac arrest the cessation of cardiac function with the patient displaying no pulse, no breathing, and unresponsiveness.
cardiac compromise reduced heart function caused by any of a variety of conditions, diseases, or injuries affecting the heart.
cardiac conduction system the specialized cardiac and conduction tissue of the heart that generates electrical impulses and causes the heart to beat. Also called the coronary conduction system.
cardiac contusion a bruise to the heart wall caused by severe blunt trauma to the chest where the heart is violently compressed between the sternum and the spinal column.
cardiac hypertrophy an increase in the size of the heart from a thickening of the heart wall, without a parallel increase in the size of the cavity.
cardiac muscle a type of involuntary muscle found only in the walls of the heart. Cardiac muscle has the property of automaticity, the ability to generate an impulse on its own, separately from the central nervous system.
cardiac output the volume of blood ejected from the left ventricle in 1 minute.
cardiogenic shock poor perfusion resulting from an ineffective pump function of the heart, typically the left ventricle.
cardiovascular system see circulatory system.
carina the point at which the trachea splits into the right and left mainstem bronchi.
carotid (kah-ROT-id) artery one of two major arteries of the neck, which supply the brain and head with blood.
carpals (KAR-pulz) the eight bones that form the wrist.
cataract clouding of the lens of the eye from pathologic changes within the lens.
cavitation a cavity formed by a pressure wave resulting from the kinetic energy of a bullet traveling through body tissue; also called pathway expansion.
central chemoreceptors receptors located in the medulla that are most sensitive to changes in carbon dioxide and the pH. See also chemoreceptors.
central cord syndrome loss of function in upper extremities caused by injury to the middle portion of the spinal cord.
central intravenous catheter a catheter that is designed to deliver medication into the central circulation of the body.
central nervous system (CNS) the brain and the spinal cord.
cerebellum part of the brain controlling equilibrium and muscle coordination.
cerebrospinal fluid (CSF) a clear fluid that surrounds and cushions the brain and the spinal cord.
cerebrum largest part of the brain, responsible for most conscious and sensory functions, the emotions, and the personality.
cervical (SER-vi-kal) spine the first seven vertebrae, or the neck.
cervix the neck of the uterus.
chain of survival a series of five interventions, or links, identified by the American Heart Association as those that provide the best chance for successful resuscitation of a cardiac arrest patient. The five links of the adult chain are immediate recognition and activation, early CPR, rapid defibrillation, effective advanced life support, and integrated post-cardiac-arrest care. The five links of the pediatric chain are prevention of arrest, early high-quality CPR performed by bystanders, rapid activation of EMS or other emergency medical responders, effective advanced life support and rapid transport to an appropriate medical facility, and integrated post-cardiac-arrest care.
chemoreceptors receptors that constantly monitor the arterial content of oxygen, carbon dioxide, and the pH of the fluid and stimulate a change in respiratory rate and depth. See also central chemoreceptors and peripheral chemoreceptors.
chief complaint the patient complaint that is the primary reason why the EMS crew was called to the scene.
child abuse physical, emotional, or sexual mistreatment or neglect of a child from newborn to 18 years of age.
cholecytitis inflammation of the gallbladder.
chronic long term, progressing gradually.
chronic kidney disease (CKD) see chronic renal failure. a progressive loss of kidney function over a period of months to years.
chronic obstructive pulmonary disease (COPD) umbrella term used to describe pulmonary diseases such as emphysema or chronic bronchitis.
chronic renal failure (CRF) a progressive loss of kidney function over a period of months to years.
circulatory system system composed of the heart and blood vessels that brings oxygen and nutrients to and takes wastes away from body cells. Also called the cardiovascular system.
circumferential burn burn that encircles a body area (e.g., arm, leg, or chest).
clammy a moist, or a cool and moist, condition; a skin condition often characteristic of shock.
clavicle (KLAV-ik-ul) the collarbone, attached to the superior portion of the sternum.
cleaning the process of washing a soiled object with soap and water.
closed injury any injury in which there is no break in the continuity of the skin.
closed-ended question a question that requires only a “yes” or “no” answer.
CNS depressants substances that inhibit or decrease central nervous system functions.
CNS stimulants substances that excite or increase central nervous system functions.
coccyx (KOK-siks) the four fused vertebrae that form the most distal end of the spine; the tailbone.
cold zone the area adjacent to the warm zone in a hazardous materials emergency. Normal triage, treatment, and stabilization are performed here. Also called support zone.
colloid oncotic pressure see plasma oncotic pressure.
coma an unconscious state in which a person does not respond to any stimulus, including pain.
combining form a word part that carries the word’s essential meaning.
commotio cordis sudden cardiac arrest caused by a projectile, such as a baseball, striking the anterior chest.
communication a dynamic process that incorporates verbal and non-verbal expressions into meaningful messages that are received and interpreted by others.
compartment syndrome a condition in which increased tissue pressure in a confined space causes decreased blood flow, leading to hypoxia and possible muscle, nerve, and vessel impairment, which may be permanent if the cells die.
compensated respiratory distress see early respiratory distress.
compensatory shock the stage of shock in which a cascade of organ and gland stimulation and hormones occurs to increase the blood pressure, restore arterial wall tension, and maintain a near normal blood pressure and perfusion of the vital organs. Also called compensated shock.
complete spinal cord injury injury to the spinal cord that results in a complete loss of motor, sensory, and autonomic function below the level of injury.
complex access a way to gain access to a patient that requires the use of tools and specialized equipment.
compliance the measure of the ability of the chest wall and lungs to stretch, distend, and expand.
compression of morbidity the concept of maximizing the number of healthy years in one’s life while simultaneously minimizing the number of years of disease/disability at the end of life.
conclusion mild injury that causes temporary loss of brain function.
conduction transfer of heat through direct physical touch with nearby objects.
constrictive heart failure (CHF) a cardiac disease in which the heart cannot pump blood sufficiently to meet the needs of the body.
conjunctiva the thin covering of the inner eyelids and exposed portion of the sclera of the eye. Pl. conjunctivae.
consensual reflex same or similar reaction of the unstimulated pupil when the other pupil is stimulated, as when a light is shined into one pupil and both pupils contract.
consent permission that must be obtained before care is rendered.
Consolidated Omnibus Budget Reconciliation Act (COBRA) a federal regulation that ensures the public’s access to emergency health care regardless of ability to pay.
constricted narrowed, made small.
contamination reduction zone see warm zone.
continuous positive airway pressure (CPAP) a form of noninvasive positive pressure ventilation. The CPAP device delivers a continuous flow of air under pressure. See also bilevel positive airway pressure ( BiPAP).
contraindications situations in which a medication should not be used; for example, because nitroglycerin lowers blood pressure, existing low blood pressure in a patient is a contraindication for nitroglycerin.
contusion a closed injury to the cells and blood vessels contained within the dermis that is characterized by discoloration, swelling, and pain; a bruise; bruising or swelling of the brain.
convection loss of body heat to the atmosphere when air passes over the body.
convulsion unresponsiveness accompanied by a generalized jerky muscle movement affecting the entire body.
cornea the clear front portion of the eye that covers the pupil and the iris.
cranial plane see frontal plane.
cranial (KOR-nal) arteries blood vessels that supply the heart with blood.
coup/contrecoup injury a brain injury in which there may be damage at the point of a blow to the head and/or damage on the side opposite the blow as the brain is propelled against the opposite side of the skull.
cranial skull bones fused together to form a helmet-like covering over the brain.
cranium (KRAY-nee-um) the bones that form the top, back, and sides of the skull plus the forehead.
crepitus the sound or feel of broken fragments of bone grinding against each other. Also called crepitation.
cricoid (KRIK-oyd) cartilage the most inferior portion of the larynx and only full cartilaginous ring of the upper airway. It is felt immediately below the thyroid cartilage.
cricoid pressure pressure applied to the cricoid cartilage to compress the esophagus. Also called Sellick maneuver.
critical incident any situation that causes unusually strong emotions that interfere with the ability to function.
critical incident stress debriefing (CISD) a session usually held within 24 to 72 hours of a critical incident, where a team of peer counselors and mental health professionals help emergency service personnel work through emotions that normally follow a critical incident.
crossed-fingers technique a technique in which the thumb and index finger are crossed with the thumb on the lower incisors and the index finger on the upper incisors. The fingers are moved in a snapping or scissor motion to open the mouth.
crowing a sound similar to that of a cawing crow that indicates that the muscles around the larynx are in spasm and beginning to narrow the opening into the trachea.
crowning the stage in delivery when the fetal head presents at the vagina.
crush injury an open or closed injury in which high-pressure forces cause serious damage to underlying soft tissues with internal bleeding, resulting in possible hemorrhagic shock.
culture the thoughts, communications, actions, and values of a racial, ethnic, religious, or social group.
cushion reflex a protective reflex by the body to maintain perfusion of the brain in a head-injured patient with increased intracranial pressure. The systolic blood pressure increases, heart rate decreases, and the respiratory pattern changes. This syndrome indicates severe head injury.
cyanide a rapid-acting agent that disrupts the ability of the cell to use oxygen, leading to severe cellular hypoxia and eventual death.
cyanosis a blue-gray color of the mucous membranes and/or skin, which indicates inadequate oxygenation or poor perfusion.
dead air space (Vd) anatomical areas in the respiratory tract (outside the alveoli) where air collects during inhalation but no gas exchange occurs.
decerebrate posturing see extension posturing.
decoder device that recognizes and responds to only certain codes imposed on radio broadcasts.
decoder process by which a received message is translated and interpreted.
decompensated respiratory failure when the respiratory compensatory mechanisms have begun to fail and respiration becomes inadequate.
decompenatory shock an advanced stage of shock in which the body’s compensatory mechanisms are no longer able to maintain a blood pressure and perfusion of the vital organs. Also called decompenated shock or progressive shock.
decorticate posturing see flexion posturing.
defamation an intentional false communication that injures another person’s reputation or good name.
defense mechanisms psychological coping strategies individuals use to protect themselves from unwanted feelings or thoughts.
defibrillation electrical shock or current delivered to the heart through the patient’s chest wall or internally from an implanted device to help the heart restore a normal rhythm.
defusing a session held prior to a critical incident stress debriefing (CISD) for emergency service personnel most directly involved to provide an opportunity to vent emotions and get information before the CISD.
delirium sudden-onset altered mental status that may involve illusions, disjointed thought processes, incoherent speech, and increased or decreased psychomotor activity.
dementia chronic condition resulting in the malfunctioning of normal cerebral processes.
deoxygenated containing low amounts of oxygen, as with venous blood.
dehemoglobin hemoglobin that does not have any oxygen molecules attached to it.
depression one of the most common psychiatric conditions, one characterized by deep feelings of sadness, worthlessness, and discouragement that often do not seem connected to the actual circumstances of the patient’s life.
dermis the second layer of the skin. See also epidermis, subcutaneous layer.
diabetes mellitus (DM) a disease in which the normal relationship between glucose and insulin is altered. See also type 1 diabetes and type 2 diabetes.
diabetic ketoacidosis (DKA) a condition typically found in type 1 diabetics where the blood glucose level is excessively elevated and insulin level is extremely low to absent, which causes glucose to be excreted in the urine, dehydrating the patient, and causes the body to metabolize fat for energy, producing ketones and creating an acidic environment.
diabetic retinopathy damage to the small blood vessels of the eye from the long-term effects of diabetes mellitus.
dialyse a special fluid used for dialysis.
dialysis an artificial process used to remove water and waste substances from the blood when the kidneys fail to function properly.
diaphragm (DI-ahfram) the major muscle of respiration that separates the chest cavity from the abdominal cavity.
diastolic (di-as-TOL-ik) blood pressure the pressure exerted against the walls of the arteries when the left ventricle is at rest. See also systolic blood pressure.
digestive (di-JES-tiv) system the structures and organs that ingest and carry food so that absorption and waste elimination can occur.
dilated expanded, made large.
diplopia double vision.
direct force direct blow. Injuries from direct force occur at the point of impact.
disaster a sudden catastrophic event that overwhelms natural order and causes great loss of property and/or life.
disinfecting in addition to cleaning, this process involves using a disinfectant such as alcohol or bleach to kill many of the microorganisms that may be present on the surface of an object.
disk fluid-filled pad of cartilage between two vertebrae.
dissipation of energy the way energy is transferred to the human body by the forces acting upon it.
distal distant, or far from the point of reference. Opposite of proximal.
distributive shock shock associated with a decrease in intravascular volume caused by massive systemic vasodilatation and an increase in the capillary permeability.
do not resuscitate (DNR) order a legal document, usually signed by the patient and his physician, that indicates to medical personnel which, if any, life-sustaining measures should be taken when the patient’s heart and respiratory functions have ceased.
dorsal toward the back or spine. Opposite of ventral.
dorsal respiratory group (DRG) respiratory rhythm center located in the brainstem that controls the rate and depth of normal quiet respiration.
dorsalis pedis (dor-SAL-iss PED-is) artery an artery of the foot, which can be felt on the top surface of the foot.
dose the amount of a medication that is given to a patient at one time; for example, a dose of nitroglycerin may be one tablet and a dose of epinephrine may be the contents of one auto-injector.
downtime the time from when the patient goes into cardiac arrest until CPR is effectively being performed. See also total downtime.
drag the factors that slow a projectile.
dressing a sterile covering for an open wound that aids in the control of bleeding and prevention of further damage and contamination.
drowning an incident in which someone is submerged or immersed in a liquid.
dysarthria defective speech caused by impairment of the tongue or other muscles necessary for speech.
dysarthria a medical condition that results from pressure changes that occur when a person descends in water or ascends in altitude.
dysmenorrhea severe pain or cramps during menstruation.
dyspnea shortness of breath or perceived difficulty in breathing.
dysrhythmias irregular contractions of the myocardium secondary to electrical disturbances in the heart.
dystonia a movement disorder that causes involuntary contractions of muscles resulting in twisting and repetitive movements that are sometimes painful.
delay respiratory distress increased respiratory effort caused by impaired respiratory function.
edema (uh-DEE-muh) swelling caused by fluid accumulating in the tissues.
edema (uh-DEE-muh) swelling caused by fluid accumulating in the tissues.
elder abuse neglect or physical, sexual, financial, or emotional/mental mistreatment of an elderly person.
embolic stroke a type of ischemic stroke caused by plaque or other material that lodges in and blocks a cerebral artery.
emergency medical treatment and active labor act (EMTALA) a federal regulation that ensures the public’s access to emergency health care regardless of ability to pay. Also known as the “anti-patient-dumping statute,” forbidding turning a patient away at the door or sending him to a public hospital because of inability to pay.
Emergency Medical Treatment and Active Labor Act (EMTALA) a federal regulation that ensures the public’s access to emergency health care regardless of ability to pay. Also known as the “anti-patient-dumping statute,” forbidding turning a patient away at the door or sending him to a public hospital because of inability to pay.
Emergency Medical Treatment and Active Labor Act (EMTALA) a federal regulation that ensures the public’s access to emergency health care regardless of ability to pay. Also known as the “anti-patient-dumping statute,” forbidding turning a patient away at the door or sending him to a public hospital because of inability to pay.
emergency move a patient move that should be performed when there is immediate danger to the patient or to the rescuer.
emotional abuse when one person shames, ridicules, embarrasses, or insults another so as to damage the victim’s self-esteem.
EMS system Emergency Medical Services system.
coder device that breaks down sound waves into unique digital codes for radio transmission.
encoding process of converting information into a message.
endocrine (EN-do-krin) system a system of ductless glands that produce hormones that regulate body functions.
endometriosis the condition in which endometrial tissue grows outside of the uterus.
endometritis inflammation of the endometrium.
endotracheal intubation placement of a tube down the trachea to facilitate airflow into the trachea and lungs.
enteral feeding provision of nutrition through a tube inserted through the nose, the mouth, or a surgical opening in the abdomen into the gastrointestinal system.
epidermis (EP-i-DER-mis) the outermost layer of the skin. See also dermis, subcutaneous layer.
epidural between the dura mater and the skull.
epidural hematoma bleeding between the dura mater and the skull.
epiglottis (EP-i-GLOT-iss) a small, leaf-shaped flap of cartilaginous tissue, located immediately posterior to the root of the tongue, that covers the opening of the larynx to keep food and liquid from entering the trachea and lungs.
epilepsy a medical disorder characterized by recurrent seizures.
epinephrine a natural hormone that, when used as a medication, contracts blood vessels to improve blood pressure, reduces leakage from blood vessels, relaxes smooth muscle in the bronchioles (causes bronchodilatation), and increases the heart rate and force of ventricular contractions.
epistaxis bleeding from the nose resulting from injury, disease, or environment; a nosebleed.
eschar the hard, tough, leathery dead soft tissue formed as a result of a full-thickness burn.
esophageal varices bulging, engorgement, or weakening of the blood vessels in the lining of the lower part of the esophagus.
esophagus (es-oh-FAY-gus) passageway at the lower end of the pharynx that leads to the stomach.
ethnocentrism the view that one culture’s way of doing things is the right way and any other way is inferior.
exhalation the passive process of breathing air out of the lungs.
excited delirium see agitated delirium.
exclusion zone see hot zone.
exhalation the passive process of breathing air out of the lungs. Also called expiration.
expiration see exhalation.
exhausted consent permission that must be obtained from every conscious, mentally competent adult before emergency treatment may be provided.
extension posturing a posture in which the patient arches the back and extends the arms straight out parallel to the body. A sign of serious head injury. Also called decerebrate posturing.
external respiration the gas exchange process that occurs between the alveoli and the pulmonary capillaries.
extremities the limbs of the body. The lower extremities include the hips, thighs, legs, ankles, and feet. The upper extremities include the shoulders, arms, forearms, wrists, and hands.
eyelids movable protective folds that can cover the eyes.
face the area of the skull between the brow and the chin.
fallopian tubes thin, flexible structures that extend from the uterus to the ovaries. Also called uterine tubes.
fallout radioactive dust and particles that may be life-threatening to people far from the epicenter of a radioactive detonation.
false imprisonment the intentional and unjustifiable detention of a person without his consent or other legal authority.
feedback any information that an individual receives about his behavior.
femoral (FEM-o-ral) artery the major artery of the thigh that supplies the groin and leg with blood.
fetus the child in the uterus from the third month of pregnancy to birth; prior to that time it is called an embryo.

fibula (FIB-u-lah) the lateral, smaller long bone of the lower leg.
flail segment two or more adjacent ribs that are fractured in two or more places and thus move independently from the rest of the rib cage.
flexion posturing a posture in which the patient arches the back and flexes the arms inward toward the chest. A sign of serious head injury. Also called decorticate posturing.
flow-restricted, oxygen-powered ventilation device (FROPVD) a device that consists of a ventilation valve and trigger or button and is driven directly by oxygen. It is used to provide positive pressure ventilation.
flushing abnormally red skin color due to vasodilation.
fractional catheter see soft catheter.
frequency of ventilation (f) the number of ventilations in 1 minute.
fracture plane a natural fracture plane that divides the body into anterior and posterior halves. Also called coronal plane.
full-thickness burn a burn that involves all the layers of the skin and can extend beyond the subcutaneous layer into the muscle, bone, or organs below; also called a third-degree burn.
gamma radiation see X-ray radiation.
gastric distention inflation of the stomach.
gastroenteritis inflammation of the stomach and small intestine.
genital system the system of an animal that includes both the reproductive organs of the male and female.
genitalia the external sex organs of males and females.
genitourinary system male organ system that includes both the reproductive and the urinary structures.
gestures nonverbal body movements that convey meaning to others.
glaucoma an abnormal increase in intraocular pressure that damages the optic nerve, resulting in loss of peripheral vision and eventual blindness.
globe the eyeball.
glucometer a device for measuring blood glucose.
glucose a form of sugar that is the body’s basic source of energy.

hallucinations substances that cause hallucinations, or false perceptions not based on reality. Also called psychedelics.
haptics the study of touching.
hard catheter see rigid catheter.
hazardous material material that in any quantity poses a threat or unreasonable risk to life, health, or property if not properly controlled during manufacture, processing, packaging, handling, storage, transportation, use, and disposal.
head-tilt, chin-lift maneuver a manual technique used to open the airway. The head is tilted back by one hand. The tips of the fingers of the other hand are placed under the chin and used to lift the mandible up and forward.
Health Insurance Portability and Accountability Act (HIPAA) a federal law enacted in 1996 that protects the privacy of patient health...
care information and gives the patient control over how the information is distributed and used.

heart the muscular organ that contracts to force blood into circulation through the body.

heel drop test see Markle test.

hematemesis vomiting of blood.

hematochezia bright red blood in the stool.

hematoxenia a condition characterized by anemia of the bone marrow due to the action of toxic agents on the bone marrow.

hematuria red blood in the urine.

hemoglobin a complex protein molecule found on the surface of the red blood cell that is responsible for carrying oxygen or giving up oxygen to the tissues.

hemoptysis coughing up blood or blood-stained sputum.

hemorrhagic hypovolemic shock shock from the loss of whole blood into the intravascular space. Often called just hemorrhagic shock.

hemorrhagic stroke a stroke caused by rupture of a blood vessel in the brain that allows blood to leak and collect in or around the brain tissue.

hemotherax blood in the pleural space, causing collapse of the lung.

hernia protrusion or thrusting forward of a portion of the intestine through an opening or weakness in the abdominal wall.

high-pressure regulator a one-gauge regulator that is used to power the flow-restricted, oxygen-powered ventilation device. The flow rate can be adjusted.

histamine the primary chemical mediator released from the mast cells in an anaphylactic reaction.

hives raised, red blotches associated with allergic and anaphylactic reactions.

horizontal plane see transverse plane.

hospice a philosophy of care that is aimed at providing relief of symptoms for the patients and support for their families during the late stages of a terminal condition.

hot zone the area where contamination is actually present. It generally is the area that is immediately adjacent to the accident site and where contamination can still occur. Also called exclusion zone.

hydric stress (HY-drihk-STAT-ik) pressure the blood pressure or force exerted against the inside of vessel walls; the "push" effect that forces fluid out of a capillary.

hypercarbia increased carbon dioxide levels in the blood. Also called hypercapnia.

hyperglycemia high blood glucose. A blood glucose level greater than 120 mg/dL.

hyperglycemic hyperosmolar nonketotic syndrome (HHNS) a condition typically found in type 2 diabetics where the blood glucose level rises excessively, causing loss of large amounts of fluid from glucose spilling into the urine, leading to severe dehydration.

hypersensitivity a state of altered reactivity to an antigen, or foreign substance, that causes allergic reactions to that substance. See also sensitization.

hyperthermia abnormally high core body temperature; core body temperature above the normal 37°C (98.6°F).

hypoglycemia low blood glucose. A blood glucose level of 60 mg/dL with signs or symptoms of hypoglycemia or a blood glucose level of less than 50 mg/dL with or without signs or symptoms of hypoglycemia.

hypoperfusion (HY-po-per-FU-zhun) see shock.

hypopnea a reduced oxygen delivery to the tissues.

iliac (IL-i-ak) crest the upper margin of the bones of the pelvis.

immune response production of antibodies by the immune system to fight off invasion by foreign substances.

immunologic system the body’s defense mechanism against invasion by foreign substances.

impaled object an object embedded in the body.

implied consent the assumption that, in a true emergency where a patient who is unresponsive or unable to make a rational decision is at significant risk of death, disability, or deterioration of condition, that patient would agree to emergency treatment. Also called the emergency doctrine.

incendiary device devices using agents such as napalm, thermite, magnesium, and white phosphorus to cause injury by burning at high temperatures.

incident command system (ICS) the standardized incident management concept that has become the standard for on-scene management of disasters and multiple-casualty incidents.

incident commander the person who is responsible for coordinating all aspects of a disaster or multiple-casualty incident.

incomplete spinal cord injury injury to the spinal cord that does not affect all spinal cord tracts: motor, light touch, and pain. May produce conflicting and confusing assessment findings as some motor and sensory functions remain intact while others do not.

index of suspicion an anticipation that certain types of accidents and mechanisms will produce specific types of injuries.

indication the common reasons for using a medication to treat a specific condition; for example, chest pain is an indication for nitroglycerin.

indirect force a force that causes injury some distance away from the point of impact.

infect child from 1 month to 1 year of age. See also neonate.

inferior beneath, lower, or toward the feet. Opposite of superior.

inferior plane everything below the transverse line (below the waist). Opposite of superior plane.

informed consent consent for treatment that is given by a competent patient based on full disclosure of possible risks and consequences.

ingested poison a poison that is swallowed and enters the gastrointestinal system.

ingestion swallowing.

inhalation the active process of breathing air into the lungs. Also called inspiration.

inhaled poison a poisonous vapor or fume that is breathed in.

injection a poison that is forced into the body, usually by the intentional injection of a drug or by the bite or sting of an insect.

injection forced introduction into the body through the skin, possibly into a muscle or blood vessel, usually via a syringe, a bite, or a sting.

in-line stabilization bringing the patient’s head into a neutral position in which the nose is in line with the navel and the neck is not flexed or extended and holding it there manually.

inspiration see inhalation.

insulin a hormone secreted by the pancreas that lowers the blood glucose level by promoting the movement of glucose from the blood into the cells.

integumentary (in-teg-yu-MENT-ub-re) system the skin.

intentional tort a wrongful act, injury, or damage that is committed knowingly.

intercostal (in-ter-KOS-tal) muscles the muscles between the ribs.

internal respiration the gas exchange process that occurs between the alveoli and capillary blood. Oxygen is absorbed by the capillaries and carbon dioxide is released into the alveoli.

intestinal obstruction blockage that interrupts the normal flow of intestinal contents.

intimate zone in American culture, the space within less than 1 1/2 feet of a person.

intact fluid pressure in the intravascular space resulting in a low blood volume.

intact fluid pressure the fluid pressure of or force exerted against the inside of vessel walls; the "push" effect that forces fluid out of a capillary.

irrigant agents or substances used to soak devitalized tissue such as devitalized bone, muscle, and other structures.

irritant receptors receptors that are found in the airways and are sensitive to irritating gases, aerosol, and particles and result in a cough, bronchoconstriction, and increased ventilatory rate when stimulated.

ischemic stroke a stroke caused by a clot obstructing a blood vessel in the brain, resulting in an inadequate amount of blood being delivered to a portion of the brain distal to the blocked vessel.

jaundice a condition characterized by yellowness of the skin, sclera of the eye, mucous membranes, and body fluids. It typically indicates liver failure or disease.

jaw-thrust maneuver a manual technique used to open the airway in the patient with a suspected spinal injury. The fingers are placed at the angles of the jaw and used to lift the mandible up and forward.
joint a place where one bone meets another.
emph{J-receptors} receptors that are found in the capillaries surrounding the alveoli and are sensitive to increases in the pressure in the capillary and cause rapid, shallow ventilation when stimulated.

Kehr sign shoulder pain referred from the diaphragm when it is irritated by blood within the abdominal cavity.

kinetic energy the energy contained by an object in motion. Kinetic energy equals mass (weight in pounds), times the velocity (feet per second) squared, divided by two.

kinetics the branch of mechanics dealing with the motions of material bodies.

kinetics of trauma the science of analyzing mechanism of injury.

kyphosis abnormal curvature of the spine with convexity backward.

Also called slouched.

labor the physiologic process by which the fetus is expelled from the uterus into the vagina and then to the outside of the body. Also called childbirth.

laceration an open injury usually caused by forceful impact with a sharp object and characterized by a wound whose edges may be linear (smooth and regular) or stellate (jagged and irregular) in appearance; a wound that penetrates the brain.

laryngeal spasm a contraction of the vocal cords that causes them to close and prevents air from passing through into the trachea. Also called laryngospasm.

laryngectomy a surgical procedure in which a patient's larynx is partially or completely removed. A stoma is created for the patient to breathe through.

larynx (LAI-inks) structure that houses the vocal cords and is located inferior to the pharynx and superior to the trachea.

lateral (LAT-er-al) refers to the left or right of the midline, or away from the midline, or to the side of the body. See also medial.

lateral recumbent a position in which the patient is lying on the left or right side. Also called recovery position.

leading questions questions that suggest an answer guided by the individual who is asking the question.

left refers to the patient's left.

left plane everything to the left of the midline.

lens the portion of the eye behind the pupil that focuses light on the retina.

libel the act of injuring a person's reputation or good name in writing or through the mass media with malicious intent or reckless disregard for the falsity of those statements.

life expectancy the average length of years of life remaining based on the individual's year of birth.

ligaments bands of fibrous tissue that connect bones about a joint and support organs.

limb presentation an abnormal obstetric presentation when an arm or single leg is the first fetal part to protrude from the vaginal opening.

living will a legal document that delineates the signer's wishes about life support measures.

local cold injury damage to tissues in a specific part of the body resulting from exposure to cold.

lordosis abnormal anterior convexity of the spine. Also called swayback.

lower airway the portion of the respiratory system that extends from the trachea to the alveoli of the lungs.

lumbar (LUM-bar) spine the five vertebrae located between the sacral and the thoracic spine that form the lower back.

lungs the principal organs of respiration.

malaise a general feeling of weakness or discomfort.

malleolus (mal-E-oh-lus) the knobby surface landmark of the ankle. There is a medial malleolus and a lateral malleolus.

mammalian diving reflex the body's natural response to submersion in cold water in which breathing is inhibited, the heart rate decreases, and blood vessels constrict in order to maintain cerebral and cardiac blood flow.

mandible (MAN-di-bl) the lower movable portion of the jaw.

manubrium (ma-NU-bre-um) the superior portion of the sternum where the clavicle is attached.

Markle test a test for the presence of peritonitis in which the patient stands on his toes, then drops to his heels, or in which the heels are struck together or struck on the bottom. The jarring of the torso will elicit pain when the peritoneal linings are inflamed. Also called the heel drop test.

maxilla the fixed upper portion of the jaw.

maximum life span theoretically the longest period of time for an organism to live.

mechanism of injury (MOI) the factors and forces that cause traumatic injury.

meconium staining a greenish or brownish yellow staining of the amniotic fluid, caused by a fetal bowel movement resulting from distress.

medial toward the midline or center of the body. See also lateral.

median plane see sagittal plane.

medical concerning illness.

medical direction medical policies, procedures, and practices that are available to EMS providers either off-line or on-line.

medical director physician who is legally responsible for the clinical and patient care aspects of an EMS system.

medical oversight the medical director's broad responsibilities, including all clinical and administrative functions and activities necessary to exercise ultimate responsibility for the emergency care provided by individual personnel and the entire emergency medical services (EMS) system.

medical oxygen oxygen administered as a medication or to support or improve a patient's oxygenation.

medical patient a patient with a condition brought on by illness or by substances or by environmental factors that affect the function of the body.

medication a drug or other substance that is used as a remedy for illness.

menarche onset of menses.

meninges layers of tissue protecting the brain. They include the dura mater, the arachnoid, and the pia mater.

menopause the permanent end of menstruation and fertility, which usually occurs in a woman's late 40s or 50s.

menses menstrual period in which the endometrium is sloughed off.

metacarpals (MET-uh-KAR-pulz) the bones of the hand.

metatarsals (MET-uh-TAR-sulz) the bones that form the arch of the foot.

minute ventilation the amount of air moved in and out of the lungs in one minute. Also called minute volume.

minute volume see minute ventilation.

miscarriage see spontaneous abortion.

mottling a skin discoloration similar to cyanosis but occurring in a blotchy pattern; a possible sign of shock.

musculoskeletal system the branch of mechanics dealing with the motions of material bodies.

multiple birth the delivery of more than one baby during a single birth, for example twins or triplets.

multiple-casualty incident (MCI) an event that places excessive demands on EMS personnel and equipment.
located in the pons of the brainstem, sends
an infection of the lungs, usually from a bacterium or virus.
the blast of an explosion.
see
any substance—liquid, solid, or gas—that impairs health or
a persistent erection of the penis resulting from injury to the
irritation and inflammation of the abdominal lining.
open; not blocked, as a patent airway.
inner layer of protective brain tissue (meninges).
the throat, or passageway for air from the nasal cav-
the pressure generated in the left ventricle at the end of diastole
the policies and procedures for all components of an EMS
the recovery period that follows the clonic phase of a
inflammation of the female repro-
blood or fluid filling the fibrous sac around the
an open injury caused by a sharp, pointed object
pressure regulator
an airway that is open and clear of any obstructions.
periocardial tamponade blood or fluid filling the fibrous sac around the
heart, causing compression of the heart and decreasing the ability of the
venicles to effectively fill and eject blood.
perineum the area of skin between a female’s vagina and anus.
peripheral chemoreceptors receptors located in the aortic arch and
the carotid bodies that are somewhat sensitive to CO₂ and pH but are most sensitive to the level of oxygen in the arterial blood. See also chemoreceptors.
peripheral nervous system that portion of the nervous system located
outside the brain and spinal cord. Abbr. PNS.
perineal
space the anterior abdominal cavity that houses the majority of the abdominal organs and is lined by the peritoneum.
peritoneum the lining of the abdominal cavity.
peritonitis irritation and inflammation of the abdominal lining.
persistence characteristic of agents that do not evaporate quickly and
tend to remain as a puddle for long periods of time.
personal protective equipment (PPE) equipment worn to protect
against injury and disease.
prenatal
negative signs or symptoms that might be expected in cer-
tain circumstances, based on the chief complaint or physical exam, but are denied by the patient or not found on examination.
phalanges (fa-LAN-jez) bones of the fingers, thumbs, and toes. Pl. of
phalanx.
pharmacology the study of drugs.
pharming raiding others’ home medicine supplies or using faked pre-
scriptions to obtain drugs.
pharynx (FAIR-inks) the throat, or passageway for air from the nasal cav-
ity to the larynx and passageway for food from the mouth to the esoph-
ae, the common passageway for the respiratory and digestive tracts.
phobia an irrational fear that often surrounds or is triggered by specific
things, places, or situations.
physical abuse improper or excessive action taken so as to injure or cause bodily harm.
physician orders for life-sustaining treatment (POLST) orders that identify the desired level of life-sustaining treatment in patients with a terminal or life-threatening illness who are not likely to survive.
physiology (FIZ-e-OL-o-je) the study of the function of the living body
and its parts.
pia mater inner layer of protective brain tissue (meninges).
placenta the fetal organ through which the fetus exchanges nourishment and waste products during pregnancy.
plantar refers to the sole of the foot.
plasma the liquid part of the blood.
plasma oncotic pressure the force created by the presence of large
molecules that tend to keep fluid inside a capillary by exerting a “pull”
effect. Also called colloid oncotic pressure or oncotnic pressure.
platelets (PLATE-lets) components of blood that are essential to the
formation of blood clots.
pleura two layers of connective tissue that surround the lungs.
pleural space a small space between the visceral and parietal pleura
that is at negative pressure and filled with serous fluid.
pneumonia infection of the lungs, usually from a bacterium or virus.
pneumotaxic center see pontine respiratory center.
pneumothorax air in the pleural space causing collapse of the lung.
pocket mask a plastic mask placed over the patient’s nose and mouth
through which ventilations can be delivered.
poison any substance—liquid, solid, or gas—that impairs health or
causes death by its chemical action when it enters the body or comes into contact with the skin.
pontine respiratory center located in the pons of the brainstem, sends
inhibitory impulses to the VRG (inspiratory neurons) to halt inspiration and permit exhalation.
positive pressure ventilation (PPV) method of aiding a patient whose
breathing is inadequate by forcing air into his lungs.
posterior (pos-TE-re-er) toward the back. Opposite of anterior.
posterior plane the back or dorsal side of the body.
promise tibial articular cartilage a type of cartilage that travels from the calf to the
foot and that can be felt on the medial surface of the ankle bone.
postictal state the recovery period that follows the clonic phase of a
generalized seizure. In a postictal state the patient commonly appears
weakened, exhausted, confused, and disoriented and progressively improves.
preadolescence: condition that occurs during pregnancy when
germination of the fetus extends beyond 42 weeks, leading to reduced oxygen and nutrient delivery to the fetus. See also postterm pregnancy.
postpartum the period following delivery of the infant.
postpartum hemorrhage the loss of greater than 500 mL of blood fol-
lowing delivery of the infant.
postterm pregnancy gestation of the fetus that extends beyond
42 weeks. See also postmaturity syndrome.
post-traumatic stress disorder (PTSD) a severe anxiety disorder
caused when an individual is exposed to traumatic events that threaten
actual or perceived immediate death, serious injury, or horrific trauma.
The symptoms are frequently delayed and may occur years or decades
after the traumatic event itself.
power grip recommended gripping technique. The palm and fingers
come in complete contact with the object and all fingers are bent at the
same angle.
power lift recommended technique for lifting. Feet are apart, knees
bent, back and abdominal muscles tightened, back as straight as pos-
sible, lifting force driven through heels and arches, upper body rising
before hips.
precipitous delivery birth of the fetus after less than 3 hours of labor.
xerox a word part added to the beginning of a word to modify its mean-
ing or to give additional or specific meaning to the word.
pregnancy-induced hypertension (PIH) in a pregnant woman, a blood
gas pressure greater than 140/90 mmHg on two or more occasions at least
6 hours apart, or an increase from prepregnancy of greater than 30 mmHg
in systolic pressure or greater than 15 mmHg in diastolic pressure.
prehospital care emergency medical treatment given to patients before
they are transported to a hospital or other facility. Also called out-of-
hospital care.
prehospital care report (PCR) documentation of an EMT’s contact
with a patient.
preload the pressure generated in the left ventricle at the end of diastole
(resting phase of the cardiac cycle).
pregnancy infant an infant weighing less than 5 pounds, or an infant
born before its 38th week of gestation.
pregnancy rupture of membranes (PROM) spontaneous rupture of the
amniotic sac prior to the onset of true labor and before the end of the
37th week of gestation.
preschooler a child 3 to 6 years of age.
pressure regulator a device that reduces the high pressure in an oxy-
gen cylinder to a safe range, from 30 to 70 psi, and controls the flow of
oxygen from 1 to 15 lpm.
prechlampsia persistent elevation of the blood pressure resulting from injury to the
spinal nerves to the genitals.
primary assessment patient assessment conducted immediately after
scene size-up to discover and treat immediately life-threatening condi-
tions, determine whether the patient is injured or ill, and establish
priorities for further assessment, care, and transport.
primary effect the blast of an explosion.
primary exposure radiation injury that occurs during or shortly
after a radioactive detonation.
primary triage evaluation of patients that occurs immediately upon ar-
ival of the first EMS crew at the actual site of the incident to quickly
categorize the severity of a patient’s condition and priority for treatment
and transport.
profile the size and shape of a bullet’s point of impact; the greater the
point of impact the greater the injury.
progressive shock see compensatory shock.
prolapsed cord when the umbilical cord rather than the head of the
fetus, is the first part to protrude from the vagina.
prone lying face down.
protocols the policies and procedures for all components of an EMS
system. Also called orders or standing orders.
proximal (PROK-sim-al) near the point of reference. Opposite of distal.
proximate cause the act of deviating from an accepted standard of care through carelessness, inattention, disregarded, inadvertence, or oversight, or the act of injuring a patient in the course of care.

psychosis state of delusion in which a person is out of touch with reality that can manifest through delusions, hallucinations, disorganized speech or behavior, and looseness of associations.

puberty the period in which the sexual organs mature during adolescence.

pubis (PYU-bis) bone of the pelvis.

pulmonary agents agents that act primarily to cause lung injury and are commonly referred to as choking agents, including phosgene (CG), other halogen compounds, and nitrogen-oxygen compounds.

pulmonary artery artery that carries deoxygenated blood from the right ventricle of the heart to the lungs.

pulmonary contusion bleeding within the lung tissue that causes a disturbance in gas exchange between the alveoli and capillaries.

pulmonary edema fluid in and around the alveoli in the lungs.

pulmonary embolism blockage in the pulmonary arteries of the lungs.

pulmonary vein vein that carries oxygenated blood from the lungs to the left atrium of the heart.

pulp the wave of blood propelled through the arteries as a result of the contraction of the left ventricle.

pulsoximeter electronic device used to determine the oxygen concentration in arterial blood.

pulse oximetry measurement of blood oxygen saturation.

pulse pressure the difference between the systolic blood pressure and the diastolic blood pressure.

pullessed electrical activity (PEA) a condition in which the heart generates relatively normal electrical rhythms but fails to perfuse the body adequately because of a decreased or absent cardiac output from cardiac muscle failure or blood loss.

pulsus paradoxus a decrease in pulse strength during inhalation; a drop in blood pressure of more than 10 mmHg during inhalation resulting from increased pressure within the chest that suppresses the filling of the ventricles of the heart with blood.

pupil the dark center of the eye; the opening that expands or contracts to allow more or less light into the eye.

purified protein derivative (PPD) tuberculin test a test to determine the presence of a tuberculosis infection based on a person’s positive reaction to tuberculin, a substance prepared from the tubercle bacillus.

quadruplegic paralyzed from the neck down.

quality improvement (QI) a system of internal and external reviews and audits of an EMS system to ensure a high quality of care. Also known as continuous quality improvement (CQI).

raccoon sign discoloration of tissue around the eyes suggestive of basilar skull injury.

radial artery a major artery of the arm, distal to the elbow joint.

radiation transfer of heat from the surface of one object to the surface of another without physical contact between the objects.

radius the lateral bone of the forearm.

rapid extrication a technique using manual stabilization rather than extrication when the time saved will make the difference between life and death.

rapid secondary assessment a head-to-toe physical exam that is swiftly conducted on a trauma patient who is unresponsive or who has a significant mechanism of injury, has altered mental status, responds to verbal or painful stimuli, or is unresponsive; or on a medical patient who is not alert, is disoriented, does not respond to verbal or painful stimuli, or is unresponsive.

reasonable force the minimum amount of force required to keep a patient from injuring himself or others.

reassessment the continuous assessment that is conducted following the secondary assessment to detect any changes in the patient’s condition, to identify any missed injuries or conditions, and to adjust emergency care as needed.

red blood cells part of the blood that gives it its color, carries oxygen to body cells, and carries carbon dioxide away from body cells.

referred pain pain that is felt in a body part removed from the point of origin of the pain.

reflex an instantaneous and involuntary movement resulting from a stimulus.

renal (RE-nuhl) referring to the kidneys.

renal calculi kidney stones.

renal system see urinary system.

repeaters devices that receive transmissions from a relatively low-powered source such as a mobile or portable radio and rebroadcast them at another frequency and a higher power.

reproductive system the male or female organs that function to accomplish human reproduction, the creation of offspring.

residual volume the air remaining in the lungs after a maximal exhalation.

respiratory the exchange of gases between an organism and its environment; the exchange of oxygen and carbon dioxide that takes place during inhalation and exhalation.

respiratory arrest complete stoppage of breathing. Also called apnea.

respiratory control centers centers in the brainstem that regulate respiration, including the dorsal respiratory group (DRG) and the ventral respiratory group (VRG).

respiratory distress increased respiratory effort resulting from impaired respiratory function, while tidal volume and respiratory rate are still adequate.

respiratory failure insufficient respiratory rate and/or tidal volume.

respiratory rate the number of breaths taken in one minute. Also called frequency.

respiratory system the organs involved in the exchange of gases between an organism and the atmosphere.

resuscitation bringing a patient back from a potential or apparent death; an attempt to restore normal or adequate physiologic function.

reticul activating system (RAS) a network of specialized nerve cells within the brainstem that controls states of arousal and consciousness including wakefulness, attentiveness, and sleep.

retina the structure at the back of the eye that is responsible for vision.

retractions depressions seen in the neck, above the clavicles, between the ribs, or below the rib cage from excessive muscle use during breathing. It is an indication of respiratory distress.

retrograde amnesia inability to remember circumstances prior to an event.

retroperitoneal cavity the space located behind the peritoneal cavity.

return of spontaneous circulation (ROSC) return of a spontaneous pulse during the cardiac resuscitation.

right refers to the patient’s right.

right plane everything to the right of the midline.

rigid catheter a rigid plastic tube that is part of a suctioning system, commonly referred to as a tonsil tip or tonsil sucker.

rigidity see involuntary guarding.

route the means by which a medication is given or taken; for example, sublingual (under the tongue), oral (by mouth), inhalation (breathed in), or injection (inserted by needle into a muscle or vein).

rule of nines standardized format to quickly identify the amount of skin or body surface area (BSA) that has been burned.

rule of ones the concept that the area of a patient’s palm is equal to the area of five vertebrae that are fused together to form a vertebra.

rule of palms see rule of ones.

sacral (SAK-ir-uhl) spine five vertebras that are fused together to form the rigid part of the posterior side of the pelvis. Also called the sacrum.

safety zones areas surrounding an accident involving hazardous materials, designated for specific rescue operations. See also hot zone, warm zone, and cold zone.

sagittal (SAJ-i-tul) plane a vertical plane that divides the body into right and left segments. Also called median plane. See also midsagittal plane.

SAMPLE history a format for taking a patient history. SAMPLE is an acronym used to remember categories of information necessary to the patient history: signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading to the injury or illness.

SBAR acronym for situation, background, assessment, and recommendation; a method of organizing communications about a patient.

scapula (SKAP-u-lah) the shoulder blade.

scene safety steps taken to ensure the safety and well-being of the EMT, his partners, patients, and bystanders.

scene size-up the assessment of the scene for safety hazards and to determine the nature of the patient’s problem and the number of patients.

schizophrenia a chronic mental illness in which a patient experiences distortions of speech and thought, bizarre delusions and hallucinations, social withdrawal, catatonic behavior, and/or lack of emotional expression, and does not return to previous level of functioning.

school-age child a child 6 to 12 years of age.

sclera the outer coating of the eye; the exposed portion is “the white of the eye.”

scope of practice the actions and care that an EMT is legally allowed to perform, as typically defined by state laws.

secondary assessment the portion of patient assessment conducted after the primary assessment, for the purpose of identifying additional serious or potentially life-threatening injuries or conditions and as a basis for further emergency care.
secondary effects effects from flying debris, shrapnel, and other projectiles. In an explosion, the flying debris can cause significant penetrating injury to the skin, muscles, and bones. In the event of a release of a toxic agent, such as chlorine gas, which is heavier than air, victims would need to lie on their backs to avoid aspiration of the gas into their lungs.

secondary triage reevaluation of the patient at the scene of the accident. This reevaluation would be performed by trained personnel to ensure the patient's ongoing safety and to ensure that appropriate care is provided.

seizure a sudden and temporary alteration of the brain that results from a rapid discharge of electric currents normally controlled by the brain. This type of stimulation is sometimes resisted by anticonvulsant drugs.

Sellick maneuver see cricoide pressure.

semi-Fowler's position a position in which the patient is lying on his side with the upper body elevated approximately 10 to 12 degrees. This position is used in cases where the patient has a risk of aspiration or where the patient has a history of respiratory problems.

sensation exposure to an allergen that results in hypersensitivity to that allergen. See also hypersensitivity.

septic shock a type of distributive shock caused by an infection that releases toxins into the bloodstream. This type of shock is often associated with septicemia, or bloodborne infection.

serious fluid fluid that acts as a lubricant to reduce the friction between the parietal and visceral pleura.

sexual abuse the involvement of a child in sexual activities for the gratification of an older or more powerful person.

shock the insufficient delivery of oxygen and other nutrients to some of the body's cells and inadequate elimination of carbon dioxide and other wastes that results from inadequate circulation of blood. Also called hypoperfusion.

shock position elevation of the legs of a supine patient approximately 12 inches; an alternative to the Trendelenburg position; sometimes useful for treating a simple faint but no longer recommended in the treatment of shock.

shoulder dystocia abnormal delivery when the fetal shoulders are larger than the fetal head and the head delivers but the shoulders are caught between the symphysis pubis and the sacrum.

side effects the undesired effects of a medication; for example, side effects of epinephrine are increased heart rate and anxiety.

signs any objective evidence of medical or trauma conditions that can be seen, heard, felt, or smelled in a patient.

silent heart attack a myocardial infarction (heart attack) that does not cause chest pain or discomfort.

simple access a way to gain access to a patient that does not require tools or specialized equipment.

skeletal muscle any muscle that can be consciously controlled by the individual. Also called voluntary muscle.

skeletal system the bony framework of the body.

skull the bony structure at the top of the spinal column that houses and protects the brain. The skull has two parts, the cranium and the face.

slander a willful act designed to end one's own life.

simple faint a brief period of unresponsiveness caused by a lack of blood supply to the brain.

soft catheter flexible tubing that is part of a suctioning system, also called a French catheter.

somatic pain pain that is conscious and located in specific parts of the body.

spacemaker a chamber that is connected to the metered-dose inhaler to collect the medication until it is inhaled.

sphygmomanometer instrument used to measure blood pressure. Also called a blood pressure cuff.

spinal column the column of 33 vertebrae that enclose and protect the spinal cord. Also called the vertebral column.

spinal cord a column of nervous tissue that exits from the brain and extends to the level of L2 within the spinal column. All nerves to the trunk and extremities originate from the spinal cord.

spinal shock shock caused by injury to the spinal cord, causing paralysis and loss of sensation below the level of the spinal cord injury. Signs include motor and sensory dysfunction. Normal to low heart rate and warm, dry, pink skin may occur if vasodilation and relative hypovolemia (neurogenic hypotension) are present.

splint any device used to immobilize a body part.

spontaneous abortion without apparent cause, the termination of a pregnancy before the fetus reaches the stage of viability, generally before the 20th week of pregnancy. Also called miscarriage.

staging unit in a multiple-casualty incident, the unit that monitors, inventories, and directs available ambulances to the treatment unit at the request of the transport officer.

standard of care emergency care that would be expected to be given to a patient by any trained EMT under similar circumstances.

Standard Precautions a method of preventing infection by disease organisms based on the premise that all blood and body fluids are infectious. Formerly called body substance isolation.

standing orders preauthorized treatment procedures; a type of treatment protocol. See also off-line medical direction, protocols.

status epilepticus a seizure lasting longer than 5 minutes or seizures that occur consecutively without a period of responsiveness between them. This is a serious medical emergency that may be life threatening.

stenosis constriction or narrowing of a passage or opening, for example of the valves of the heart.

sterile free from living microorganisms such as bacteria, viruses, or spores that may cause infection.

sterilization the process by which an object is subject to certain chemical or physical substances (typically, superheated steam in an autoclave) that kill all microorganisms on the surface of an object.

sternum the breastbone.

stoma a permanent surgical opening into the neck and trachea. See also tracheostomy.

stretch receptors receptors found in the smooth muscle of the airways that monitor the size and volume of the lungs. These receptors stimulate a decrease in the rate and volume of ventilation when stretched by high tidal volumes to protect against lung overinflation.

stridor a harsh, high-pitched sound heard on inspiration that indicates swelling of the larynx or obstruction of the upper airway.

stroke a sudden disruption in blood flow to the brain that results in brain cell damage. Blood flow might be interrupted by a ruptured artery or blocked by a clot or other foreign matter in an artery that supplies the brain.

stroke volume the volume of blood ejected by the left ventricle with each contraction.

subarachnoid hemorrhage bleeding that occurs between the arachnoid membrane and the surface of the brain.

subarachnoid space a lattice of fibrous, spongy tissue filled with cerebrospinal fluid that separates the arachnoid membrane and the pia mater.

subcutaneous (SUB-kyu-TAY-ne-us) layer a layer of fatty tissue just below the dermis. See also dermis, epidermis.

subdural beneath the dura mater.

subdural hematoma bleeding between the brain and the dura mater.

sucking chest wound an open wound to the chest that permits air to enter into the thoracic cavity.

sudden death death of a patient within 1 hour of the onset of signs and symptoms.

sudden infant death syndrome (SIDS) the sudden and unexpected death of an infant or young child in which an autopsy fails to identify the cause of death. SIDS typically occurs while the infant is asleep.

suffixed a word part added to the end of a word to modify its meaning or to give additional or specific meaning to the word.

suicide a willful act designed to end one's own life.

superficial burn burn that involves only the epidermis and results from inadequate circulation of blood. Also called first-degree burn.

superior above; toward the head. Opposite of inferior.

superior plane everything above the transverse line (above the waist).

supine lying face up.

supine hypotensive syndrome inadequate return of venous blood to the heart, reduced cardiac output, and lowered blood pressure resulting from pressure on the inferior vena cava, caused by the weight of the uterus and fetus when the patient in late pregnancy is in a supine position.

support zone the zone of the body protected by the support structure beneath the skin.

surfactant a substance responsible for maintaining surface tension in the alveoli.

surgically implanted medication delivery devices medication administration devices that are surgically placed beneath the skin outside the rib cage. Also called totally implantable venous access system (TIVAS).

survival term applied to a patient who survives cardiac arrest to be discharged from the hospital.

symptoms conditions that must be described by the patient because they cannot be observed by another person.

syringe a brief period of unresponsiveness caused by a lack of blood flow to the brain; fainting.

systemic vascular resistance the resistance of blood flow through a vessel based on the diameter of the vessel.

systolic (sis-TOL-ik) blood pressure the pressure exerted against the walls of the arteries when the left ventricle contracts. See also diastolic blood pressure.
tachycardia a heart rate greater than 100 beats per minute.
tachypnea a breathing rate that is faster than the normal rate.
tardive dyskinesia a movement disorder that causes involuntary move-
ments of the tongue, lips, face, trunk, and extremities.
tarsals the bones of the ankle, hindfoot, and midfoot.
tender-ness pain in response to palpation.
tension pneumothorax a condition in which the buildup of air and
pressure within the thoracic cavity associated with an injured lung is
so severe that it begins to shift the injured lung to the uninjured side,
resulting in compression of the heart, large vessels, and the uninjured
lung.
terminally ill the condition of an individual who has a disease process
that is realistically expected to result in the death of the patient, despite
medical treatment.
tertiary effects in an explosion, injuries produced by propulsion, for
example when a person is propelled by a blast or shock wave and
strikes the ground or other objects, resulting in blunt trauma.
therapy regulator a device that controls the flow and pressure of oxy-
gen from the tank to allow for a consistent delivery of oxygen by liters per
minute.
themoreceptor a sensory receptor that is stimulated by temperature.
thoracic (tho-RAS-ik) spine the 12 vertebrae directly below the cervi-
cal vertebrae that comprise the upper back.
thorax (THO-ralks) the chest, or that part of the body between the base of
the neck and the diaphragm.
thrombotic stroke a type of ischemic stroke caused by a stationary clot
that forms in and blocks a cerebral artery.
thyroid cartilage the bulbous cartilage that forms the anterior portion of
the larynx. Also called the Adam’s apple.
tibia the medial, larger bone of the lower leg; the shinbone.
tidal volume (V̇) the amount of air breathed in and out in one normal
respiration.
tilt test see orthostatic vital signs.
toddler a child 1 to 3 years of age.
tonsil tip or tonsil sucker rigid suction catheter.
tort a wrongful act, injury, or damage. See also intentional tort.
total downtime the total time from when a patient goes into cardiac
arrest until he is delivered to the emergency department. See also down-
time.
totally implantable venous access system (TIVAS) see surgically im-
planted medical delivery device.
toxico-logy the study of toxins, antidotes, and the effects of toxins on
the body.
toxins drugs or substances that are poisonous to humans and will cause
certain adverse effects that may ultimately lead to death. Toxin is some-
times considered a synonym to poison, sometimes defined more nar-
rowly as a poisonous substance of plant or animal origin.
trachea (TRAY-ke-ah) the tube-like structure that leads from the larynx
to the lungs.
tracheostomy a surgical opening in the trachea.
tracheostomy tube a hollow tube that is inserted into a tracheostomy to
allow the patient to breathe.
trajecto-ry the path of a projectile during its travel; a trajectory may be
flat or curved.
 transient ischemic attack (TIA) brief, intermittent episode with stroke-
like symptoms that typically disappear within minutes, but usually last
no longer than 1 hour. TIAs are caused by an oxygen deficit in the
brain tissue (ischemia) and are often a precursor to a stroke.
transport unit in a multiple-casualty incident, the unit that coordinates
patient transportation with the triage and staging units. Its officer com-
municates with the hospitals involved.
transverse line an imaginary line drawn horizontally through the waist.
transverse plane a plane that divides the body into superior and infer-
ior segments. Also called horizontal plane.
trauma concerning injury.
traumatic patient a patient who has a physical injury or wound caused by
external force or violence.
traumatic asphyxia a severe and sudden compression of the thorax
that causes a rapid increase in pressure within the chest that affects
blood flow, ventilation, and oxygenation.
traumatic brain injury (TBI) an alteration in brain function, or other
evidence of brain pathology, caused by an external force, such as con-
cussion, whose signs and symptoms may emerge over time.
treatment unit in a multiple-casualty incident, the unit that is respon-
sible for collecting and treating patients in a centralized treatment area.
Trendelenburg (tren-DELL-en-burg) position lying on the back with the
lower part of the body elevated higher than the head on an inclined plane.
triage the process of sorting patients to determine the order in which
they will receive care or transportation to definitive care.
triage tag a tag containing key information that is attached to a patient
during a multiple-casualty incident.
triage unit in a multiple-casualty incident, the unit that is responsible for
prioritizing patients for emergency medical care and transport.
tripod position a position in which the patient sits upright, leans slightly forward, and supports the body with the arms in front and el-
bows locked. This is a position commonly found in respiratory distress.
twisting force a force that twists a bone while one end is held stationary.
type 1 diabetes a form of diabetes in which the patient’s pancreas
typically does not produce or secrete any insulin. Also called insulin-
dependent diabetes mellitus (IDDM). See also diabetes mellitus (DM).
type 2 diabetes a form of diabetes where the pancreas continues to
produce and secrete insulin; however, the insulin is not completely
effective in controlling the blood glucose level. Type 2 diabetes does
not usually require the patient to take insulin and can, instead, be
regulated by diet, exercise, and drugs other than insulin. Also called
non-insulin-dependent diabetes mellitus (NIDDM). See also diabetes
mellitus (DM).
ulcers open wounds or sores within the digestive tract.
ulna the medial bone of the forearm.
umbilical cord an extension of the placenta through which the fetus
receives nourishment while in the uterus.
umblicus the navel.
umwitnessed cardiac arrest for the purposes of emergency medical
services and providers: an arrest, with the patient already unresponsive, apneic, and pulseless,
when EMS arrives on the scene.
upper airway the portion of the respiratory system that extends from
the nose and mouth to the larynx.
urban hypothermia hypothermia precipitated by cold environments
such as with persons who live on the streets in cold weather or whose
indoor environment is too cool.
uurgent move a patient move made because there is an immediate threat
to life because of the patient’s condition and the patient must be moved
quickly for transport.
urinary catheter a device that is used to divert urine out of the bladder.
urinary (YUR-in-air-e) system the organs and structures responsible
for filtering and excreting wastes from the blood. Also called the renal
system.
urology branch of medicine that studies the urinary system in females
and the genitourinary system in males.
uterus an organ of the female reproductive system for containing and
nourishing the embryo and fetus from the time the fertilized egg is
implanted to the time of birth.
vagina the passageway through which the fetus is delivered. The lower
part of the birth canal.
valves structures within the heart and circulatory system that keep blood
flowing in one direction and prevent backflow.
vascular access device a medical device that is used when a patient is
in need of ongoing intravenous medications.
vein vessel that carries blood toward the heart.
vena cavae the principal veins that carry deoxygenated blood to the
heart. Pl. of vena cava. The superior vena cava carries blood from the
upper body; the inferior vena cava carries blood from the lower body.
ventilation the mechanical process by which air is moved in and out of
the lungs, primarily caused by changes in pressure inside the chest.
ventilation/perfusion (V/Q) ratio the dynamic relationship between
the amount of ventilation the alveoli receive and the amount of perfu-
son through the capillary surrounding the alveoli.
ventral toward the front, or toward the anterior portion of the body.
ventral respiratory group (VRG) respiratory rhythm center located in
the brainstem that has both inspiratory and expiratory neurons. It be-
comes active and stimulates accessory muscles when an increase in
ventilatory effort is necessary.
ventricles the two lower chambers of the heart.
ventricular assist device (VAD) a medical device that is used to assist
the pump function of one or both ventricles, most commonly the left
ventricle.
ventricular fibillation (VF or V-Fib) a continuous, uncoordinated,
chaotic rhythm that does not produce pulses.
ventricular tachycardia (VT or V-Tach) a very rapid heart rhythm that
may or may not produce a pulse and is generally too fast to adequately
perfuse the body’s organs.
venule the smallest branch of a vein.
vertebrae (VER-tuh-bray) the 33 bony segments of the spinal column.
Pl. of vertebra.
vertebral (VER-tuh-bruhl) column see spinal column.
vesicants chemical agents that cause blistering, burning, and tissue damage on contact as well as causing generalized illness if a significant amount is absorbed. Vesicants include sulfur and nitrogen mustards, lewisite, and phosgene oxime.
visceral pain poorly localized, intermittent, crampy, dull, or aching pain associated with ischemia, tearing, or distention of an organ.
visceral pleura innermost layer of the pleura that covers the lung.
vital signs the traditional signs of life; assessments related to breathing, pulse, skin, pupils, and blood pressure.
vitreous body the large chamber of the eye, containing the vitreous humor.
vitreous humor the clear jelly that fills the large chamber of the eye.
volatile inhalants substances that are easily vaporized and inhalable.
volatile guarding a deliberate abdominal wall muscle contraction.
volatile muscle see skeletal muscle.
volatile nervous system part of the nervous system that influences voluntary muscles and movements of the body.
warm zone the area that is established surrounding or immediately adjacent to the hot zone in a hazardous materials emergency, the purpose of which is to prevent the spread of contamination. Lifesaving emergency care is performed here. Also called contamination reduction zone.
water chill the increase in rate of cooling in the presence of water or wet clothing.
weapons of mass destruction weapons intended to cause widespread and indiscriminate death and destruction.
white blood cells the part of the blood that helps the body's immune system defend against infection.
wind chill the combined cooling effect of wind speed and environmental temperature.
withdrawal a syndrome that occurs after a period of abstinence from the alcohol or drugs to which a person's body has become accustomed.
witnessed cardiac arrest for the purposes of emergency medical services and provision of resuscitation and defibrillation, a cardiac arrest in which an EMT or other emergency responder witnesses the patient become unresponsive, apneic, and pulseless (does not refer to a layperson witnessing the patient collapse).
xiphoid (ZI-foyd) process inferior portion of the sternum.
X-ray radiation X-ray radiation and gamma radiation are the same type of powerful and penetrating radiation that may be generated by the reaction in a nuclear bomb or through the decay of radioactive particles, as in fallout. Gamma radiation is both an external and an internal hazard associated with a nuclear detonation or reactor accident.
zygomatic (ZI-go-MAT-ik) bones the cheekbones.

summary: assessment and
care
Assessment Summary,
692f
Face, eye, and neck trauma (Cont.)
globe injuries, 930, 930f
impaled object in the eye or extruded eyeball, 931–932, 931f, 938–939
lid injuries, 930, 930f
nuclear weapons, 1245
orbit injury, 930
face injuries (See also face injuries)
assessment and care guidelines, 934–936, 935f
described, 934, 939–940
ear injuries, 934, 939–940
Emergency Care Protocol, 936f
impaled object in the cheek, 935
midface and jaw injuries, 935, 935f
nose injuries, 935–936, 940
nuclear weapons, 1245
orbit injury, 930
nuclear weapons, 1245
lid injuries, 930, 930f
nuclear weapons, 1245
Emergency Care Protocol, 937f
Skills, 938–942
Eye contact, 85
Eye injuries
assessment and care guidelines, 928–932, 928f, 929f, 930f, 931f
described, 929, 930–940
ear injuries, 934, 936
contact lens removal, 932–933, 935f, 935f
Emergency Care Protocol, 932f
foreign object in the eye, 929–930, 929f, 938
globe injuries, 930, 930f
impaled object in the eye or extruded eyeball, 931–932, 932f, 932f, 938–939
lid injuries, 930, 930f
nuclear weapons, 1245
orbit injury, 930
Eyelids, injury to, 928–930, 930f
Eyes
anatomy, 925–926
burn injury location, 815, 816f, 817f
dressings for burns, 822, 822f
lightning strike injuries, 708
movements, assessing, 928, 928f
personal protective equipment, 26, 26f
physical exam for head trauma, 872–873, 873f
secondary assessment, 355–356, 356f, 382–383
stress, 618, 618f
Face
anatomy, 926, 926f
described, 125
rapid secondary assessment, 351–352, 357f
secondary assessment, 335, 335f, 382
stroke, 533, 535f, 535f
Face injuries
airway control and artificial ventilation, 248
assessment and care guidelines, 944–946, 955f
burn injury location, 815, 817f
described, 934, 939–940
ear injuries, 936, 941
Emergency Care Protocol, 956f
frontal impact vehicle collisions, 755–756, 755f
gunshot wounds, 764
impaled object in the cheek, 935
midface and jaw injuries, 935, 935f
nose injuries, 935–936, 940
tooth avulsion, 935
Face mask removal with football helmets, 900, 901, 919
Facilitated communication, 83
Facilitation, in active listening, 351–352, 387
Facilitation, in active listening, 351–352, 387
Fallon tubes
described, 989–990
female reproductive system, 152, 155f

Oxygen therapy

Oxygen cylinders, 1128
Oxygen concentrators, 1128
Oxygenation,
- hazards of, 251
- facial injuries, 934
- epiglottitis, 460, 1052
- drowning events, 716
- decompression sickness, 727
- COPD, 453, 1099
- congenital heart disease,
  - clinical decisions regarding,
  - cardiac compromise and
  - carbon monoxide
- bone and joint injuries, 842
- blow-by, for newborns,
  - 1018, 1018f
- blow-by, for pediatric respiratory emergencies, 1048, 1048f
- bone and joint injuries, 842
- carbon monoxide poisoning, 622
- cardiac compromise and
  - acute coronary syndrome emergency care protocol, 518f
- cardiovascular emergency assessment and care, 515, 515f
- clinical decisions regarding, 251–252
- congenital heart disease, pediatric, 1056
- COPD, 453, 1099
- cyanide, 1241
- decompression sickness, 727
- drowning, pediatric, 1065
- drowning events, 716
- electrical burns, 824
- epiglottitis, 460, 1052
- equipment for,
  - 253–255, 255f,
  - 254f, 255f
- external bleeding, 778
- facial injuries, 934
- gas form of medication, 403, 403f
- generalized hypothermia, 688
- hazards of, 251
- head injury, 871
- heart failure, 506
- indications for, 250–251
- inhalation route of, 101
- inhaled poisons, 615, 615f
- lightning strike injuries, 708
- limb presentation, 1008
- medical oxygen
  - problems with systems,
  - 1128–1129, 1129f
- sources for home use, 1128
- medication carried on the EMS unit, 398, 400f
- overview, 248, 249f
- oxygen cylinders, 248–249, 249f
- oxygen humidifiers, 250, 250f
- pediatric patients in respiratory distress, 469, 469f
- pediatric respiratory emergencies
  - 1048–1049, 1048f
- pediatric trauma patients, 981
- pneumonia, 456
- pneumonia, respiratory, 1099
- pneumonia, pediatric, 1056
- poisoning, pediatric, 1067, 1068
- poisonous inhalation injury, 463
- premature infant, 1009–1010
- pressure regulators, 249–250
- primary assessment, 326
- pulmonary agents as
  - weapons, 1241
- pulmonary edema, 1098
- pulmonary embolism, 456–457, 1099
- riot-control agents, 1241
- safety precautions, 249
- shock, pediatric, 1057
- stroke, 538
- suicide bags, 626
- terminating therapy, 253
- transferring the oxygen source, 253
- trauma, pediatric, 1072
- Oxygen toxicity, 251
- Oxyhemoglobin, 179
- Oxytocin, 1006

PABS (bath salts)

emergency medical care, 641
overview, 640
signs and symptoms, 640–641
Packaging patients for transportation
- air transport, 108
equipment
- backboards, 102f, 105, 106f
- bariatric stretchers and devices,
  - 105–104, 114
- basket stretchers, 102f
- 106–107, 107f
- flexible stretchers, 102f
- 107, 107f
- portable stretchers, 102f
- 104, 104f
- scoop stretchers, 102f
- 105–106, 106f, 115
- stair chairs, 102, 104–105,
  - 104f, 105f
- 114
- wheeled stretchers, 101f
- 102f, 102–103, 103f
- 113
- patient positioning, 107–108
- PaCO2 (partial pressure of carbon dioxide), 1270
Pain
- abdominal, types of, 650–651, 652f
- assessment, with spinal injuries, 890, 903
- cardiovascular emergency
  - assessment and care,
  - 514, 514f
- combat veterans, and PTSD, 1149
- decompression sickness, 726
- nerve tracts, 359
- pain stimulus and motor response, 891
- respiratory rate, 269
- stimulus to check
  - responsiveness level, 320–322, 320f, 320r, 321f
- Pain tracts, in the spinal cord, 884
- Pale skin, 329
- Palliation, in OPQRST history, 286
- Palliative care, defined, 1141
- Pallor
  - baseline vital sign, 272, 273f
  - respiratory emergency
  - assessment and care, 473
- Palm
  - defined, 122, 122f
- Palp
  - of the hand, and determination of BSA, 818
- Palpation
  - abdominal aortic aneurysm, 657
  - blood pressure measurement,
    - 747, 748, 280
- Partial assessment, 326
- Partial laryngectomy, 246, 246f
- Partial abruptio placentae, 994
- Partial airway obstruction
  - 323–324, 323f, 1045
  - See also
    - airway obstruction
- Partial laryngectomy, 246, 246f
- Partial pressure of oxygen (PaO2), 1270
- Partial pressure of end-tidal CO2 (PetCO2), 1209, 1270
- Partial rebreather masks, 255, 255f
- Partial seizures, 548
- Partial-thickness burns
  - described, 814–815, 814f, 828
  - signs and symptoms, 820
- PAG. See pulmonary antishock garment (PAG)
- Passive rewarming, 690, 690f
- Passport, 1135
- PAT. See Pediatric Assessment Triangle (PAT)
- Patella, 127, 128f, 836, 836f
- Patent airway, defined, 213, 322
- Pathogens, defined, 23
- Pathophysiology, 164–189
- adequate perfusion, components for
  - airway patency, 169–170, 169f
  - ambient air, composition of,
    - 168–169, 168f
  - blood pressure, 186–187, 186f, 187f
  - blood volume, 180–181, 180f, 181f
  - microcirculation, 185–186, 185f
  - overview, 167–168
  - oxygen and carbon dioxide transport in the blood, 178–187
  - pump function of the myocardium, 181–183, 182f
  - systemic vascular resistance,
    - 185–185, 185f
  - ventilation, mechanics of,
    - 170–174, 171f, 172f
  - ventilation, regulation of,
    - 174–176, 174f
  - ventilation/perfusion ratio,
    - 176–178, 177f, 178f
- case study, 165, 188–189
- cellular metabolism
  - aerobic metabolism,
    - 165–166, 166f
  - anaerobic metabolism,
    - 166–167, 166f, 167f, 168f
  - sodium-potassium pump, 166–167, 167f, 168f
- chapter review, 188–189
- Pathophysiology
  - Pears, 184
  - abdominal contents in the peritoneum, 652
  - abdominal injury signs and symptoms, 35
  - abdominal pain, quality of, 339
  - abdominal rigidity, 659
Patient assessment (Cont.)

trauma patients
mechanism of injury, 435–437, 436f
modified secondary assessment, 345, 365, 367
overview, 344–345
rapid secondary assessment (See rapid secondary assessment)

Skills for, 381–391

Patient dumping, described, 50

Patient history
absorbed poisons, 617
acute abdomen, 658
altered mental status, 526–527
altered mental status in a diabetic emergency, 578
anaphylactic reactions, 591
asthma, 1053–1054
cardiovascular emergency assessment and care, 474
child abuse and neglect, 1087
childhood, dealing with, 1076
childhood trauma patients, 981
comatose patient, 480f
copycat behavior, 475f
diabetic emergency, 578
drug and alcohol emergencies, 631
gastrointestinal disorders, 1067
gingivitis, 667
heat stroke, 122
illness, 1066
injuries, 1028
injured patients, 380
injured population, 380
injured soldiers, 380
injured survivors, 380
intraocular injuries, 835
ivey syndrome, 1066
junctural injuries, 835
kneecap, 835
malignant hyperthermia, 1066
massive hemorrhage, 1066
malnutrition, 1068
massive injury, 1066
medical patients, 374–376, 377f, 378f
medical patients, 374–376
mechanism of injury, 435–437, 436f
mechanism of injury, 435–437
modified secondary assessment, 345, 365, 367
Overview, 344–345

Patient information
abbreviations for, 63t
demographics, for PCRs, 61
gathering, 267–268

Patient narrative, for PCRs, 62–65

Patient priorities
